Seventh Edition

Textbook of BIOCHEMISTRY With Clinical Correlations

EDITED BY

Thomas M. Devlin

Professor Emeritus
Department of Biochemistry and Molecular Biology
College of Medicine
Drexel University

John Wiley & Sons, Inc.

IMAGE ON FRONT COVER

Model of a partial telomerase elongation complex. The enzyme telomerase is a ribonucleoprotein reverse transcriptase responsible for maintaining the length and integrity of the ends of linear chromosomes, termed telomeres, present in eukaryotes. The figure depicts the partial structure of the telomerase elongation complex at the end of a chromosome (blue spheres). The catalytic subunit of telomerase (red rods) uses an integral RNA template (green spheres) to add multiple identical repeats of deoxyribonucleotides to the 3' end of the DNA strand of the chromosome. Telomerase and telomere dysfunction are considered to contribute to replicative senescence and programmed cell aging. Activation of telomerase is associated with the uncontrollable proliferation of cells found in about 85 percent of human cancers. A discussion of telomerase is presented in chapter 4. Gillis, A, J., Schuller, A. P., Skordalakes, E. Structure of the *Tribolium castaneum* telomerase catalytic subunit TERT. *Nature* 455:633, 2008. Figure generously supplied by Dr. Emmanuel Skordalakes, The Wistar Institute, Philadelphia, PA 19104, USA

Contents in Brief

Part I
STRUCTURE OF MACROMOLECULES

1 Eukaryotic Cell Structure 1
2 DNA and RNA: Composition and Structure 25
3 Proteins I: Composition and Structure 75

Part II
TRANSMISSION OF INFORMATION

4 DNA Replication, Recombination, and Repair 139
5 RNA: Transcription and RNA Processing 181
6 Protein Synthesis: Translation and Posttranslational Modifications 209
7 Recombinant DNA and Biotechnology 255
8 Regulation of Gene Expression 303

Part III
FUNCTIONS OF PROTEINS

9 Proteins II: Structure–Function Relationships in Protein Families 333
10 Enzymes: Classification, Kinetics, and Control 377
11 The Cytochromes P450 and Nitric Oxide Synthases 425
12 Biological Membranes: Structure, Receptors, and Solute Transport 457
13 Fundamentals of Signal Transduction 503

Part IV
METABOLIC PATHWAYS AND THEIR CONTROL

14 Bioenergetics, Mitochondria, and Oxidative Metabolism 541
15 Carbohydrate Metabolism I: Major Metabolic Pathways and Their Control 591
16 Carbohydrate Metabolism II: Special Pathways and Glycoconjugates 647
17 Lipid Metabolism I: Synthesis, Storage, and Utilization of Fatty Acids and Triacylglycerols 673
18 Lipid Metabolism II: Pathways of Metabolism of Special Lipids 707
19 Amino Acid and Heme Metabolism 751
20 Purine and Pyrimidine Nucleotide Metabolism 807
21 Metabolic Interrelationships 839
22 Biochemistry of Hormones 883

Part V
PHYSIOLOGICAL PROCESSES

23 Molecular Cell Biology 939
24 Cell Cycle, Programmed Cell Death, and Cancer 1003
25 Digestion and Absorption of Basic Nutritional Constituents 1029
26 Vitamins and Minerals: Requirements and Function 1063
27 Macronutrients: Metabolic Effects and Health Implications 1101

Appendix: Review of Organic Chemistry 1123
Glossary 1135
Index 1159

Contents

Part I

STRUCTURE OF MACROMOLECULES

1 Eukaryotic Cell Structure 1

Thomas M. Devlin

KEY CONCEPTS

1.1 CELLS ARE THE BASIS OF LIVING ORGANISMS 2
Classification of Living Cells 2

1.2 THE ENVIRONMENT OF CELLS: WATER AND SOLUTES 4
Hydrogen Bonds Form between Water Molecules 4
Water Has Unique Solvent Properties 5
Electrolytes: Dissociation of Molecules in Water 5
Water Is a Weak Electrolyte 6

1.3 pH, WEAK ACIDS, AND THEIR CONJUGATE BASES 6
Henderson–Hasselbalch Equation Defines the Relationship between pH and Concentrations of Conjugate Acid and Base 9
Buffering Is Important to Control pH 10

1.4 EUKARYOTES: MAMMALIAN CELLS AND TISSUES 11
Mammalian Cells 13
Chemical Composition of Mammalian Cells 13

1.5 FUNCTIONS OF SUBCELLULAR ORGANELLES AND MEMBRANE SYSTEMS IN EUKARYOTE CELLS 14
Plasma Membrane Is Limiting Boundary of a Cell 14
Nucleus Is Site of DNA and RNA Synthesis 15
Endoplasmic Reticulum Has a Role in Protein Synthesis and Many Synthetic Pathways 16
Golgi Apparatus Is Involved in Secretion of Proteins 17
Mitochondria Supply Most of the Cellular Need for ATP 17
Lysosomes Are Required for Intracellular Digestion 18
Peroxisomes Have an Important Role in Lipid Metabolism 20
Cytoskeleton Organizes the Intracellular Contents 21
Cytosol Contains Soluble Cellular Components 21

1.6 INTEGRATION AND CONTROL OF CELLULAR FUNCTIONS 21

2 DNA and RNA: Composition and Structure 25

Stephen A. Woski and Francis J. Schmidt

KEY CONCEPTS

2.1 NUCLEIC ACIDS AND BIOLOGICAL INFORMATION 26
Central Dogma of Molecular Biology 26
DNA Can Transform Cells 26
Information Capacity of DNA Is Enormous 27

2.2 STRUCTURAL COMPONENTS OF NUCLEIC ACIDS: NUCLEOBASES, NUCLEOSIDES, AND NUCLEOTIDES 27
Physical Properties of Nucleosides and Nucleotides 28
Structural Properties of Nucleosides and Nucleotides 29

2.3 STRUCTURE OF DNA 30
Polynucleotide Structure and Properties 30
Double-Helical DNA 32
Noncanonical DNA Structures 41

2.4 HIGHER-ORDER STRUCTURE OF DNA 48
Genomic DNA May Be Linear or Circular 49
DNA Is Superhelical 49
Topoisomerases 51
Packaging of Prokaryotic DNA 53
Organization of Eukaryotic Chromatin 54

2.5 SEQUENCE AND FUNCTION OF DNA 58
Restriction Endonucleases and Palindromes 58
Most Prokaryotic DNA Codes for Specific Proteins 58
Only a Small Percentage of Eukaryotic DNA Consists of Functional Genes 59
Repeated Sequences 61

2.6 STRUCTURE OF RNA 62
RNA Is a Polymer of Ribonucleoside 5′-Monophosphates 62
Secondary Structure of RNA Involves Intramolecular Base-Pairing 62
RNA Molecules Have Tertiary Structures 63

2.7 TYPES OF RNA 65
Transfer RNA Has Two Roles: Activating Amino Acids and Recognizing Codons in mRNA 65
Ribosomal RNA Is Part of the Protein Synthesis Apparatus 65
Messenger RNAs Carry the Information for the Primary Structure of Proteins 67
Mitochondria Contain Unique RNA Species 68
RNA in Ribonucleoprotein Particles 68
Catalytic RNA: Ribozymes 68
RNAs Can Bind Other Molecules 69
RNAs Control Translation 69

3 Proteins I: Composition and Structure 75

Richard M. Schultz

KEY CONCEPTS

3.1 FUNCTIONAL ROLES OF PROTEINS IN HUMANS 76

3.2 AMINO ACID COMPOSITION OF PROTEINS 76
Common Amino Acids 77
Amino Acids Are Joined into Peptides and Proteins 80

3.3 CHARGE AND CHEMICAL PROPERTIES OF AMINO ACIDS AND PROTEINS 82
Ionizable Groups of Amino Acids and Proteins Are Critical for Biological Function 82
General Relationship between Charge Properties of Amino Acids and Proteins, and pH 85
Amino Acids and Proteins Can Be Separated on the Basis of their Differences in pI 85
Amino Acid Side Chains Have Polar and Apolar Properties 86
Amino Acids Undergo a Variety of Chemical Reactions 89
3.4 PRIMARY STRUCTURE OF PROTEINS 90
3.5 HIGHER LEVELS OF PROTEIN ORGANIZATION 92
Secondary Structure 92
Tertiary Structure 96
Quaternary Structure 97
Unstructured Proteins 98
Protein Complexes, Networks, and Interactomes 99
Bioinformatics Relates Structure and Function of Protein Gene Products 101
Homologous Fold Structures Are Often Formed from Nonhomologous Amino Acid Sequences 101
3.6 NONGLOBULAR STRUCTURED PROTEINS 103
Collagen 103
Elastin Is a Fibrous Protein with Allysine-Generated Cross-Links 106
Keratin and Tropomyosin 106
Plasma Lipoproteins Are Complexes of Lipids with Proteins 107
Glycoproteins Contain Covalently Bound Carbohydrate 112
3.7 FOLDING OF PROTEINS FROM RANDOMIZED TO UNIQUE STRUCTURES: PROTEIN STABILITY 112
The Protein Folding Problem 112
Chaperone Proteins Assist the Protein Folding Process 116
Noncovalent Forces Lead to Protein Folding and Contribute to a Protein's Stability 116
Denaturation Leads to Loss of Native Structure 120
3.8 DYNAMIC ASPECTS OF PROTEIN STRUCTURE 120
3.9 CHARACTERIZATION, PURIFICATION, AND DETERMINATION OF PROTEIN STRUCTURE AND ORGANIZATION 121
Separation of Proteins on Basis of Charge 121
Separation of Proteins Based on Molecular Mass or Size 123
Polyacrylamide Gel Electrophoresis in the Presence of a Detergent 124
HPLC Techniques Separate Amino Acids, Peptides, and Proteins 124
Affinity Chromatography 124
General Approach to Protein Purification 124
Proteomic Techniques Determine All the Proteins Expressed in a Cell or Tissue in a Single Assay 125
Determination of Amino Acid Composition of a Protein 127
X-Ray Diffraction Techniques Are Used to Determine the Three-Dimensional Structure of Proteins 129
Spectroscopic Methods for Evaluating Protein Structure and Function 131
Nuclear Magnetic Resonance 133

Part II

TRANSMISSION OF INFORMATION

4 DNA Replication, Recombination, and Repair 139

Howard J. Edenberg

KEY CONCEPTS
4.1 COMMON FEATURES OF REPLICATION, RECOMBINATION, AND REPAIR 140
4.2 DNA REPLICATION: FUNDAMENTAL MECHANICS 140
The Basics 140
Chemistry of Chain Elongation 141
DNA Polymerases 142
Separating Parental Strands: The Replication Fork 144
Solving the Polarity Problem: Semi-discontinuous DNA Synthesis 145
Replication Fork Movement 145
Choreography in Three Dimensions: The Replisome 150
Termination of Replication in Circular Genomes 150
Termination of Replication in Linear Genomes: Telomeres 150
Epigenetics 151
4.3 DNA REPLICATION: ENZYMES AND REGULATION 151
Prokaryotic Enzymes of Replication 151
Eukaryotic Enzymes of Replication 153
Cell Cycle 157
Replication of RNA Genomes 158
4.4 RECOMBINATION 158
Homologous Recombination 159
Key Proteins of Recombination in *E. Coli* 162
Nonhomologous Recombination 163
Pseudogenes 164
4.5 DNA DAMAGE AND MUTATIONS 164
Mutations 164
4.6 DNA REPAIR 167
Excision Repair 167
Direct Demethylation 172
Photoreactivation 173
Lesions Can Block Replication 174
Double-Strand Break Repair 175
Regulation of DNA Repair: The SOS Regulon 175

5 RNA: Transcription and RNA Processing 181

Frank J. Schmidt and David R. Setzer

KEY CONCEPTS
5.1 INTRODUCTION 182
5.2 MECHANISMS OF TRANSCRIPTION 182
Initial Process of RNA Synthesis Is Transcription 182
DNA Sequence Information Signals RNA Synthesis 182
RNA Polymerase Catalyzes the Transcription Process 183
Steps of Transcription in Prokaryotes 185
5.3 TRANSCRIPTION IN EUKARYOTES 187
Nature of Active Chromatin 188
Transcription Activation Operates by Recruitment of RNA Polymerase 188
Transcription by RNA Polymerase II 189

Transcription by RNA Polymerase I 190
Transcription by RNA Polymerase III 191
The Common Enzymatic Basis for RNA Polymerase Action 192

5.4 RNA PROCESSING 193
Transfer RNA Is Modified by Cleavage, Addition, and Base Modification 193
Ribosomal RNA Processing Releases Several RNAs from a Longer Precursor 195
Messenger RNA Processing Ensures the Correct Coding Sequence 196
RNA Polymerase II Recruits Processing Enzymes during Transcription in Eukaryotes 196
Mutations in Splicing Signals Cause Human Diseases 198
Alternate Pre-mRNA Splicing Can Lead to the Synthesis of Multiple Protein Isoforms from a Single DNA Coding Sequence 199

5.5 RNA EXPORT AND QUALITY CONTROL 199

5.6 RNA INTERFERENCE 201

5.7 TRANSCRIPTION-COUPLED DNA REPAIR 201

5.8 NUCLEASES AND RNA TURNOVER 202
Cytoplasmic Messenger RNA Turnover Is Coupled to Translation 203

6 Protein Synthesis: Translation and Posttranslational Modifications 209

Dohn Glitz

KEY CONCEPTS

6.1 INTRODUCTION 210

6.2 COMPONENTS OF THE TRANSLATIONAL APPARATUS 210
Messenger RNA Transmits Information Encoded in DNA 210
Transfer RNA Is a Bilingual Translator Molecule 210
The Genetic Code Uses a Four-Letter Alphabet of Nucleotides 211
Codon–Anticodon Interactions Permit Reading of mRNA 212
Aminoacylation of Transfer RNA Activates Amino Acids for Protein Synthesis 216
Ribosomes Are Machines for Protein Biosynthesis 217

6.3 PROTEIN BIOSYNTHESIS 221
Translation Is Directional and Colinear with mRNA 221
Initiation of Protein Synthesis Is a Complex Process 221
Elongation Is the Stepwise Formation of Peptide Bonds 223
Termination of Polypeptide Synthesis Requires a Stop Codon 226
Translation Has Significant Energy Cost 229
Protein Synthesis in Mitochondria Differs Slightly 229
Many Antibiotics and Toxins Target Protein Biosynthesis 229

6.4 PROTEIN MATURATION: FOLDING, MODIFICATION, SECRETION, AND TARGETING 230
Chaperones Aid in Protein Folding 231
Proteins for Export Follow the Secretory Pathway 231
Glycosylation of Proteins Occurs in the Endoplasmic Reticulum and Golgi Apparatus 232

6.5 MEMBRANE AND ORGANELLE TARGETING 235
Sorting of Proteins in the Secretory Pathway 235
Import of Proteins by Mitochondria Is Complex 237
Targeting Signals Direct Proteins to Specific Organelles 239

6.6 FURTHER POSTTRANSLATIONAL MODIFICATIONS 240
Partial Proteolysis Releases Insulin and Activates Zymogens 240
Amino Acids Can Be Modified after Incorporation into Proteins 240
Collagen Biosynthesis Requires Many Posttranslational Modifications 243

6.7 REGULATION OF TRANSLATION 245

6.8 PROTEIN DEGRADATION AND TURNOVER 248
ATP-Dependent Proteolysis Occurs in Proteasomes 248
Intracellular Digestion of Some Proteins Occurs in Lysosomes 249
Other Proteolytic Systems 249

7 Recombinant DNA and Biotechnology 255

Gerald Soslau

KEY CONCEPTS

7.1 INTRODUCTION 256

7.2 POLYMERASE CHAIN REACTION 256
Nested PCR 257
Quantitative Real-Time PCR 257

7.3 RESTRICTION ENDONUCLEASE, RESTRICTION MAPS, AND DNA SEQUENCING 258
Restriction Endonucleases Selectively Hydrolyze DNA 258
Restriction Maps Permit Routine Preparation of Defined Segments of DNA 259
Interrupted Enzymatic Cleavage Method: Sanger Procedure 260
Dye-Terminator Sequencing 262

7.4 RECOMBINANT DNA, CLONING, AND SELECTION OF CLONES 262
DNA from Different Sources Can Be Ligated to Form a New DNA Species: Recombinant DNA 262
Recombinant DNA Vectors Are Produced by Cloning 264
Directional Cloning: DNA Inserted into Vector DNA in a Specific Direction 265
Bacteria Transformed with Recombinant DNA and the Need for a Selection Process 265
Recombinant DNA Molecules in a Gene Library 266
Selection of Transformed Bacteria by Loss of Antibiotic Resistance 266
α-Complementation for Selecting Bacteria Carrying Recombinant Plasmids 268
PCR Circumvents the Need to Clone DNA 268

7.5 DETECTION AND IDENTIFICATION OF NUCLEIC ACIDS AND DNA-BINDING PROTEINS 268
Nucleic Acids as Probes for Specific DNA or RNA Sequences 268
Southern Blot Technique for Identifying DNA Fragments 271
Single-Strand Conformation Polymorphism 271
Detection of mRNA 272
Detection of Sequence-Specific DNA-Binding Proteins 272

7.6 COMPLEMENTARY DNA AND COMPLEMENTARY DNA LIBRARIES 275
mRNA as Template for DNA Synthesis Using Reverse Transcriptase 275

7.7 BACTERIOPHAGE, COSMID, AND YEAST CLONING VECTORS AND ANALYSIS OF LONG STRETCHES OF DNA 277
Bacteriophage as Cloning Vectors 277
Cloning DNA Fragments into Cosmid and Artificial Chromosome Vectors 278
Subcloning Permits Definition of Large Segments of DNA 279
Chromosome Walking Defines Gene Arrangement in Long Stretches of DNA 279
7.8 EXPRESSION VECTORS AND FUSION PROTEINS 281
Foreign Genes Expressed in Bacteria Allow Synthesis of Their Encoded Proteins 281
Expression Vectors in Eukaryotic Cells 282
7.9 SITE-DIRECTED MUTAGENESIS 284
Role of DNA Flanking Regions Evaluated by Deletion and Insertion Mutations 284
Site-Directed Mutagenesis of a Single Nucleotide 284
7.10 APPLICATIONS OF RECOMBINANT DNA TECHNOLOGIES 288
Antisense Nucleic Acids in Research and Therapy 289
Molecular Techniques Applied to the Whole Animal 290
Recombinant DNA in Agriculture Has Commercial Impact 294
7.11 GENOMICS, PROTEOMICS, AND MICROARRAY ANALYSIS 295
Microarray Analysis 296
Human Genome 298

8 Regulation of Gene Expression 303
Daniel L. Weeks and John E. Donelson
KEY CONCEPTS
8.1 INTRODUCTION 304
8.2 UNIT OF TRANSCRIPTION IN BACTERIA: THE OPERON 304
8.3 LACTOSE OPERON OF *E. COLI* 305
Repressor of Lactose Operon Is a Diffusible Protein 306
Operator Sequence of Lactose Operon Is Contiguous with a Promoter and Three Structural Genes 307
RNA Polymerase and a Regulator Protein Recognize Promoter Sequence of Lactose Operon 309
Catabolite Activator Protein Binds Lactose Promoter 309
8.4 TRYPTOPHAN OPERON OF *E. COLI* 310
Tryptophan Operon Is Controlled by a Repressor Protein 310
Attenuator Region of Tryptophan Operon 312
Transcription Attenuation Controls Other Operons for Amino Acid Biosynthesis 313
8.5 OTHER BACTERIAL OPERONS 314
Synthesis of Ribosomal Proteins Is Regulated in a Coordinated Manner 314
Stringent Response Controls Synthesis of rRNAs and tRNAs 315
8.6 BACTERIAL TRANSPOSONS 316
Transposons Are Mobile Segments of DNA 316
Transposon *Tn3* Contains Three Structural Genes 316
8.7 GENE EXPRESSION IN EUKARYOTES 317
Eukaryotic DNA Is Bound by Histones to Form Chromatin 317
Methylation of DNA Correlates with Gene Inactivation 319
8.8 PREINITIATION COMPLEX IN EUKARYOTES: TRANSCRIPTION FACTORS, RNA POLYMERASE II, AND DNA 320
Eukaryotic Promoters and Other Sequences That Influence Transcription 321
Modular Design of Eukaryotic Transcription Factors 322
Common Motifs in Proteins That Bind DNA and Regulate Transcription 322
8.9 REGULATION OF EUKARYOTIC GENE EXPRESSION 325
Regulating the Regulators 326
Activation of Transcription of the LDL Receptor Gene Illustrates Many Features Found in Eukaryotic Gene Regulation 326
Epigenetic Control of Gene Expression 328

Part III
FUNCTIONS OF PROTEINS

9 Proteins II: Structure–Function Relationships in Protein Families 333
Richard M. Schultz
KEY CONCEPTS
9.1 INTRODUCTION 334
9.2 ANTIBODY MOLECULES: THE IMMUNOGLOBULIN SUPERFAMILY OF PROTEINS 334
Antibody Molecules Contain Four Polypeptide Chains 335
Immunoglobulins in a Class Contain Homologous C_H Regions 338
There Are Two Antigen-Binding Sites per Antibody Molecule 340
Genetics of the Immunoglobulins 342
Immunoglobulin Fold Is Found In a Large Family of Proteins with Different Functional Roles 343
9.3 PROTEINS WITH A COMMON CATALYTIC MECHANISM: SERINE PROTEASES 343
Proteolytic Enzymes Are Classified by Their Catalytic Mechanism 343
Serine Proteases Are Synthesized as Zymogens and in Multiple Domain Proteins 347
Tertiary Structures of the Catalytic Domains of Serine Proteases Are Similar 348
Serine Proteases Have Similar Structure–Function Relationships 350
Sequence Homology in Serine Proteases 351
Mechanism of Serine Protease Catalysis 352
Specific Protein Inhibitors of Serine Proteases 352
9.4 HEMOGLOBIN AND MYOGLOBIN 353
Human Hemoglobin Occurs in Several Forms 353
Myoglobin: A Single Polypeptide with One O_2-Binding Site 354
The Heme Prosthetic Group Is Site of O_2 Binding 355
X-Ray Crystallography Has Defined the Structures of Hemoglobin and Myoglobin 355
A Simple Equilibrium Defines O_2 Binding to Myoglobin 357
Binding of O_2 to Hemoglobin Involves Cooperativity between Subunits 358
Hemoglobin Facilitates Transport of CO_2 and NO 360
Decrease in pK_a of Acid Groups with Change from T to R Conformation Releases Protons 360
Hemoglobin Delivers Nitric Oxide (NO) to the Capillary Wall of Tissues Where It Promotes O_2 Delivery 366

9.5 THE BASAL LAMINA PROTEIN COMPLEX 367
Protein Composition of the Basal Lamina 368
The Molecular Structure of Basal Lamina Is Formed from Networks of Laminin and Type IV Collagen 369
Focal Contact in Cell Membrane Interconnects Extracellular Matrix with Cytoskeleton 373

10 Enzymes: Classification, Kinetics, and Control 377

Henry Weiner

KEY CONCEPTS
10.1 INTRODUCTION 378
10.2 CLASSIFICATIONS OF ENZYMES 378
Class 1: Oxidoreductases 379
Class 2: Transferases 380
Class 3: Hydrolases 380
Class 4: Lyases 380
Class 5: Isomerases 381
Class 6: Ligases 382
10.3 GENERAL CONCEPTS OF ENZYME MECHANISMS 382
Thermodynamic Considerations 382
Binding of Substrate by an Enzyme 383
Transition State 383
Covalent Binding of Substrate to Enzyme 386
pH Alters a Reaction by Affecting General Acids and Bases 387
10.4 ACTIVE SITE OF AN ENZYME 387
Stereochemistry of Active Site 388
Influence of Groups on the Substrate Distal to the Bond Being Modified 388
10.5 COENZYMES, CO-SUBSTRATES, AND COFACTORS 390
Coenzymes 390
Adenosine Triphosphate May Be a Second Substrate or a Modulator of Activity 393
Metal Ion Cofactors 393
10.6 KINETICS OF CHEMICAL REACTIONS 395
Rate of Product Formation 395
Rate of Substrate Disappearance 396
Reversible Reactions 397
10.7 ENZYME KINETICS OF ONE-SUBSTRATE REACTIONS 397
Michaelis–Menten Equation 400
Significance of k_{cat} in the Michaelis–Menten Equation 402
Low K_m versus High k_{cat} 403
Calculating the Constants 404
Effect of Assay Conditions 404
10.8 KINETICS OF TWO-SUBSTRATE REACTIONS 405
Sequential Mechanism 405
Ping-Pong Mechanism 405
K_{mapp} 407
10.9 INHIBITORS 407
Competitive Inhibition 407
Uncompetitive Inhibition 408
Noncompetitive Inhibition 408
Lineweaver–Burk Plots in the Presence of Inhibitors 409
Other Inhibitors 410
Enzyme Inhibitors as Drugs 411
10.10 REGULATION OF ENZYME ACTIVITY 413
Covalent Modification 413
Allosteric Control of Enzyme Activity 413
Multi-subunit Enzymes: Cooperativity 414
Regulatory Subunits Modulate the Activity of Catalytic Subunits 417
10.11 REGULATION OF METABOLIC PATHWAYS 417
10.12 CLINICAL APPLICATIONS OF ENZYMES 418
Measurement of Plasma Enzymes 418
Metabolomics and Proteomics 420

11 The Cytochromes P450 and Nitric Oxide Synthases 425

Linda J. Roman and Bettie Sue Siler Masters

KEY CONCEPTS
11.1 INTRODUCTION 426
11.2 CYTOCHROMES P450: PROPERTIES AND FUNCTION 426
11.3 CYTOCHROME P450 ELECTRON TRANSPORT SYSTEMS 427
NADPH-Cytochrome P450 Reductase Is the Obligatory Flavoprotein Electron Donor in the Endoplasmic Reticulum 428
NADPH-Adrenodoxin Reductase is the Flavoprotein Electron Donor in Mitochondria 430
11.4 CYTOCHROMES P450: NOMENCLATURE AND ISOFORMS 430
11.5 CYTOCHROMES P450: SUBSTRATES AND PHYSIOLOGICAL FUNCTIONS 431
Cytochromes P450 Participate in the Synthesis of Steroid Hormones and Oxygenation of Endogenous Compounds 432
Cytochromes P450 Oxidize Exogenous Lipophilic Substrates 436
11.6 CYTOCHROME P450: INDUCTION AND INHIBITION 440
Drug–Drug Interactions 440
Cytochrome P450 Genetic Polymorphisms 442
Therapeutic Inhibition of Cytochrome P450 444
11.7 NITRIC OXIDE SYNTHASES: PROPERTIES AND ENZYMATIC FUNCTION 444
11.8 NITRIC OXIDE SYNTHASE ISOFORMS AND PHYSIOLOGICAL FUNCTIONS 447
NOSI 447
NOSII 448
NOSIII 450

12 Biological Membranes: Structure, Receptors, and Solute Transport 457

Thomas M. Devlin

KEY CONCEPTS
12.1 INTRODUCTION 458
12.2 CHEMICAL COMPOSITION OF MEMBRANES 458
Lipids Are Major Components of Membranes 458
Glycerophospholipids Are the Most Abundant Lipids of Membranes 458
Sphingolipids Are Present in Membranes 460
Cholesterol Is an Important Component of Plasma Membranes 462
Lipid Composition Varies between Membranes 462
Membrane Proteins 463
Membrane Carbohydrates Are Part of Glycoproteins or Glycolipids 463
12.3 MICELLES, LIPID BILAYERS, AND LIPOSOMES 463
Lipids Form Vesicular Structures 463
General Properties of Lipid Bilayers 465

12.4 STRUCTURE OF BIOLOGICAL MEMBRANES 466
Mosaic Model of Biological Membranes 466
Lipids Are Asymmetrically Distributed in Membranes 467
Integral Membrane Proteins 468
Peripheral Membrane Proteins: Lipid Anchors 470
Lipids and Proteins Diffuse in Membrane Leaflets 472
Microdomains of Lipid–Protein Complexes Are Present in Membranes 473
Dynamic Environment of Membranes 474
12.5 MEMBRANE RECEPTORS 474
12.6 TRANSLOCATION OF MOLECULES THROUGH MEMBRANES 475
Some Molecules Diffuse through Cell Membranes 475
Protein-Based Mechanisms for Translocation 476
12.7 MEMBRANE CHANNELS AND PORES 477
Structures of Membrane Channels 477
Control and Selectivity of Membrane Channels 478
Representative Membrane Channels and Pores 479
12.8 MEMBRANE TRANSPORT PROTEINS 485
Energetics of Membrane Transport Systems 486
Mammalian Membrane Transporters 487
12.9 ELECTROCHEMICAL-POTENTIAL-DRIVEN TRANSPORTERS 487
Representative Electrochemical-Potential-Driven Transporters 488
12.10 PRIMARY ACTIVE TRANSPORTERS 491
Representative Primary Active Transporters 491
12.11 PORE-FORMING TOXINS AND IONOPHORES 496

13 Fundamentals of Signal Transduction 503
George R. Dubyak
KEY CONCEPTS
13.1 SIGNAL TRANSDUCTION BETWEEN CELLS 504
13.2 INTERCELLULAR SIGNAL TRANSDUCTION 504
Two Fundamental Modes of Intercellular Signal Transduction 504
Secreted Signaling Molecules 507
13.3 RECEPTORS FOR SECRETED MOLECULES 507
13.4 INTRACELLULAR SIGNAL TRANSDUCTION BY CELL SURFACE RECEPTORS 509
Ligands, Receptors, and Receptor–Ligand Interactions 509
Relationships between Receptors, Effectors, and Second Messengers 509
Protein Phosphorylation in Signal Transduction 510
GTP-Binding Regulatory Proteins in Signal Transduction 511
Other Components of Receptor-Mediated Signaling Complexes and Cascades 511
Ligand–Receptor Interaction and Downstream Signaling Events 512
Termination of Signal Transduction by Cell Surface Receptors 513
13.5 LIGAND-GATED ION CHANNEL RECEPTORS 514
Ion Channel Receptors 515
Termination of Signaling by Ion Channel Receptors 516
Other Ligands of Ion Channel Receptors 516
13.6 ENZYME-LINKED RECEPTORS 516
Physiological Roles and Extracellular Ligands 516
Receptor Tyrosine Kinases (RTK) 517
Receptor Serine/Threonine Kinases 519
13.7 CYTOKINE RECEPTORS 520
Cytokine Receptors: Structure and Function 521
13.8 G PROTEIN-COUPLED RECEPTORS 522
Physiological Roles and Extracellular Ligands 522
Structure of G Protein-Coupled Receptors 523
Heterotrimeric G Proteins 525
The G Protein Cycle 526
13.9 CYCLIC AMP-BASED SIGNAL TRANSDUCTION 528
Regulation of Cyclic AMP Synthesis and Degradation 528
Intracellular Signaling Mechanisms of Cyclic AMP 529
13.10 CYCLIC GMP-BASED SIGNAL TRANSDUCTION 530
Regulation of Cyclic GMP Synthesis and Degradation 530
Intracellular Signaling Mechanisms of Cyclic GMP 531
13.11 CALCIUM-BASED SIGNAL TRANSDUCTION 532
Regulation of Cytosolic Ca^{2+} Concentration 532
Calcium Activation of Calmodulin-Dependent Protein Kinases and Phosphatases 534
13.12 PHOSPHOLIPID-BASED SIGNAL TRANSDUCTION 534
Regulated Phospholipid Metabolism as a Component of Intracellular Signaling Pathways 534
Regulation of Phospholipase C and Phospholipase D 535
Diacylglycerol and Protein Kinase C 535
PIP_3, Phosphatidylinositol 3-Kinases, and Protein Kinase B 535
Phospholipase A_2 and Generation of Arachidonic Acid Metabolites 536
13.13 INTEGRATION OF SIGNAL TRANSDUCTION PATHWAYS INTO SIGNAL TRANSDUCTION NETWORKS 537

Part IV
METABOLIC PATHWAYS AND THEIR CONTROL

14 Bioenergetics, Mitochondria, and Oxidative Metabolism 541
Diana S. Beattie
KEY CONCEPTS
14.1 ENERGY-PRODUCING AND ENERGY-UTILIZING SYSTEMS 542
ATP Links Energy-Producing and Energy-Utilizing Systems 542
NAD^+ and NADPH in Catabolism and Anabolism 543
14.2 THERMODYNAMIC RELATIONSHIPS AND ENERGY-RICH COMPONENTS 543
Free Energy Is Energy Available for Useful Work 544
Caloric Value of Dietary Components 545
Compounds Are Classified on the Basis of Energy Released on Hydrolysis of Specific Groups 546
Free-Energy Changes Can Be Determined from Coupled Enzyme Reactions 547
High-Energy Bond Energies of Various Groups Can Be Transferred from One Compound to Another 547
14.3 SOURCES AND FATES OF ACETYL COENZYME A 548
Metabolic Sources and Fates of Pyruvate 549
Pyruvate Dehydrogenase Is a Multienzyme Complex 550
Acetyl CoA Is Used in Several Different Pathways 552
14.4 THE TRICARBOXYLIC ACID CYCLE 552
Reactions of the Tricarboxylic Acid Cycle 553
Conversion of the Acetyl Group of Acetyl CoA to CO_2 and H_2O Conserves Energy 555

Tricarboxylic Acid Cycle Is a Source of Biosynthetic Intermediates 555
Anaplerotic Reactions Replenish Intermediates of the Tricarboxylic Acid Cycle 557
Activity of Tricarboxylic Acid Cycle Is Carefully Regulated 557
14.5 STRUCTURE AND COMPARTMENTATION BY MITOCHONDRIAL MEMBRANES 559
Inner and Outer Mitochondrial Membranes Have Different Compositions and Functions 560
14.6 ELECTRON TRANSPORT CHAIN 561
Oxidation–Reduction Reactions 561
Mitochondrial Electron Transport Is a Multi-component System 563
Complex I: NADH–Ubiquinone Oxidoreductase 564
Complex II: Succinate–Ubiquinone Oxidoreductase 565
Complex III: Ubiquinol–Cytochrome *c* Oxidoreductase 566
Complex IV: Cytochrome *c* Oxidase 569
Electron Transport Chain Inhibitors 570
14.7 OXIDATIVE PHOSPHORYLATION 572
Coupling of ATP Synthesis and Electron Transport 573
ATP Synthase 575
14.8 MITOCHONDRIAL INNER MEMBRANE CONTAINS SUBSTRATE TRANSPORT SYSTEMS 577
Transport of Adenine Nucleotides and Phosphate 577
Substrate Shuttles Transport Reducing Equivalents across the Inner Mitochondrial Membrane 579
Acetyl Units Are Transported as Citrate 579
Mitochondria Have a Specific Calcium Transporter 581
Uncoupling Proteins 581
14.9 MITOCHONDRIAL GENES AND DISEASES 582
14.10 REACTIVE OXYGEN SPECIES (ROS) 583
Production of Reactive Oxygen Species 584
Damage Caused by Reactive Oxygen Species 586
Cellular Defenses against Reactive Oxygen Species 587

15 Carbohydrate Metabolism I: Major Metabolic Pathways and Their Control 591

Robert A. Harris

KEY CONCEPTS
15.1 INTRODUCTION 592
15.2 GLYCOLYSIS 592
Glycolysis Occurs in All Human Cells 592
Glucose Is Metabolized Differently in Various Cells 595
15.3 GLYCOLYSIS PATHWAY 596
Glycolysis Occurs in Three Stages 596
ATP Yield and Balanced Equation for Anaerobic Glycolysis 601
NADH Generated by Glycolysis Has to Be Oxidized Back to NAD^+: Role of Lactate Dehydrogenase and Substrate Shuttles 601
Shuttles Are Important in Other Oxidoreduction Pathways 602
Sulfhydryl Reagents and Fluoride Inhibit Glycolysis 603
Hyperglycemia Inhibits Glycolysis 603
Arsenate Prevents Net Synthesis of ATP without Inhibiting Glycolysis 604
15.4 REGULATION OF GLYCOLYSIS 604
Hexokinase and Glucokinase Have Different Properties 606
6-Phosphofructo-1-kinase Is a Regulatory Enzyme of Glycolysis 608
Hormonal Control of 6-Phosphofructo-1-kinase by cAMP and Fructose 2,6-bisphosphate 612
The Bifunctional Enzyme 6-Phosphofructo-2-kinase/Fructose 2,6-bisphosphatase Is Regulated by Phosphorylation 614
Heart Contains a Different Isoenzyme of 6-Phosphofructo-2-kinase/Fructose 2,6-bisphosphate 616
Pyruvate Kinase Is Also a Regulatory Enzyme of Glycolysis 617
15.5 GLUCONEOGENESIS 619
Glucose Synthesis Is Required for Survival 619
Glucose Synthesis from Lactate 621
Glucose Is Synthesized from Most Amino Acids 622
Glucose Can Be Synthesized from Fatty Acids with an Odd but Not an Even Number of Carbons 625
Glucose Is Also Synthesized from Fructose 625
Gluconeogenesis Requires Expenditure of ATP 626
Gluconeogenesis Has Several Sites of Regulation 626
Hormonal Control of Gluconeogenesis Is Critical for Homeostasis 627
Alcohol Oxidation Inhibits Gluconeogenesis 628
15.6 GLYCOGENOLYSIS AND GLYCOGENESIS 629
Glycogen Is the Storage Form of Glucose 629
Glycogen Phosphorylase Initiates Glycogenolysis 630
Debranching Enzyme Is Required for Glycogenolysis 631
Glycogenesis Requires Unique Enzymes 632
Special Features of Glycogenolysis and Glycogenesis 633
Glycogen Synthesis and Degradation Are Highly Regulated 635
Effector Control of Glycogen Metabolism 638
Phosphorylase *a* is a "Glucose Receptor" in Liver 639
Hormonal and Neural Control of Glycogen Synthesis and Degradation 640

16 Carbohydrate Metabolism II: Special Pathways and Glycoconjugates 647

Nancy B Schwartz

KEY CONCEPTS
16.1 PENTOSE PHOSPHATE PATHWAY 648
Pentose Phosphate Pathway Has Two Phases 648
Glucose 6-Phosphate Oxidization Conserves Redox Equivalents as NADPH and Decarboxylation Supplies Pentose Phosphates 648
Interconversions of Pentose Phosphates Lead to Intermediates of Glycolysis 649
Glucose 6-Phosphate Can Be Completely Oxidized to CO_2 651
Pentose Phosphate Pathway Serves as a NADPH Regenerating System and Supplier of Pentose Phosphates 651
16.2 SUGAR INTERCONVERSIONS AND NUCLEOTIDE-LINKED SUGAR FORMATION 652
Isomerization and Phosphorylation Are Common Reactions for Interconverting Carbohydrates 652
Nucleotide-Linked Sugars Are Intermediates in Many Sugar Transformations 653
Epimerization Interconverts Nucleotide-Linked Glucose and Galactose 654
Glucuronic Acid Is Formed by Oxidation of UDP-Glucose 654
Decarboxylation, Oxidoreduction, and Transamidation of Sugars Yield Necessary Products 655
Sialic Acids Are Derived from *N*-Acetylglucosamine 657

16.3 BIOSYNTHESIS OF COMPLEX POLYSACCHARIDES 658
16.4 GLYCOPROTEINS 659
Glycoproteins Contain Variable Amounts of Carbohydrate 659
Synthesis of *N*-Linked Glycoproteins Involves Dolichol Phosphate 660
Glycan Function 663
16.5 PROTEOGLYCANS 664
There Are Six Classes of Proteoglycans 664
Biosynthesis of Chondroitin Sulfate Is Typical of Glycosaminoglycan Formation 666

17 Lipid Metabolism I: Synthesis, Storage, and Utilization of Fatty Acids and Triacylglycerols 673

Martin D. Snider, J. Denis McGarry (deceased) and Richard W. Hanson

KEY CONCEPTS
17.1 INTRODUCTION 674
17.2 CHEMICAL NATURE OF FATTY ACIDS AND ACYLGLYCEROLS 674
Fatty Acids Are Alkyl Chains Terminating in a Carboxyl Group 674
Most Fatty Acids in Humans Occur as Triacylglycerols 675
The Hydrophobicity of Triacylglycerols Is Important for Their Functions 676
17.3 INTERORGAN TRANSPORT OF FATTY ACIDS AND THEIR PRIMARY PRODUCTS 678
Lipid Transport in the Fed State 678
Lipid Transport in the Fasted State 679
17.4 SYNTHESIS OF FATTY ACIDS: LIPOGENESIS 680
Glucose Is the Major Precursor for Fatty Acid Synthesis 680
Pathway of Fatty Acid Biosynthesis 680
The Citrate Cleavage Pathway Provides Acetyl CoA and NADPH for Lipogenesis in the Cytosol 684
Modification of Fatty Acids 685
Fatty Acid Synthase Can Produce Fatty Acids other than Palmitate 686
Fatty Acyl CoAs May Be Reduced to Fatty Alcohols 687
17.5 STORAGE OF FATTY ACIDS AS TRIACYLGLYCEROL 687
Triacylglycerols Are Synthesized from Fatty Acyl CoAs and Glycerol 3-Phosphate 688
Mobilization of Triacylglycerols Requires Hydrolysis 689
Triacylglycerol Synthesis Occurs during Fasting as Part of a Triacylglycerol–Fatty Acid Cycle Involving Glyceroneogenesis 689
17.6 UTILIZATION OF FATTY ACIDS FOR ENERGY PRODUCTION 691
β-Oxidation of Straight-Chain Fatty Acids Is a Major Energy-Producing Process 691
Energy Yield from the β-Oxidation of Fatty Acids 693
Comparison of Fatty Acid Synthesis and Oxidation 694
β-Oxidation of Some Fatty Acids Requires Additional Steps 694
Ketone Bodies Are Formed from Acetyl CoA 697
Utilization of Ketone Bodies by Nonhepatic Tissues Requires Formation of Acetoacetyl CoA 700
Peroxisomal Oxidation of Fatty Acids Serves Many Functions 701
17.7 REGULATION OF LIPID METABOLISM 701
Regulation in the Fed State 701
Regulation in the Fasted State 701
Regulation of Fatty Acid Oxidation 702
Fatty Acids as Regulatory Molecules 702

18 Lipid Metabolism II: Pathways of Metabolism of Special Lipids 707

Robert H. Glew

KEY CONCEPTS
18.1 INTRODUCTION 708
18.2 PHOSPHOLIPIDS 708
Phospholipids Contain Phosphatidic Acid Linked to a Base 708
Phospholipids in Membranes Serve a Variety of Roles 709
Biosynthesis of Phospholipids 712
Asymmetric Distribution of Fatty Acids in Phospholipids Is due to Remodeling Reactions 716
Plasmalogens Are Synthesized from Fatty Alcohols 716
18.3 CHOLESTEROL 718
Cholesterol Is Widely Distributed in Free and Esterified Forms 718
Cholesterol Is Synthesized from Acetyl CoA 719
Plasma Lipoproteins 722
Cholesterol Synthesis Is Regulated 726
Cholesterol Is Excreted Primarily as Bile Acids 728
18.4 SPHINGOLIPIDS 729
Synthesis of Sphingosine 729
Ceramides Are Fatty Acid Amide Derivatives of Sphingosine 730
Sphingomyelin Is a Phosphorus-Containing Sphingolipid 730
Glycosphingolipids Usually Contain Galactose or Glucose 732
Sphingolipidoses Are Lysosomal Storage Diseases 734
18.5 PROSTAGLANDINS AND THROMBOXANES 737
Prostaglandins and Thromboxanes Are Derivatives of Monocarboxylic Acids 737
Synthesis of Prostaglandins Involves a Cyclooxygenase 739
Prostaglandins Exhibit Many Physiological Effects 741
18.6 LIPOXYGENASE AND OXY-EICOSATETRAENOIC ACIDS 742
Monohydroperoxyeicosatetraenoic Acids Are Products of Lipoxygenase Action 742
Leukotrienes, Hydroxyeicosatetraenoic Acids, and Lipoxins Are Hormones Derived from HPETEs 743
Leukotrienes and HETEs Affect Several Physiological Processes 744

19 Amino Acid and Heme Metabolism 751

Marguerite W. Coomes

KEY CONCEPTS
19.1 INCORPORATION OF NITROGEN INTO AMINO ACIDS 752
Most Amino Acids Are Obtained from the Diet 752
Amino Groups Are Transferred from One Amino Acid to Form Another 752
Pyridoxal Phosphate Is Cofactor for Aminotransferases 755
Glutamate Dehydrogenase Incorporates and Produces Ammonia 755
Free Ammonia Is Incorporated into and Produced from Glutamine 756
Amino Acid Oxidases Remove Amino Groups 757

19.2 TRANSPORT OF NITROGEN TO LIVER AND KIDNEY 757
Protein Is Degraded Constantly 757
Ammonia Is Released in Liver and Kidney 758
19.3 UREA CYCLE 759
Nitrogen Atoms of Urea Come from Ammonia and Aspartate 759
Synthesis of Urea Requires Five Enzymes 759
Urea Synthesis Is Regulated by an Allosteric Effector and by Enzyme Induction 760
Metabolic Disorders of Urea Synthesis Have Serious Consequences 761
19.4 BIOSYNTHESIS OF NONESSENTIAL AMINO ACIDS 763
19.5 DEGRADATION OF AMINO ACIDS 764
Nonessential Amino Acids 764
Essential Amino Acids 767
Branched-Chain Amino Acids 775
19.6 IMPORTANT METABOLITES DERIVED FROM AMINO ACIDS 778
Metabolites Made from More than One Amino Acid 787
Glutathione 789
19.7 HEME BIOSYNTHESIS 791
Enzymes Involved in Heme Biosynthesis 791
ALA Synthase Catalyzes Rate-Limiting Step of Heme Biosynthesis 796
Porphyrias 797
19.8 HEME CATABOLISM 797
Bilirubin Is Conjugated to Form Bilirubin Diglucuronide in Liver 797
Intravascular Hemolysis Requires Scavenging of Iron 801

20 Purine and Pyrimidine Nucleotide Metabolism 807

Joseph G. Cory and Ann H. Cory

KEY CONCEPTS
20.1 INTRODUCTION 808
20.2 METABOLIC FUNCTIONS OF NUCLEOTIDES 808
Distribution of Nucleotides Varies with Cell Type 808
20.3 5′-PHOSPHORIBOSYL-1-PYROPHOSPHATE AND GLUTAMINE IN *DE NOVO* SYNTHESIS OF NUCLEOTIDES 809
20.4 SYNTHESIS OF PURINE NUCLEOTIDES 810
Formation of IMP 811
Purine Nucleotide Synthesis Is Highly Regulated 813
Purine Bases and Nucleosides Are Salvaged to Reform Nucleotides 815
Purine Nucleotides Are Interconverted to Balance Cellular Levels of Adenine and Guanine Nucleotides 817
20.5 GTP IS THE PRECURSOR OF TETRAHYDROBIOPTERIN 817
20.6 URIC ACID IS THE END PRODUCT OF PURINE DEGRADATION IN HUMANS 820
20.7 METABOLISM OF PYRIMIDINE NUCLEOTIDES 821
Synthesis of Pyrimidine Nucleotides 821
Pyrimidine Nucleotide Synthesis Is Regulated at the Level of Carbamoyl Phosphate Synthetase II 823
Pyrimidine Bases Are Salvaged to Reform Nucleotides 824
20.8 DEOXYRIBONUCLEOTIDE FORMATION 824
Deoxyribonucleotides Are Formed by Reduction of Ribonucleoside 5′-Diphosphates 824
Deoxythymidylate Synthesis Requires N^5, N^{10}-Methylene H_4Folate 825
Pyrimidine Interconversions: Deoxyribopyrimidine Nucleosides and Nucleotides 825
20.9 DEGRADATION OF PYRIMIDINE NUCLEOTIDES 826
20.10 NUCLEOSIDE AND NUCLEOTIDE KINASES 827
20.11 NUCLEOTIDE METABOLIZING ENZYMES AS A FUNCTION OF THE CELL CYCLE 828
20.12 NUCLEOTIDE COENZYME SYNTHESIS 829
20.13 CHEMOTHERAPEUTIC AGENTS THAT INTERFERE WITH PURINE AND PYRIMIDINE NUCLEOTIDE METABOLISM 831
Inhibitors of Purine and Pyrimidine Nucleotide Metabolism 832
Biochemical Basis for Responses to Chemotherapeutic Agents 835

21 Metabolic Interrelationships 839

Robert A. Harris and David W. Crabb

KEY CONCEPTS
21.1 INTRODUCTION 840
21.2 STARVE–FEED CYCLE 842
In the Well-Fed State the Diet Supplies the Energy Requirements 842
In the Early Fasting State Hepatic Glycogenolysis Maintains Blood Glucose 844
The Fasting State Requires Gluconeogenesis from Amino Acids and Glycerol 845
In the Early Refed State Glycogen Is Formed by the Indirect Pathway 847
Important Interorgan Metabolic Interactions 847
Energy Requirements, Reserves, and Caloric Homeostasis 849
The Five Phases of Glucose Homeostasis 850
21.3 MECHANISMS INVOLVED IN SWITCHING LIVER METABOLISM BETWEEN THE WELL-FED AND STARVED STATES 852
Substrate Availability Controls Many Metabolic Pathways 852
Allosteric Effectors Regulate Key Enzymes 853
Covalent Modification Regulates Key Enzymes 855
Changes in the Amounts of Key Enzymes Provide Long-Term Adaptation 859
21.4 INTERRELATIONSHIP OF TISSUES IN NUTRITIONAL AND HORMONAL STATES 863
Obesity 863
Dieting 864
Type 2 Diabetes Mellitus 865
Type 1 Diabetes Mellitus 866
Cancer 868
Aerobic and Anaerobic Exercise 869
Pregnancy 871
Lactation 871
Stress and Injury 872
Liver Disease 873
Renal Disease 874
Consumption of Alcohol 875
Acid–Base Balance 876
Colon 877

22 Biochemistry of Hormones 883

Thomas J. Schmidt

KEY CONCEPTS

22.1 INTRODUCTION 884

22.2 HORMONES AND THE HORMONAL CASCADE SYSTEM 885
Hormonal Cascade Systems Amplify Specific Signals 885
Major Polypeptide Hormones and Their Actions 887

22.3 SYNTHESIS OF POLYPEPTIDE AND AMINO-ACID-DERIVED HORMONES 892
Polypeptide Hormones: Gene Coding 892
Amino-Acid-Derived Hormones 895
Inactivation and Degradation of Amino-Acid-Derived Hormones 896

22.4 PROTEIN HORMONE SIGNALING 897
Overview of Signaling 897
Cyclic Hormonal Systems 901
Ovarian Cycle Is Controlled by Pulsatile and Cyclic Secretion of Gonadotropin-Releasing Hormone 901

22.5 MEMBRANE HORMONE RECEPTORS 905
Some Hormone-Receptor Interactions Involve Multiple Hormone Subunits 905
Internalization of Receptors 906

22.6 INTRACELLULAR HORMONE CASCADES: PROTEIN KINASES 909
Insulin Receptor: Transduction through Tyrosine Kinase 910
Activity of Vasopressin: Protein Kinase A 912
Gonadotropin-Releasing Hormone (GnRH): Protein Kinase C 912
Activity of Atrial Natriuretic Factor (ANF): Protein Kinase G 913

22.7 STEROID HORMONES 916
Structures and Functions of Steroid Hormones 916
Biosynthesis of Steroid Hormones 919
Metabolism of Steroid Hormones 921
Regulation of Steroid Hormone Synthesis 922
Vitamin D_3 926
Transport of Steroid Hormones: Plasma-Binding Proteins 928

22.8 STEROID HORMONE RECEPTORS 929
Steroid Hormones Bind Intracellular Receptor Proteins 929
Orphan Receptors 934
Down-regulation of Steroid Receptor by Ligand 934
Nuclear Hormone Receptors, Coactivators, and Corepressors 935
Nongenomic Steroid Effects 935

Part V

PHYSIOLOGICAL PROCESSES

23 Molecular Cell Biology 939

Thomas E. Smith

KEY CONCEPTS

23.1 NERVOUS TISSUE: METABOLISM AND FUNCTION 940
Essential Concepts 940
ATP and Transmembrane Electrical Potential in Neurons 942
Neuron–Neuron Interaction Occurs through Synapses 943
Synthesis, Storage, and Release of Neurotransmitters 945
Termination of Signals at Synaptic Junctions 948
Neuropeptides Are Derived from Precursor Proteins 951

23.2 THE EYE: METABOLISM AND VISION 953
Cornea Derives ATP from Aerobic Metabolism 953
Lens Consists Mostly of Water and Protein 954
Retina Derives ATP from Anaerobic Glycolysis 956
Visual Transduction Involves Photochemical, Biochemical, and Electrical Events 957
Rods and Cones are Photoreceptor Cells 958
Color Vision Originates in Cones 963

23.3 MOLECULAR MOTORS AND ASSOCIATED PROTEINS 967
Muscle Contraction 967
Skeletal Muscle: Structural Organization of its Components 967
Skeletal Muscle Contraction 974
Cardiac Muscle: Structure and Contraction 977
Smooth Muscle Contraction: Calcium Regulation 978
Energy Reservoirs for Muscle Contraction 979
Other Classes of Myosins and Molecular Motors 979

23.4 MECHANISM OF BLOOD COAGULATION 982
Biochemical Processes of Hemostasis 982
Procoagulation Phase of Hemostasis (Phase 1) 983
Some Properties of Proteins Involved in Clot Formation 985
Anticoagulation Phase of Hemostasis (Phase 2) 989
Fibrinolysis Phase of Hemostasis (Phase 3) 994
Role of Gla Residues in Blood Coagulation Factors 994

24 Cell Cycle, Programmed Cell Death and Cancer 1003

Richard M. Schultz

KEY CONCEPTS

24.1 INTRODUCTION 1004

24.2 CELL DIVISION CYCLE 1004
Regulation of Cell Cycle 1005
Growth Factor Signal Transduction Pathway 1008

24.3 APOPTOSIS: PROGRAMMED CELL DEATH 1010
Major Pathways of Apoptosis 1011
p53 Induction of Apoptosis 1014
MAPK Pathways Regulate Both Cell Death and Cell Survival 1015

24.4 CANCER 1016
Oncogenes and Tumor Suppressor Genes 1016
Properties of Cancer Cells 1017
Multiple Mutations Are Required to Form a Cancer 1020
Genetic and Biochemical Heterogeneity of Cancers 1023
Mutagens and Promoters Cause Cancers 1023
Biochemical Analysis of Individual Cancers 1023

25 Digestion and Absorption of Basic Nutritional Constituents 1029

Ulrich Hopfer

KEY CONCEPTS

25.1 INTRODUCTION 1030
Nutrient Types 1030
Several Gastrointestinal Organs Contribute to Food Digestion 1030

25.2 GENERAL CONSIDERATIONS 1032
Different Sites of Digestion 1032
Digestive Enzymes Are Secreted as Proenzymes 1033
Secretion Is Regulated by Many Secretagogues 1033

25.3 EPITHELIAL TRANSPORT 1036
Solute Transport May Be Transcellular or Paracellular 1036

NaCl Absorption Depends on Na^+/K^+-exchanging ATPase, Membrane Transporters, and Channels 1037
NaCl Secretion Depends on Na^+/K^+-exchanging ATPase, Membrane Transporters, and Channels 1039
Ion Concentration Gradients and Electrical Potentials Energize Transport of Nutrients 1041
Gastric Parietal Cells Secrete HCl 1042
25.4 DIGESTION AND ABSORPTION OF PROTEINS 1043
Peptidases Assure Efficient Protein Digestion 1043
Amino Acid and Di- and Tripeptide Transporters 1046
25.5 DIGESTION AND ABSORPTION OF CARBOHYDRATES 1049
Disaccharides and Polysaccharides Require Hydrolysis 1049
Monosaccharide Transporters 1051
25.6 DIGESTION AND ABSORPTION OF LIPIDS 1051
Digestion of Lipids Requires Overcoming Their Limited Water Solubility 1051
Lipids Are Digested by Gastric and Pancreatic Lipases 1052
Bile Acid Micelles Solubilize Lipids during Digestion 1053
Most Absorbed Lipids Are Incorporated into Chylomicrons 1057
25.7 BILE ACID METABOLISM 1058
Bile Acid Chemistry and Synthesis 1058
Bile Acid Transport 1058

26 Vitamins and Minerals: Requirements and Function 1063

Stephen G. Chaney

KEY CONCEPTS
26.1 INTRODUCTION 1064
26.2 ASSESSMENT OF MALNUTRITION 1064
26.3 DIETARY REFERENCE INTAKES 1065
26.4 FAT-SOLUBLE VITAMINS 1065
Vitamin A Is Derived from Plant Carotenoids 1065
Vitamin D Synthesis Requires Sunlight 1067
Vitamin E Is a Mixture of Tocopherols and Tocotrienols 1072
Vitamin K Is a Quinone Derivative 1073
26.5 WATER-SOLUBLE VITAMINS 1075
26.6 ENERGY-RELEASING WATER-SOLUBLE VITAMINS 1075
Thiamine Forms the Coenzyme Thiamine Pyrophosphate 1075
Riboflavin Forms the Coenzymes FAD and FMN 1077
Niacin Forms the Coenzymes NAD and NADP 1077
Pyridoxine (Vitamin B_6) Forms the Coenzyme Pyridoxal Phosphate 1078
Pantothenic Acid and Biotin Form Coenzymes Involved in Energy Metabolism 1077
α-Lipoic Acid Plays Multiple Roles in the Body 1079
26.7 HEMATOPOIETIC WATER-SOLUBLE VITAMINS 1079
Folic Acid Functions as Tetrahydrofolate in One-Carbon Metabolism 1079
Vitamin B12 (Cobalamin) Contains Cobalt in a Tetrapyrrole Ring 1082
26.8 OTHER WATER-SOLUBLE VITAMINS 1084
Ascorbic Acid Functions in Reduction and Hydroxylation Reactions 1084
Choline and Carnitine Perform Several Functions 1085
26.9 MACROMINERALS 1085
Calcium Has Many Physiological Roles 1085
Magnesium Is Required by Many Enzymes 1086
26.10 TRACE MINERALS 1087
Iron Deficiency Causes Anemia and Decreased Immunocompetence 1087
Iodine Is Incorporated Into Thyroid Hormones 1091
Zinc Is Required by Many Proteins 1091
Copper Is a Cofactor for Important Enzymes 1092
Chromium Is a Component of Chromodulin 1093
Selenium Is Found in Selenoproteins 1093
Manganese, Molybdenum, Fluoride, and Boron Are Essential Trace Elements 1094
26.11 THE AMERICAN DIET: FACT AND FALLACY 1094
26.12 ASSESSMENT OF NUTRITIONAL STATUS IN CLINICAL PRACTICE 1094
26.13 NUTRIGENOMICS–THE FUTURE OF NUTRITION 1095

27 Macronutrients: Metabolic Effects and Health Implications 1101

Stephen G. Chaney

KEY CONCEPTS
27.1 INTRODUCTION 1102
27.2 ENERGY METABOLISM 1102
Energy Content of Food Is Measured Primarily in Kilocalories 1102
Energy Expenditure Is Influenced by Four Factors 1102
27.3 PROTEIN METABOLISM 1103
Dietary Protein Serves Many Roles Including Energy Production 1103
Nitrogen Balance Relates Intake to Excretion of Nitrogen 1103
Essential Amino Acids Must Be Present in the Diet 1103
Protein Sparing Is Related to Dietary Content of Carbohydrate and Fat 1104
Normal Adult Protein Requirements 1104
Protein Requirements Are Increased during Growth and Illness 1106
27.4 PROTEIN-ENERGY MALNUTRITION 1107
27.5 EXCESS PROTEIN-ENERGY INTAKE 1107
Obesity Has Dietary and Genetic Components 1107
Obesity, Insulin Resistance, Metabolic Syndrome, and Type 2 Diabetes 1108
Obesity Has Significant Health Implications 1110
27.6 CARBOHYDRATES 1111
27.7 FATS 1112
27.8 FIBER 1113
27.9 COMPOSITION OF MACRONUTRIENTS IN THE DIET 1114
Composition of the Diet Affects Serum Cholesterol 1114
Carbohydrates, Glycemic Index, and Glycemic Load 1115
Nutritional Protein Requirements Are Achieved by Mixing Vegetable and Animal Proteins 1115
Fiber from Varied Sources Is Desirable 1116
Dietary Recommendations 1116
27.10 NUTRIGENETICS AND DIET COMPOSITION 1118

Appendix: Review of Organic Chemistry 1123

Clinical Correlations

1 Eukaryotic Cell Structure

1.1 Abnormal Medical Conditions as Reflected in the pH of Blood 7
1.2 Importance of Blood HCO_3^- in Metabolic Acidosis 11
1.3 Accelerated Aging and the Cell Nucleus 16
1.4 Mitochondrial Diseases 18
1.5 Lysosomal Enzymes and Gout 19
1.6 Lysosomal Acid Lipase Deficiency 20
1.7 Peroxisome Biogenesis Disorders (PBD) 21

2 DNA and RNA: Composition and Structure

2.1 DNA Vaccines 28
2.2 Diagnostic Use of DNA Arrays in Medicine and Genetics 39
2.3 Antitumor Antibiotics That Change the Shape of DNA 42
2.4 Hereditary Persistence of Fetal Hemoglobin 46
2.5 Telomerase as a Target for Anticancer Agents 46
2.6 Expansion of DNA Triple Repeats and Human Disease 48
2.7 Topoisomerases in the Treatment of Disease 52
2.8 Epigenetic Treatments for Cancer 57
2.9 Staphylococcal Resistance to Erythromycin 66

3 Proteins I: Composition and Structure

3.1 Plasma Proteins in Diagnosis of Disease 87
3.2 Differences in Insulins Used in Treatment of Diabetes Mellitus 92
3.3 Hyperlipoproteinemias 109
3.4 Hypolipoproteinemias 110
3.5 Glycosylated Hemoglobin, HbA_{1c} 113
3.6 Prion Diseases and Proteins as Infectious Agents: Human Transmissible Spongiform Encephalopathies (TSEs) 114
3.7 Use of Amino Acid Analysis in Diagnosis of Disease 127

4 DNA Replication, Recombination, and Repair

4.1 Chemotherapy Can Target Precursors of DNA Synthesis 142
4.2 Nucleoside Analogs and Drug Resistance in HIV Therapy 144
4.3 Topoisomerases as Antibiotics 152
4.4 Cancer and the Cell Cycle 158
4.5 Recombination and Cancer 159
4.6 Recombination and Gene Therapy 164
4.7 Cisplatin and the Tour de France 165
4.8 Thiopurine Base Analogs as Drugs 166
4.9 Personalized Medicine 167
4.10 Xeroderma Pigmentosum 170
4.11 Mismatch Repair and Cancer 172

5 RNA: Transcription and RNA Processing

5.1 Antibiotics and Toxins That Target RNA Polymerase 185
5.2 Fragile X Syndrome: A Chromatin Disease? 189
5.3 Involvement of Transcriptional Factors in Carcinogenesis 191
5.4 Thalassemia due to Defects in Messenger RNA Synthesis 197
5.5 Autoimmunity in Connective Tissue Disease 198
5.6 Nucleic Acid Editing Enzymes: An Antiviral Defense as well as a Way of Altering Genes Expression 201
5.7 Involvement of MicroRNAs in Oncogenesis 202
5.8 Cockayne Syndrome 203

6 Protein Synthesis: Translation and Posttranslational Modifications

6.1 Silent Mutations May Not Be Silent: (1) Hutchinson-Gilford Progeria Syndrome and (2) Multidrug Resistance 1 Gene 214
6.2 Missense Mutations: Hemoglobinopathies 214
6.3 Mutations to Form a Terminator Codon 214
6.4 α-Thalassemia 215
6.5 Programmed Frameshifting in Biosynthesis of HIV Proteins 216
6.6 Mutations in Mitochondrial rRNA and tRNA Results in Antibiotic-Induced Deafness 229
6.7 Deletion of a Codon, Incorrect Folding, and Premature Degradation: Cystic Fibrosis 231
6.8 Diseases of Lysosome Targeting: I-Cell Disease 238
6.9 Enzyme Replacement Therapy for Lysosomal Storage Diseases 238
6.10 Defective Mitochondrial Protein Import and Disease 239
6.11 Familial Hyperproinsulinemia 241
6.12 Absence of Posttranslational Modification: Multiple Sulfatase Deficiency 243
6.13 Defects in Collagen Synthesis 246
6.14 Protein Misfolding and Aggregation: Huntington Disease and Alzheimer Disease 250
6.15 Defects in the Ubiquitin–Proteasome System 250

7 Recombinant DNA and Biotechnology

7.1 The Polymerase Chain Reaction 258
7.2 Quantitative Real-Time PCR (qRT–PCR) in the Analysis of a Gene Associated with Prostate Cancer 259
7.3 Restriction Mapping and Evolution 260
7.4 Direct Sequencing of DNA for Diagnosis of Bloom Syndrome: A Genetic Disorder 262
7.5 Multiplex PCR Analysis of HGPTase Gene Defects in the Lesch–Nyhan Syndrome 268
7.6 Restriction Fragment Length Polymorphisms Determine the Clonal Origin of Tumors 273
7.7 Single-Strand Conformational Polymorphism for Detection of Spontaneous Mutations that May Lead to SIDS 274
7.8 The Use of Yeast Artificial Chromosome (YAC) Transgenic Mice to Study Huntington Disease 279
7.9 The Use of Chromosome Walking and Jumping to Identify the Cystic Fibrosis Gene 281
7.10 Site-Directed Mutagenesis of Type VIII Collagen (C7) 286
7.11 siRNA-Mediated Regulation of Gene Expression 290
7.12 Gene Therapy: Normal Genes Can Be Introduced into Cells with Defective Genes 291

7.13 Transgenic Animal Models 292
7.14 Knockout Mice to Define a Role for the $P2Y_1$ Purinoceptor 293
7.15 Microarray Techniques to Detect and Treat Diseases 296

8 Regulation of Gene Expression
8.1 Transmissible Multiple-Drug Resistance 316
8.2 The Bacterial Pathogen of the Stomach: *Helicobacter pylori* 317
8.3 Rubinstein–Taybi Syndrome 319
8.4 Tamoxifen and Targeting of Estrogen Receptor 326
8.5 Transcription Factors and Cardiovascular Disease 326
8.6 Cancer Treatment Using Drugs That Target Histone and DNA Modification: Epigenetic Therapy 328

9 Proteins II: Structure–Function Relationships in Protein Families
9.1 The Complement Proteins 336
9.2 Functions of Different Antibody Classes 338
9.3 Immunization 338
9.4 Fibrin Formation in a Myocardial Infarct and Use of Recombinant Tissue Plasminogen Activator (rt-PA) 344
9.5 Involvement of Serine Proteases in Tumor Cell Metastasis 345
9.6 Hemoglobinopathies 354

10 Enzymes: Classification, Kinetics, and Control
10.1 Hydrolysis of Asparaginase and Leukemia 381
10.2 Mutation of a Coenzyme-Binding Site Results in Clinical Disease 390
10.3 A Case of Gout Demonstrates Two Phases in the Mechanism of Enzyme Action 400
10.4 Physiological Effect of Changes in Enzyme K_m Values 402
10.5 Thermal Lability of Glucose-6-Phosphate Dehydrogenase Results in Hemolytic Anemia 404
10.6 Alcohol Dehydrogenase Isoenzymes with Different pH Optima 405
10.7 Inhibitors of Xanthine Oxidase Isolated from Plants 407
10.8 Design of a Selective Inhibitor 408
10.9 A Case of Poisoning 411
10.10 Mushrooms and Alcohol Metabolism 412
10.11 Testosterone and Prostate Cancer 412
10.12 Natural Products as Inhibitors of Enzymes 413
10.13 A Case of Gout Demonstrates the Difference between an Allosteric- and Substrate-Binding Site 414
10.14 Ambiguity in the Assay of Mutated Enzymes 415
10.15 Identification and Treatment of an Enzyme Deficiency 419

11 The Cytochromes P450 and Nitric Oxide Synthases
11.1 Congenital Adrenal Hyperplasia: Deficiency of CYP21A2 435
11.2 Steroid Hormone Production during Pregnancy 435
11.3 Cytochrome P450 Inhibition: Drug–Drug Interactions and Adverse Effects 438
11.4 Role of Cytochrome P450 2E1 in Acetaminophen-Induced Liver Toxicity 440
11.5 Cytochrome P450 Induction: Drug–Drug Interactions and Adverse Effects 441
11.6 Genetic Polymorphisms of P450 Enzymes 443
11.7 Genetic Polymorphisms of NADPH-Cytochrome P450 Reductase: Antley–Bixler Syndrome 443
11.8 Mechanism of Action of Sildenafil 449
11.9 Nitric Oxide Overproduction in Septic Shock 450
11.10 History and Biological Effects of Nitroglycerin 451
11.11 Therapeutic Uses of Inhaled Nitric Oxide 452
11.12 The Role of eNOS in Endothelial Dysfunction 452

12 Biological Membranes: Structure, Receptors, and Solute Transport
12.1 Liposomes as Carriers of Drugs, Proteins, and Nucleic Acids 466
12.2 Abnormalities of Cell Membrane Fluidity in Disease 472
12.3 The Mammalian Kidney and Aquaporins 480
12.4 Diseases due to Loss of Membrane Transport Systems 488
12.5 Cystic Fibrosis and the Cl^- Channel 496
12.6 Diseases Involving the Superfamily of ABC Transporters 497

13 Fundamentals of Signal Transduction
13.1 ErbB/HER-Receptor Tyrosine Kinases as Targets for Cancer Chemotherapy 518
13.2 Endogenous Antagonists of Interleukin-1 Receptors as Therapy for Inflammatory Diseases 521
13.3 G Protein-Coupled Chemokine Receptors as Targets for the Human Immunodeficiency Virus (HIV) 523
13.4 G Protein Mutations in Pituitary Gland Tumors and Endocrine Diseases 525
13.5 Alterations in β-Adrenergic Receptor Signaling Proteins in Congestive Heart Failure 528
13.6 Nitric Oxide/cGMP Signaling as Therapeutic Targets in Cardiac and Vascular Disorders 531

14 Bioenergetics, Mitochondria, and Oxidative Metabolism
14.1 Pyruvate Dehydrogenase Deficiency 552
14.2 Fumarase Deficiency 555
14.3 Cyanide Poisoning 572
14.4 Leber Hereditary Optic Neuropathy 583
14.5 Mitochondrial Myopathies from Mutations in Mitochondrial tRNA genes 583
14.6 Exercise Intolerance in Patients with Mutations in Cytochrome *b* 584
14.7 NADPH Oxidase (NOX) in Health and Disease 585
14.8 Myocardial Reperfusion Injury 586

15 Carbohydrate Metabolism I: Major Metabolic Pathways and Their Control
15.1 Alcohol and Barbiturates 603
15.2 Arsenic Poisoning 605
15.3 Fructose Intolerance 607
15.4 Diabetes Mellitus 609
15.5 Lactic Acidosis 611
15.6 Pickled Pigs and Malignant Hyperthermia 612
15.7 Angina Pectoris and Myocardial Infarction 613
15.8 Pyruvate Kinase Deficiency and Hemolytic Anemia 618
15.9 Hypoglycemia and Premature Infants 620
15.10 Hypoglycemia and Alcohol Intoxication 628
15.11 Glycogen Storage Diseases 633

16 Carbohydrate Metabolism II: Special Pathways and Glycoconjugates

16.1 Glucose 6-Phosphate Dehydrogenase Deficiency 648
16.2 Wernicke–Korsakoff Syndrome: Associated Anomalies in Transketolase Activity 651
16.3 Essential Fructosuria and Fructose Intolerance: Deficiency of Fructokinase and Fructose 1-Phosphate Aldolase 653
16.4 Galactosemia: Inability to Transform Galactose into Glucose 654
16.5 Pentosuria: Deficiency of Xylitol Dehydrogenase; L-Xylulose Reductase 656
16.6 Ascorbic Acid (Vitamin C) Is Derived from Glucuronic Acid 656
16.7 Glucuronic Acid: Physiological Significance of Glucuronide Formation 656
16.8 Blood Group Substances 658
16.9 Congenital Disorders of Glycosylation (CDGs) 662
16.10 Defects in Catabolism of Glycoproteins 663
16.11 Glycolipid Disorders 664
16.12 Heparin Is an Anticoagulant 665
16.13 Chondrodystrophies due to Sulfation Defects 667
16.14 Mucopolysaccharidoses 668

17 Lipid Metabolism I: Synthesis, Storage, and Utilization of Fatty Acids and Triacylglycerols

17.1 Obesity 676
17.2 The Key Role of Fatty Acid Metabolism in Type 2 Diabetes: A Tribute to J. Denis McGarry 677
17.3 Triacylglycerol/Fatty Acid Cycle 690
17.4 Genetic Deficiencies in Carnitine Transport or Carnitine Palmitoyltransferase 693
17.5 Genetic Deficiencies in the Acyl CoA Dehydrogenases 694
17.6 Refsum Disease 697
17.7 Ketone Bodies as a Fuel: The Atkins Diet 699
17.8 Fatty Acids as Regulatory Molecules 703

18 Lipid Metabolism II: Pathways of Metabolism of Special Lipids

18.1 Clearance of Red Blood Cells: Role of Phosphatidylserine 710
18.2 Respiratory Distress Syndrome 711
18.3 Treatment of Hypercholesterolemia 727
18.4 Atherosclerosis 728
18.5 Diagnosis of Gaucher Disease in an Adult 737

19 Amino Acid and Heme Metabolism

19.1 Carbamoyl Phosphate Synthetase and *N*-Acetylglutamate Synthetase Deficiencies 762
19.2 Deficiencies of Urea Cycle Enzymes 762
19.3 Selenoproteins 765
19.4 Nonketotic Hyperglycinemia: Glycine Encephalopathy 766
19.5 Proline Dehydrogenase Deficiency 766
19.6 Deficiencies in the Glutamic Semialdehyde Pathway 767
19.7 Phenylketonuria 769
19.8 Tyrosinemias 769
19.9 Alkaptonuria 771
19.10 Homocysteinemia and Homocysteinuria 771
19.11 Diseases Involving Cystine 774
19.12 Diseases of Glutaric Acid Metabolism 774
19.13 Hyperlysinemia and Lysinuric Protein Intolerance 776
19.14 Histidinemia and Formiminotransferase Deficiency 777
19.15 Maple Syrup Urine Disease and Other Diseases in the Branched-Chain Amino Acid Degradative Pathways 778
19.16 Propionic Acidemia and Methylmalonic Aciduria 780
19.17 Primary Hyperoxaluria 781
19.18 Methionine Adenosyltransferase (MAT) Deficiency 782
19.19 Parkinson Disease 785
19.20 Tetrahydrobiopterin 786
19.21 Albinism 786
19.22 Tryptophan Hydroxylase Deficiency 787
19.23 Acute Intermittent Porphyria 794
19.24 Cytoprotective Role of Heme Oxygenase 798
19.25 Neonatal Isoimmune Hemolysis 798
19.26 Bilirubin UDP-Glucuronosyltransferase Deficiency 799
19.27 Elevation of Serum-Conjugated Bilirubin 800

20 Purine and Pyrimidine Nucleotide Metabolism

20.1 Loss-of-Function Mutations in Phosphoribosylpyrophosphate Synthetase1 (PRPS1): Arts Syndrome 810
20.2 Gout 811
20.3 Lesch–Nyhan Syndrome 816
20.4 Increased Cytosolic 5′-Nucleotidase Activity 819
20.5 Immunodeficiency Diseases Associated with Defects in Purine Nucleoside Degradation 820
20.6 Tumor Lysis Syndrome (TLS) 821
20.7 Hereditary Orotic Aciduria 823
20.8 Mitochondrial Neurogastrointestinal Encephalopathy Syndrome (MNGIE) 828

21 Metabolic Interrelationships

21.1 Obesity and the Metabolic Syndrome 840
21.2 Protein–Calorie Malnutrition 841
21.3 Starvation 842
21.4 Hyperglycemic, Hyperosmolar Coma 850
21.5 Hyperglycemia and Protein Glycation 852
21.6 Diabetes Mellitus, Type 2 866
21.7 Hypoglycemia and Diabetes 867
21.8 Diabetes Mellitus, Type 1 868
21.9 Cancer Cachexia 869

22 Biochemistry of Hormones

22.1 Hypopituitarism 891
22.2 Precocious Puberty 901
22.3 Decreased Insulin Receptor Kinase Activity in Gestational Diabetes Mellitus 911
22.4 Oral Contraception 926

Preface

In the early 1980s, we were motivated to prepare the First Edition of the **Textbook of Biochemistry with Clinical Correlations** because at that time no biochemistry text emphasized the astonishing advances in the second half of the twentieth century regarding our knowledge about normal and abnormal mammalian cell biochemistry, specifically that of humans. Thus the decision was made that in this textbook the focus of the presentation would be on the basic cellular biochemistry of eukaryotes, with an emphasis on mammalian cells and tissues. The depth and scope of the presentation is still that of a basic biochemistry text. In the preparation of the First Edition we also wanted students to catch a glimpse of how biochemical research has lead to an understanding of the causes of many human diseases. This was accomplished by presenting descriptions of the biochemistry of selected diseases in separate **Clinical Correlation** boxes. These correlations provide significance to the biochemistry, thus facilitating the learning process. The popularity of the correlations with students encouraged us to add new ones in all subsequent editions.

Why a Seventh Edition?

The ever-increasing depth of our knowledge of the biochemistry and control mechanisms of normal cells and tissues has been the primary incentive to update the content of the textbook.

Results of recent research have lead to an understanding of the molecular events of many cellular and physiological processes, which until now were poorly understood, such as the extracellular matrix proteins, programmed cell death, molecular motors, and cell signaling. Thus, it is appropriate to include these and other such topics in this textbook. In addition, many of these topics are now presented in biochemistry courses.

Finally it was also deemed necessary to reorganize some topics as research has uncovered the complex relationships between many cellular and tissue processes. Along with these changes the scope and number of Clinical Correlations has increased, covering topics as diverse as HIV infections, hypercholesteremia, diabetes, and Parkinson disease.

Objectives and Scope of Presentation for the Seventh Edition

The following objectives were established for the First Edition and have been retained in all subsequent editions. They are

- To present a clear and precise discussion of the biochemistry of eukaryotic cells, with an emphasis on those of mammalian tissues
- To have the scope and depth of presentation meet the requirements of upper-level undergraduate, graduate level, and professional school courses in biochemistry
- To relate biochemical events at the cellular level to physiological processes in the whole animal;
- To cite examples of abnormal biochemical processes in human disease

The textbook is organized and written such that any sequence of topics considered most appropriate by an instructor can be presented. Throughout this text, results from research of nonmammalian organisms are presented if the information is more advanced than that of similar studies with mammalian cells. Thus the book presents a current picture of our biochemical knowledge of eukaryotic cells.

Significant Changes in the Seventh Edition

Every chapter was updated with inclusion of new information and condensation of some material. Some of the changes are

- An expanded discussion of microRNAs
- An in-depth presentation of the basal lamina protein complex, molecular motors, programmed cell death, and cancer
- A presentation of membrane transport mechanisms that conforms to current nomenclature and research directions
- A discussion of unstructured proteins
- A reorganized discussion of amino acid metabolism that separates the synthesis, degradation, and roles of amino acids;
- A discussion of heme metabolism included with the amino acids, which is the more usual placement in a teaching program
- A comprehensive presentation of the absorption and transport of iron
- An inclusive discussion of the function of vitamins concentrated in one chapter
- An updating of chapter bibliographies, with selection of references from readily available sources, many accessible on the Web. References are generally to review articles and seminal publications; carefully selected websites are also listed
- Approximately one half of the questions and annotated answers are new to this edition; they are similar to those used in graduate and professional school admission examinations, some are based on data presented in a clinical vignette, and each set of questions has several problem-solving questions.

In addition, in response to reviewer recommendations, sections in many chapters have been reorganized for a better flow of information. Related content that in previous editions was presented in several different chapters has been consolidated into single presentations. Illustrations were updated and new figures added. The adage "A picture is worth a thousand words" is appropriate, and the reader is encouraged to study the illustrations because they are meant to clarify confusing aspects of a

topic. As in previous editions, there is frequent cross-referencing between chapters.

New Features in the Seventh Edition

To facilitate the students' learning, we have added several new features to the text.

- **Key Concepts:** A list of Key Concepts appears at the beginning of each chapter for students to use as a guide while studying the chapter and as a reference for self-evaluation at completion of study.
- **A Closer Look:** These boxes contain supplementary information on the topic under discussion.
- **Key Terms:** A list of Key Terms appears at the end of each chapter;
- **Online Mendelian Inheritance in Man (OMIM):** Accession numbers associated with a disease or enzyme in the Online Mendelian Inheritance in Man (OMIM) database are indicated at appropriate places in the text. The OMIM database (www.ncbi.nlm.nih.gov/Omim) catalogues known diseases with a genetic component.

Content and Organization of the Seventh Edition

The content of the seventh edition is divided into five major parts.

- **Part I, Structure of Macromolecules**, contains an introductory chapter on eukaryotic cell structure (Chapter 1), followed by two chapters on the chemistry and structure of nucleic acids (Chapter 2) and protein (Chapter 3).
- **Part II, Transmission of Information**, begins with separate chapters on the synthesis of the major cellular macromolecules, that is, DNA (Chapter 4), RNA (Chapter 5), and proteins (Chapter 6). A chapter on recombinant DNA and biotechnology is included because the knowledge and techniques in this area have had and continue to have a profound impact on research in nearly all facets of biochemistry (Chapter 7). Part II concludes with a chapter on the Regulation of Gene Expression in which mechanisms of both prokaryotes and eukaryotes are presented (Chapter 8).
- **Part III, Functions of Proteins**, opens with a presentation of the structure-function relationship of four major families of proteins, that is, antibody molecules, serine proteases, hemoglobin, and basal lamina proteins (Chapter 9). This is followed by a detailed discussion of enzyme function and kinetics (Chapter 10) and a separate chapter on the cytochromes P450, a unique and important family of enzymes (Chapter 11). A chapter on membrane structure and the essentials of transmembrane transport mechanisms (Chapter 12), and a chapter on the basic mechanisms of cellular signal transduction conclude Part III (Chapter 14). These chapters present the fundamentals of these topics and subsequent chapters present their role in specific cellular processes.
- **Part IV, Metabolic Pathways and Their Control**, opens with a chapter on bioenergetics and oxidative metabolism (Chapter 14). Separate chapters describe the major metabolic pathways of carbohydrates (Chapter 15), and special pathways of carbohydrates and glycoconjugates (Chapter 16). This is followed by a chapter covering the synthesis, storage, and utilization of energy in lipid form (Chapter 17), then one describing the metabolism of phospholipids, sphingolipids, cholesterol, and prostaglandins (Chapter 18). Amino acid and heme metabolism are covered in Chapter 19, followed by the synthesis and degradation of the purine and pyrimidine nucleotides (Chapter 20). A chapter on the integration of these metabolic pathways in humans completes this part (Chapter 21). A major emphasis throughout Part IV is on the controls of each pathway or process.
- **Part V, Physiological Processes**, covers those areas unique to mammalian cells and tissues beginning with a chapter on hormones that emphasizes their biochemical functions as messengers (Chapter 22) and a chapter on molecular cell biology containing discussions of four major physiological signal-transducing systems: the nervous system, the eye, muscle contraction and molecular motors, and blood coagulation (Chapter 23). A discussion of the cell cycle, programmed cell death, and cancer, three closely related topics, is presented (Chapter 24). A chapter on the complex and integrated biochemistry of digestion and absorption of basic nutritional constituents (Chapter 25) is followed by one on the functions and nutritional requirements of vitamins and minerals in metabolism (Chapter 26). The last chapter covers the general principles of human nutrition for proteins, carbohydrates, and fats (Chapter 27).

A **Glossary** with precise definitions serves as a ready reference to the most common words in the ever-expanding language of the biochemical sciences. New terms have been added to enrich this section.

A **Review of Organic Chemistry**, as an Appendix, is designed as a ready reference for the nomenclature and structures of important organic molecules encountered in biochemistry; it is not intended as a comprehensive review. The reader should become familiar with the content of the Appendix so that it can be used when necessary while reading the main text.

Clinical Correlations boxes in every chapter describe examples of human diseases where the ramifications of deviant biochemical processes are well established. There are 260 Clinical Correlations presenting the aberrant biochemistry of very common to relatively rare medical conditions, and in some cases their treatment based on the biochemical knowledge of the condition. The presentations are discussions of the altered biochemistry rather than a medical case study. In some instances, the same clinical condition is presented in different chapters, but each time it is based on the biochemistry being presented. In the case of several major diseases, as example diabetes, a single Clinical Correlation is designated as the primary discussion and other Correlations on the same disease cite the primary one for general background information. An understanding of the material in the main text does not require a reading of the Clinical Correlations. References are included in the Correlations to facilitate exploration of the topic in more detail. In a few cases, clinical conditions are discussed as part of the primary text because studies of the medical condition have lead to an understanding of a basic biochemical process.

Supplements

The *Textbook of Biochemistry with Clinical Correlations*, 7e offers a variety of innovative resources to support both students and instructors:

For students

Guided Explorations. 50 self-contained presentations, many with narration, employing extensive animated computer graphics to enhance student understanding of key topics.

Interactive Exercises. 22 molecular structures that have been rendered in Jmol, a browser-independent interface for manipulating structures in three dimensions, and paired with questions to facilitate comprehension of concepts.

Animated Figures. 25 figures illustrating various concepts, techniques, and processes; presented as brief animations that serve as helpful learning tools.

For instructors

PowerPoint Slides: Includes all of the figures in the text.

Image Gallery: All of the figures in the text in JPEG format.

Test Bank: Over 2,700 multiple choice questions, many derived from question banks compiled by the Association of Medical and Graduate Departments of Biochemistry.

In Conclusion

As in previous editions, this work is a multicontributor textbook. Each contributor holds a senior academic rank, and they are all members of the faculties of different universities. All of the contributors have been involved actively in teaching biochemistry in a graduate and/or medical program and each has an active research interest in the subject presented in the chapter that he or she has written. They prepared their chapters from the perspective of the classroom instructor, with the experience to select the topics and determine the emphasis required for students in a general biochemistry course.

Every contributor brings to the book an individual approach, leading to some differences in presentation. Every chapter, however, was edited to have a consistent writing style and to eliminate unnecessary repetitions and redundancies. A few topics are discussed in two different places in the book in order to make the individual discussions complete and self-contained. This repetition should facilitate the learning process.

The textbook is not intended as a compendium of biochemical facts or a review of the current literature, but each chapter contains sufficient detail on the subject to make it useful as a resource. Contributors were requested not to reference individual researchers and not to dwell on the historical aspects of their topic; our apologies to the many scientists who deserve recognition for their outstanding research contributions that have made this book possible.

One person must accept the responsibility for the final product in any project. The decisions concerning the selection of topics and format and reviewing the drafts and the responsibility for the final checking of the book were entirely mine. I accept full responsibility for these decisions. I welcome comments, criticisms, and suggestions from students, faculty, and professionals. It is our hope that this work will be of value to those embarking on the exciting experience of learning about the chemistry of life for the first time, as well as to those returning to a topic in which the information is expanding so rapidly.

Acknowledgments

The seventh edition of the *Textbook of Biochemistry with Clinical Correlations* was made possible by the efforts and encouragement of many people, and I extend to everyone my most sincere thank you. I am very indebted to each of the contributors for accepting the challenge of preparing the chapters, sharing their ideas to improve the book, readily accepting suggestions to modify their contributions, and cooperating throughout the preparation. To each I extend my deepest appreciation for a job well done. The contributors and I extend a special acknowledgement to our former teachers, colleagues, and students for their support and inspiration that made this text possible.

In the preparation of this edition, chapters from the 6th edition were critically reviewed by the following: Dr. David J. Edwards, University of Pittsburgh, Dr. Kevin Gaston, University of Bristol, UK, Professor James J. A. Heffron, University College Cork, Ireland, Dr. Thomas E. Smith, Howard University, Dr. Frank Vella, University of Saskatchewan, and Dr. Edward J.Wood, University of Leeds, UK. We, the contributors and I, are deeply indebted to them; their excellent comments and suggestions were the basis for major changes in the seventh edition. With regrets I note the death of Dr. Edward J. Wood in December, 2008; we have lost a dedicated and inspiring colleague. Our gratitude is extended to Dr. Emmanuel Skordalakes, The Wistar Institute, Philadelphia, PA, for supplying a model of a partial telomerase elongation complex for the cover.

I extend my sincerest appreciation and thanks to the members of the staff of the Higher Education Division of John Wiley & Sons for their participation in the production of this edition. It has been a pleasure to work with an extremely intelligent, professional, and encouraging group of individuals. My deepest gratitude is extended to Joan Kalkut, Biochemistry Editor, who patiently and conscientiously guided me during the production of this edition, and coordinated my activities. Joan made many valuable suggestions and was always available to answer my queries. I extend my appreciation to Kaye Pace, Vice President, and Executive Publisher for Sciences, for her commitment to the project. I am in debt to Petra Recter, Associate Publisher of Chemistry and Physics, Micheline Frederick, Production Manager and Kerry Weinstein, Senior Production Editor, for their efforts; each demonstrated the highest standards of professionalism. A special acknowledgement to Hilary Newman, Manager, Photo Department and many thanks to Yelena Zolotorevskaya, Editorial Program Assistant, who handled efficiently the administrative details. I extend my deepest appreciation to Marc Wezdecki, Media Editor, and Kevin Murphy, Senior Designer, and Hope Miller, designer, who created the cover. The attractive design of the pages was created by Laura Ireardi, to whom I offer special thanks. Marketing had an important role in the design of the book and I extend my deepest appreciation to Kristine Ruff for her very valuable input.

The copyediting and compositing of this edition were the responsibility of MPS Content Services, Macmillan Publishing Solutions. I want to express my special thanks to John Sollami, Vice President, Onshore Content Services, for his support and counsel. John and I worked together on the fourth edition, and it was my good fortune to be able to interact with him again. We wish to acknowledge Pat O'Maley, Operations Director, who was responsible for overseeing this phase of the project. The person responsible for the day by day activities of production was Edward Dionne, Project Manager, who patiently and meticulously oversaw the transformation of our manuscripts to pages. Ed kept me well informed, managed the many details involved, acted promptly to my suggestions and concerns, and kept us on schedule. It has been a pleasure to work with an efficient, knowledgeable, and conscientious professional, as well as a very pleasant individual; I extend my heartfelt thanks to him. The excellent copy-editing of the manuscripts was completed by Carol A. Loomis, and the Index was prepared by Diana Witt; to both my sincerest thank you.

I would be amiss if I did not acknowledge the members of the STM Division of John Wiley who guided the preparation of the manuscripts and gave me invaluable assistance and support. My special thanks to Michael Forster, Vice President and Associate Publishing Director, Physical Sciences, Wiley-Blackwell, for his continuing support, and Darla P. Henderson, Senior Acquisitions Editor, Anita Lekhwani Senior Acquisitions Editor, and Rebekah Amos, Senior Editorial Assistant, who were a constant support and had an important and valuable role in the completion of the seventh edition.

Finally, a very special note of gratitude to my wife, Marjorie, who had the foresight many years ago to encourage me to undertake the preparation of a textbook, who supported me during the days of intensive work, and who created an environment in which I could devote the many hours required for the preparation of this textbook. To Marjorie, my deepest and sincerest thank you.

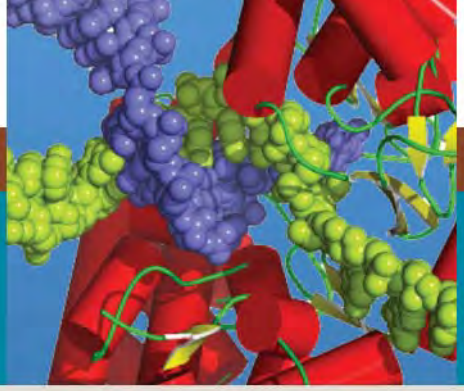
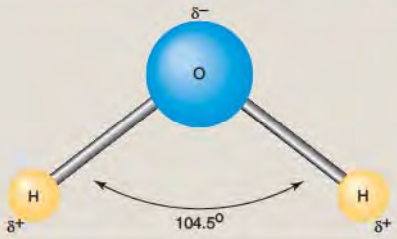
STRUCTURE OF MACROMOLECULES



1

Eukaryotic Cell Structure



Thomas M. Devlin

Professor Emeritus, Drexel University College of Medicine

1.1 • CELLS ARE THE BASIS OF LIVING ORGANISMS 2

1.2 • THE ENVIRONMENT OF CELLS: WATER AND SOLUTES 4

1.3 • pH, WEAK ACIDS, AND THEIR CONJUGATE BASES 6

1.4 • EUKARYOTES: MAMMALIAN CELLS AND TISSUES 11

1.5 • FUNCTIONS OF SUBCELLULAR ORGANELLES AND MEMBRANE SYSTEMS IN EUKARYOTE CELLS 14

1.6 • INTEGRATION AND CONTROL OF CELLULAR FUNCTIONS 21

CLINICAL CORRELATIONS

1.1 Abnormal Medical Conditions as Reflected in the pH of Blood 7
1.2 Importance of Blood HCO_3^- in Metabolic Acidosis 11
1.3 Accelerated Aging and the Cell Nucleus 16
1.4 Mitochondrial Diseases 18
1.5 Lysosomal Enzymes and Gout 19
1.6 Lysosomal Acid Lipase Deficiency 20
1.7 Peroxisome Biogenesis Disorders (PBD) 21

Key Concepts

- All living organisms consist of individual cells, delineated by an outer lipid membrane. Cells can have a variety of intracellular structures.
- Living cells include archae, eubacteria, and eukaryotes. Multicellular organisms can have a variety of specialized cells.
- Living cells control their internal environment, extract material from the environment for energy and synthesis of required molecules, and can replicate themselves.
- Water is an essential component of living cells. Water molecules form hydrogen bonds with each other and other molecules.
- Weak acids and acidic groups on macromolecules permit cells to control their intracellular hydrogen ion concentration (pH).
- Mammalian cells are compartmentalized into a variety of intracellular structures each with specialized functions.
- Cellular functions are integrated and can be controlled by both intracellular mechanisms and extracellular influences.

1.1 • CELLS ARE THE BASIS OF LIVING ORGANISMS

The basis of all living organisms, from the simplest to the most complex, is a unit of space enclosed by a membrane. This unit of space is termed a cell. The space enclosed can have a diameter of from 10 to 10,000 microns and varying degrees of internal structural complexity depending on the organism. Living cells exist as single independent cells, such as bacteria, and as multicellular organisms, such as humans with over 100 trillion cells. Regardless of the complexity of the organism, individual biological cells have the following characteristics in common:

- Many of the same inorganic ions and organic molecules, including carbohydrates and lipids, and the macromolecules, proteins, and nucleic acids.
- An external cellular membrane, the **plasma membrane**, composed of **amphipathic** phospholipids and protein. This delineates the space occupied and separates a variable and potentially hostile environment outside from a relatively constant intracellular milieu.
- Systems that link the interior to the external milieux.
- The ability to transform external energy sources into utilizable energy to power endergonic reactions in the cell. These extracellular sources include light, organic molecules, and concentration gradients of molecules across membranes.
- The ability to convert ingested nutrients into required cellular constituents and to eliminate degraded and toxic materials. The reactions of these processes are catalyzed by protein catalysts, that is, enzymes.
- The ability to synthesize macromolecules such as nucleic acids and proteins.
- A genome of **deoxyribonucleic acid (DNA)** containing the instructions for all cell functions.
- The ability to replicate, transferring the cells hereditary genomic information to progeny.

Approximately 3.7 billion years ago under conditions not entirely clear and in a time span difficult to comprehend, the elements hydrogen, oxygen, nitrogen, sulfur, and phosphate formed simple chemical compounds. These combined, dispersed, and recombined to form a variety of larger molecules until structures were achieved that were capable of replication. There is no conclusive record, however, of the environmental conditions that fostered these reactions. With continued formation of ever more complex molecules, these self-replicating molecules became encapsulated by a membrane to form cells. With the passage of time these simple life forms evolved into a cell that would become the "last common ancestor" of all the millions of species and subspecies on Earth, including humans. The "last common ancestor" of all humans appeared about 450 million years ago. The evolution of organisms continues. The vast diversity of life today, from the simplest bacteria to complex multicellular organisms such as plants and animals, is the product of these evolutionary changes.

Classification of Living Cells

All organisms are grouped into one of three major domains: archaea, eubacteria, and eukaryotes. The evidence is that all three were derived from an unknown common precursor cell. Archaea, which may be the most primitive of the domains, and eubacteria, that is, common bacteria, are classified as **prokaryotes** because they have many common structural features, including the lack of a defined nucleus or internal membrane structures. They are usually unicellular (Figure 1.1*a*) but in some cases form colonies or filaments. Prokaryotes have a variety of shapes and sizes and can live under a variety of conditions, some very extreme. The plasma membrane is often invaginated. DNA of prokaryotes is a single circular strand and often segregated into a discrete mass in the cell, the **nucleoid** region, which is not surrounded by a membrane or envelope. Even without defined membrane compartments, the intracellular milieu of prokaryotes is organized into functional compartments.

Eukaryotes include single-cell organisms such as yeasts, fungi, and multicellular plants and animals. Their cell volume is 1000 to 10,000 times larger than most prokaryotic cells.

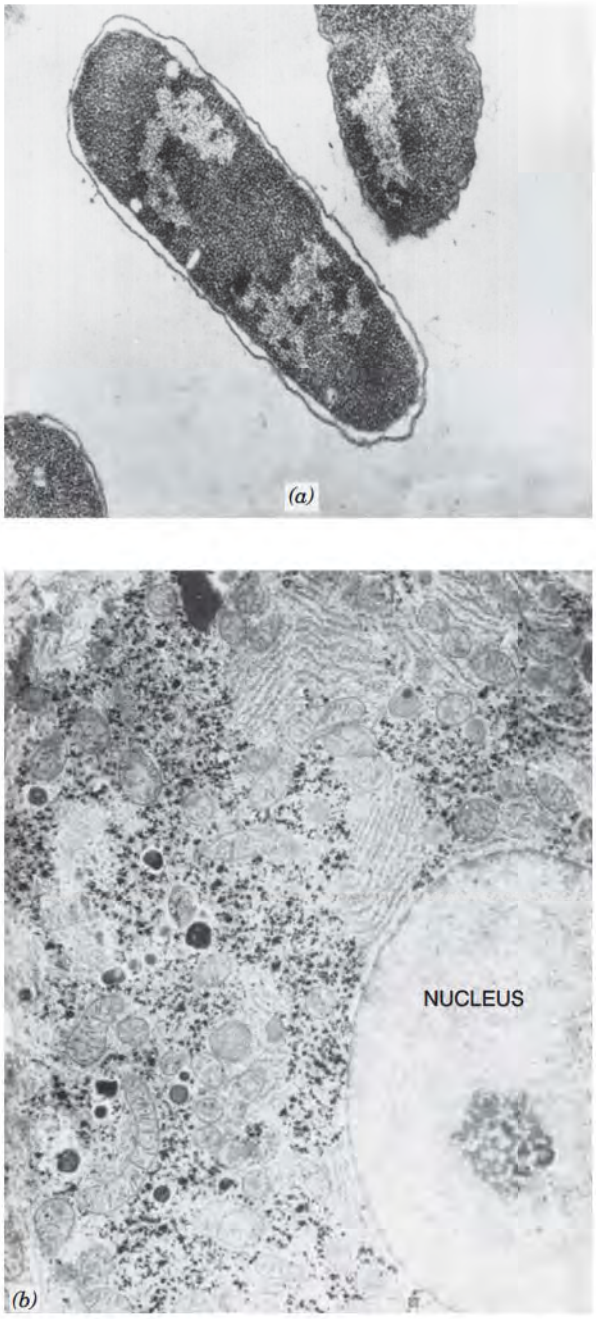


Figure 1.1 Cellular organization of prokaryotic and eukaryotic cells. (*a*) Electron micrograph of *Escherichia coli,* a representative prokaryote; approximate magnification ×30,000. There is some apparent intracellular organization but no membrane enclosed organelles. Chromatin is condensed in a nucleoid but not surrounded by a membrane. Prokaryotic cells are much smaller than eukaryotic cells. (*b*) Electron micrograph of a thin section of a liver cell (rat hepatocyte), a representative eukaryotic cell; approximate magnification ×7500. Note the distinct nuclear membrane, different membrane-bound organelles or vesicles, and extensive membrane systems.
Photograph (*a*) generously supplied by Dr. M. E. Bayer, Fox Chase Cancer Institute, Philadelphia, PA. Photograph (*b*) reprinted with permission of Dr. K. R. Porter, from Porter, K. R., and Bonneville, M. A. In *Fine Structure of Cells and Tissues.* Philadelphia: Lea & Febiger, 1972.

Eukaryotes have a defined **nucleus** with a well-defined membrane that contains the bulk of the cell's DNA. They also have extensive membrane systems and intracellular **organelles** surrounded by membranes (Figure 1.1*b*). These intracellular membrane systems establish distinct cellular compartments (p. 14), permitting a unique degree of subcellular organization. By compartmentalization, different chemical reactions that require different environments can occur simultaneously.

The basic chemical components and fundamental chemical reactions of all living cells, whether prokaryotes or eukaryotes, are very similar. There are many noteworthy differences, however, in chemical composition and biochemical activities between eukaryotes and prokaryotes. As an example, prokaryotes do not contain histones, a highly conserved class of proteins in all eukaryotes that complex with DNA (p. 54). There are also differences in enzyme content and in the ribonucleic acid–protein complexes, called ribosomes, involved in biosynthesis of proteins. The universality of many biochemical phenomena permits many extrapolations from prokaryotes to eukaryotes, including humans.

Emphasis throughout this book is on the biochemistry of eukaryotes, particularly mammals, but much of our knowledge of the biochemistry of living cells has come from studies of prokaryotic and non-mammalian eukaryotic cells.

1.2 • THE ENVIRONMENT OF CELLS: WATER AND SOLUTES

Life as we know it exists because of **water**, a common component of all biological cells and their extracellular environment.

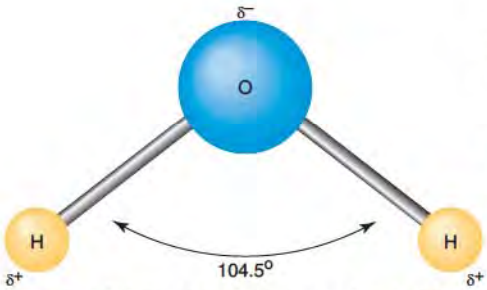

Figure 1.2 Structure of a water molecule. The H—O—H bond angle is 104.5°. Both hydrogen atoms carry a partial positive charge and the oxygen atom a partial negative charge, creating a dipole.

Hydrogen Bonds Form between Water Molecules

The dynamic interaction of individual water molecules leads to a dynamic "water structure" in aqueous systems. A water molecule is formed when two hydrogen atoms share their electrons with an unshared pair of electrons of an oxygen atom (Figure 1.2). Water is a polar molecule because the oxygen nucleus has a stronger attraction for shared electrons than hydrogen, and positively charged hydrogen nuclei are left with an unequal share of electrons. This creates a partial positive charge on both hydrogens and a partial negative charge on oxygen. The bond angle between hydrogens and oxygen is 104.5°, making the molecule electrically asymmetric, and thus producing an electric dipole.

Water molecules interact with each other because positively charged hydrogen atoms on one molecule are attracted to negatively charged oxygen atoms on other water molecules. A weak bond between two water molecules is formed (Figure 1.3*a*). This bond, indicated by a dashed line, is a **hydrogen bond**. Recent studies suggest that the bond between two water molecules is partially covalent. Hydrogen bonds are relatively weak compared to covalent bonds but their large number is the reason for the stability of liquid water. A detailed discussion of noncovalent interactions, including electrostatic, van der Waals, and hydrophobic, between molecules is presented on page 116.

Five molecules of water form a **tetrahedral structure** by hydrogen bonding (Figure 1.3*b*), with each oxygen sharing its electrons with four hydrogen atoms and each hydrogen with another oxygen. This tetrahedral lattice structure is responsible for the crystalline structure of ice. In the transition from ice to liquid water, only some hydrogen bonds are broken. Liquid water has a rapidly changing structure as hydrogen bonds break and new bonds form; the half-life of hydrogen bonds in water is less than 1×10^{-11} s. Thus the structure of liquid water is constantly fluctuating with a variety of structures containing many water molecules being constantly formed and changed. Water at the molecular level is heterogeneous with dynamic structures containing clusters of water molecules of varying size involving hundreds of molecules. Even at 100°C, liquid water contains a significant number of hydrogen bonds, which accounts for its high heat of vaporization. In the transformation from liquid to vapor state, hydrogen bonds are disrupted. Many models for the structure of liquid water have been proposed but none adequately explains all its properties.

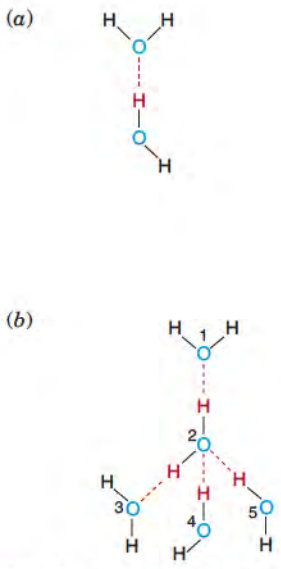

Figure 1.3 Hydrogen bonding in water. (a) Hydrogen bonding, indicated by dashed lines, between two water molecules. (b) Tetrahedral hydrogen bonding of five water molecules. Water molecules 1, 2, and 3 are in the plane of the page, 4 is below, and 5 is above.

The structure of pure water is altered when its atoms hydrogen-bond to other ions and chemical structures. Interaction of water molecules with other molecules leads to substantial changes in the orientation of water. As an example, water molecules are more ordered near the surface of membranes because of the amphiphilic nature of the membrane phospholipids (p. 465). Water present on and within molecules of proteins and nucleic acids stabilizes these macromolecules. Water structure may be different in the extracellular aqueous environment from that of the intracellular because of differences in ionic composition.

Substances required for the existence of cells are dissolved or suspended in an aqueous medium and their activities are influenced by the organization of the water molecules. Microenvironments with different water structures form in and on the surface of macromolecules and on the surface of lipid membranes because of the interaction of water with groups on these molecules. The presence of these microenvironments can lead to variations in activity of ions and molecules within different sites in a cell.

Hydrogen bonding also occurs between molecules other than water, wherever electronegative oxygen or nitrogen atoms come in close proximity with hydrogen covalently bonded

to another electronegative atom. Representative hydrogen bonds are presented in Figure 1.4. Intramolecular hydrogen bonding occurs extensively in large macromolecules such as proteins and nucleic acids; it is partially responsible for their structural stability.

Water Has Unique Solvent Properties

The polar nature of water and its ability to form hydrogen bonds are the basis for the ability of water to dissolve a variety of inorganic and organic molecules. Polar molecules such as salts are dispersed readily in water. The crystal lattice of **salts** is held together by attraction of positively and negatively charged atoms or groups. They dissolve in water because electrostatic forces in the crystal can be overcome by the attraction of the charged components to the dipole of water. The attraction of the charged Na^+ and Cl^- atoms in NaCl is overcome by interaction of Na^+ with the negative charge on oxygen atoms of water, and Cl^- with the positive charge on hydrogen atoms. In solution, the individual ions are surrounded by a shell of water. The number of weak charge-charge interactions between water and Na^+ and Cl^- ions is sufficient to maintain the physical separation of the charged ions.

Nonionic organic molecules containing weakly polar groups are also soluble in water because of attraction of the polar groups to molecules of water. Sugars and alcohols are readily soluble for this reason. Compounds that contain both polar and nonpolar groups, that is, **amphipathic** molecules, disperse in water if attraction of the polar group for water can overcome hydrophobic interactions of nonpolar portions of the molecules. Very hydrophobic molecules, such as lipids containing long hydrocarbon chains do not readily disperse as single molecules in water. They interact with one another to exclude the polar water molecules (p. 463).

Electrolytes: Dissociation of Molecules in Water

Molecules that dissociate in water form **cations** (positively charged ions) and **anions** (negatively charged ions). These are classified as **electrolytes** because the ions facilitate conductance of an electrical current. Sugars or alcohols are **nonelectrolytes** because they dissolve readily in water but do not carry a charge or dissociate into charged species.

Salts of alkali metals (e.g., Li, Na, and K) and acids such as hydrochloric and sulfuric at low concentrations dissociate completely when dissolved in water but not necessarily at high concentrations. In biological systems, such compounds as well as salts of organic acids are considered to be dissociated totally because of their low concentrations. If a solution contains a number of different salts (e.g., NaCl and K_2SO_4), these molecules do not exist as such in solution, only the dissociated ions (e.g., Na^+, K^+, and SO_4^{2-}) are present. Salts that dissociate completely are referred to as **strong electrolytes**. In water, the dissociated anions of organic salts react to some degree with free protons (H^+) from dissociation of water to form the undissociated acid (Figure 1.5).

In contrast to salts, many acids when dissolved in water do not dissociate totally but establish equilibrium between undissociated and dissociated components. Thus lactic acid, an important metabolic intermediate, dissociates partially into a lactate anion and a proton as follows:

$$CH_3{-}CHOH{-}COOH \rightleftharpoons CH_3{-}CHOH{-}COO^- + H^+$$

A dynamic equilibrium is established in which the products of the reaction reform the undissociated reactant while other molecules dissociate. The degree of dissociation of such an electrolyte depends on the affinity of the anion for an H^+. There will be more dissociation if the weak dipole forces of water that interact with the anion and cation are stronger than the electrostatic forces between the anion and H^+. On a molar basis such compounds, termed **weak electrolytes**, have a lower capacity to carry an electrical charge in comparison to those that dissociate totally.

In partial dissociation of a weak electrolyte, represented by HA, the concentration of various species can be determined from the equilibrium equation

$$K'_{eq} = \frac{[H^+][A^-]}{[HA]} \qquad (1.1)$$

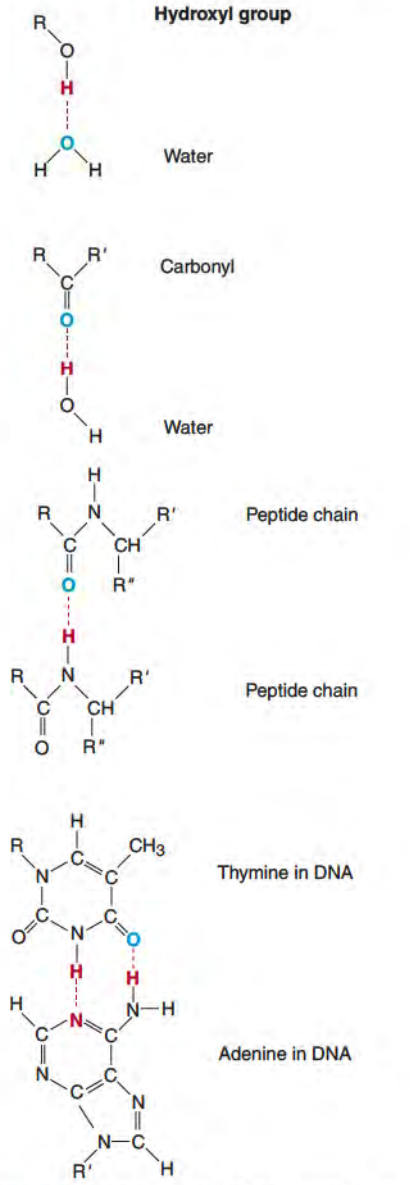

Figure 1.4 Representative hydrogen bonds of importance in biological systems.

Figure 1.5 Reactions that occur when sodium lactate is dissolved in water.

where K'_{eq} is a physical constant, A^- represents the dissociated anion, and square brackets indicate the concentration of each component in units such as moles per liter (mol/L or M) or millimoles per liter (millimol/L or mM). The **activity** of each species rather than concentration should be employed in the equilibrium equation, but since most compounds of interest in biological systems are present in low concentration, the value for the activity approaches that of concentration. The equilibrium constant, however, is notated as $\boldsymbol{K'_{eq}}$ to indicate that it is an apparent constant based on concentrations. Since the dissociation of an acid increases with increasing temperatures, the K'_{eq} will also increase.

From the dissociation equation, it is apparent that K'_{eq} will be a small number if the degree of dissociation of a substance is small (large denominator in Eq. 1.1) but large if the degree of dissociation is large (small denominator). A K'_{eq} cannot be determined for strong electrolytes because at equilibrium there is no remaining undissociated solute.

Water Is a Weak Electrolyte

Water dissociates as follows:

$$HOH \rightleftharpoons H^+ + OH^-$$

Protons that dissociate interact with oxygens of other water molecules to form clusters of water molecules, that is, $H^+(H_2O)_n$, where n has been determined to be from 6 to 27. This hydration of H^+ is often presented as $\mathbf{H_3O^+}$, the **hydronium ion**. It is a generally accepted practice, and one that will be employed in this book, to present the proton as H^+ rather than H_3O^+, while recognizing that $H^+(H_2O)_n$ is the actual chemical species. At 25°C the value of K'_{eq} for dissociation of water is about 1.8×10^{-16}.

$$K'_{eq} = 1.8 \times 10^{-16} = \frac{[H^+][OH^-]}{[H_2O]} \tag{1.2}$$

With such a small K'_{eq} an extremely small number of water molecules actually dissociate relative to the number of undissociated molecules. The concentration of water, which is 55.5 M, is essentially unchanged by the very small dissociation and is a constant. Therefore, Eq. 1.2 can be rewritten as follows:

$$K'_{eq} \times [H_2O] = [H^+][OH] \tag{1.3}$$

$K'_{eq} \times [55.5]$ is a constant and is termed the **ion product of water**. Its value at 25°C is 1×10^{-14}. In pure water the concentration of H^+ equals OH^-, and by substituting $[H^+]$ for $[OH^-]$ in Eq. 1.3, $[H^+] = 1 \times 10^{-7}$ M. Similarly, $[OH^-] = 1 \times 10^{-7}$ M. The equilibrium reaction of H_2O, H^+, and OH^- always exists in aqueous solutions regardless of the presence of dissolved substances. If the $[H^+]$ is increased, as occurs on addition of an acid, a decrease of $[OH^-]$ must occur in order to satisfy the equilibrium relationship of water. Similarly, if the $[OH^-]$ is increased, $[H^+]$ will decrease. Using the equation for ion product, $[H^+]$ or $[OH^-]$ can be calculated if the concentration of one ion is known. The importance of hydrogen ions in biological systems will become apparent in discussions of enzyme activity (p. 387) and metabolism.

TABLE 1.1 • Relationships Between $[H^+]$, pH, $[OH^-]$, and pOH

$[H^+]$ (M)	pH	$[OH^-]$ (M)	pOH
1.0	0	1×10^{-14}	14
0.1 (1×10^{-1})	1	1×10^{-13}	13
1×10^{-2}	2	1×10^{-12}	12
1×10^{-3}	3	1×10^{-11}	11

1×10^{-14}	14	1.0	0

1.3 • pH, WEAK ACIDS, AND THEIR CONJUGATE BASES

For convenience $[H^+]$ is usually expressed in terms of pH, defined as

$$\mathbf{pH = \log \frac{1}{[H^+]}} \tag{1.4}$$

In pure water $[H^+]$ and $[OH^-]$ are both 1×10^{-7} M, and pH = 7.0. $[OH^-]$ can also be expressed as pOH and has a value of 7. For the equation describing dissociation of water, $1 \times 10^{-14} = [H^+][OH^-]$; taking negative logarithms of both sides, the equation becomes 14 = pH + pOH. Table 1.1 presents the relationship between pH and $[H^+]$.

CLINICAL CORRELATION 1.1

Abnormal Medical Conditions as Reflected in the pH of Blood

In mammals, the different pHs of the various intra- and extracellular aqueous environments are in a dynamic steady state, with changes in one leading to changes in other compartments. Blood pH reflects changes in pH in tissues, and values above or below the normal range of pH of 7.35 to 7.45 indicates a potential pathological condition. Blood pH values below 7.0 (H^+ = 0.0000001 M) or above 7.8 (H^+ = 0.000000016 M) are life threatening, and medical intervention is necessary. Many medical conditions can cause significant changes of blood pH from normal. If the blood pH falls below 7.35, the condition is referred to as an **acidosis**, and above 7.45, as an **alkalosis**. Conditions of acidosis or alkalosis are further defined on the basis of the source of the increase of acid or base in the body, that is, whether it is due to a metabolic or respiratory change.

A **metabolic acidosis** can be due to excess production of organic acids (e.g., lactic acid or ketone bodies [p. 697]) or loss of HCO_3^- from the body. Excess production of acids can occur in diabetes, hypoxemia (e.g., excess lactic acid production as occurs in long-distance runners), and metabolism of xenobiotics that form acids. Loss of HCO_3^-, which changes the balance of base and acid, happens in severe diarrhea, uremia, and chronic renal diseases. A **respiratory acidosis** occurs when there is retention of CO_2, the anhydride of H_2CO_3, and is caused by conditions restricting the exhaling of CO_2 from the lungs such as when there is an accumulation of fluids in the lungs from conditions such as emphysema or asthma, restriction in breathing as in trauma, poliomyelitis, and severe obesity.

The major causes of **metabolic alkalosis** are retention of HCO_3^- and ingestion of bases. A **respiratory alkalosis** occurs by hyperventilation due to hysteria or tenseness, overdose of some drugs (e.g., salicylate), and fever.

Measurement of blood pH to monitor the acid–base status is a routine in many diseases because an uncontrolled decrease or increase in blood pH can lead to rapid and severe consequences.

Preston, R. A. *Acid-Base, Fluids, and Electrolytes Made Ridiculously Simple*. Miami, FL: Medmaster, 2002.

pH values of different biological fluids are presented in Table 1.2. In blood plasma, $[H^+]$ is 0.00000004 M or a pH of 7.4. Other cations such as Na^+ and K^+ are between 0.001 and 0.10 M, well over 10,000 times higher than $[H^+]$. Clin. Corr. 1.1 describes the significance of changes in the pH of blood.

The definitions of an acid as a **proton donor** and of a base as a **proton acceptor**, proposed by Lowry and Brønsted, are convenient in considering biological systems. HCl and H_2SO_4 are defined as strong acids because they dissociate totally, releasing protons. OH^- is a strong base because it readily associates with available protons to form H_2O. Addition of either an acid or base to water will lead to the establishment of a new equilibrium of $OH^- + H^+ \rightleftharpoons H_2O$. When a strong acid and OH^- are combined, H^+ from the acid and OH^- interact essentially totally and neutralize each other. Anions produced when strong acids dissociate, such as Cl^- from HCl, are not bases because they do not reassociate with protons in dilute solution.

Most organic acids found in biological systems dissociate partially and are classified as **weak acids**. They establish equilibrium between HA (proton donor), an anion (A^-) of the dissociated acid, and an H^+ as follows:

$$HA \rightleftharpoons A^- + H^+$$

The anion formed in this dissociation is a base because it can accept a proton to reform the acid. A weak acid and its base (anion) formed on dissociation are referred to as a **conjugate pair**. Some biologically important conjugate pairs are presented in Table 1.3. The ammonium ion (NH_4^+) is a weak acid because it dissociates to yield H^+ and uncharged ammonia (NH_3), a conjugate base. Phosphoric acid (H_3PO_4) is an acid and PO_4^{3-} is a base, but $H_2PO_4^-$ and HPO_4^{2-} are either a base or acid depending on whether the phosphate group is accepting or donating a proton.

The tendency of a conjugate acid to release H^+ can be assessed from the K'_{eq} (Eq. 1.1). The smaller the value of K'_{eq}, the less the tendency to give up a proton and the weaker the acid. The larger the value of K'_{eq} the greater the tendency to dissociate and the stronger the acid. Water is a very weak acid with a K'_{eq} of 1.8×10^{-16} at 25°C.

A convenient method of stating the K'_{eq} is in the form of pK', defined as

$$\mathbf{p}K' = \log \frac{1}{K'_{eq}} \qquad (1.5)$$

TABLE 1.2 • pH of Some Biological Fluids

Fluid	*pH*
Blood plasma	7.4
Interstitial fluid	7.4
Intracellular fluid	
Cytosol (liver)	6.9
Lysosomal matrix	Below 5.0
Gastric juice	1.5–3.0
Pancreatic juice	7.8–8.0
Human milk	7.4
Saliva	6.4–7.0
Urine	5.0–8.0

TABLE 1.3 • Some Conjugate Acid–Base Pairs of Importance in Biological Systems

Proton Donor (Acid)		*Proton Acceptor (Base)*
$CH_3—CHOH—COOH$ (lactic acid)	$\rightleftharpoons$	$H^+ + CH_3—CHOH—COO^-$ (lactate)
$CH_3—CO—COOH$ (pyruvic acid)	$\rightleftharpoons$	$H^+ + CH_3—CO—COO^-$ (pyruvate)
$HOOC—CH_2—CH_2—COOH$ (succinic acid)	$\rightleftharpoons$	$2H^+ + {}^-OOC—CH_2—CH_2—COO^-$ (Succinate)
$^+H_3NCH_2—COOH$ (glycine)	$\rightleftharpoons$	$H^+ + {}^+H_3N—CH_2—COO^-$ (glycinate)
H_3PO_4	$\rightleftharpoons$	$H^+ + H_2PO_4^-$
$H_2PO_4^-$	$\rightleftharpoons$	$H^+ + HPO_4^{2-}$
HPO_4^{2-}	$\rightleftharpoons$	$H^+ + PO_4^{3-}$
Glucose 6-PO_3H^-	$\rightleftharpoons$	H^+ + glucose 6-PO_3^{2-}
H_2CO_3	$\rightleftharpoons$	$H^+ + HCO_3^-$
NH_4^+	$\rightleftharpoons$	$H^+ + NH_3$
H_2O	$\rightleftharpoons$	$H^+ + OH^-$

Note the similarity of this definition with that of pH; as with pH and $[H^+]$, the relationship between pK' and K'_{eq} is an inverse one, and the smaller K'_{eq}, the larger pK'. Representative values of K'_{eq} and of pK' for conjugate acids of importance in biological systems are presented in Table 1.4. Details of the **carbonic acid**/bicarbonate system are presented in A Closer Look 1.1.

A CLOSER LOOK 1.1

Carbonic Acid (H_2CO_3) Is a Weak Acid Important in the Homeostasis of Animals

Carbonic acid (H_2CO_3), a weak acid, is very important in control of pH in mammals. CO_2 is constantly produced in catabolic reactions in tissues and is removed by the lungs in expired air. Measurements of blood CO_2 are important in determining the acid /base status of a patient. Medical conditions restricting the release of CO_2 from the body lead to an accumulation of H_2CO_3 and a condition of respiratory acidosis (see Clin. Corr. 1.1, p. 7).

Carbon dioxide when dissolved in aqueous systems is involved in the following equilibrium reactions:

$$CO_2 + H_2O \underset{}{\overset{K_2'}{\rightleftharpoons}} H_2CO_3 \overset{K_1'}{\rightleftharpoons} H^+ + HCO_3^-$$

Carbonic acid has a pK_1 of 3.77, which is comparable to organic acids such as lactic acid. The equilibrium equation for this reaction is

$$K_1' = \frac{[H^+][HCO_3^-]}{[H_2CO_3]} \tag{1}$$

H_2CO_3 is, however, in equilibrium with dissolved CO_2 and the equilibrium equation for this reaction is

$$K_2' = \frac{[H_2CO_3]}{[CO_2][H_2O]} \tag{2}$$

By solving Eq. 2 for H_2CO_3 and substituting for the H_2CO_3 in Eq. 1, the two equilibrium reactions can be combined into one equation.

$$K_1' = \frac{[H_1^+][HCO_3^-]}{K_2'[CO_2][H_2O]} \tag{3}$$

Rearranging to combine constants, including the concentration of H_2O (55.5 M), simplifies the equation and yields a new combined constant 3′ as follows:

$$K_1'K_2'\,[H_2O] = K_3' = \frac{[H^+][HCO_3^-]}{[CO_2]} \tag{4}$$

It is common practice in medicine to refer to dissolved CO_2 as the conjugate acid; it is the acid anhydride of H_2CO_3. The term K_3' has a value of 7.95×10^{-7} and $PK_3' = 6.1$. If the aqueous system is in contact with an air phase, dissolved CO_2 will also be in equilibrium with CO_2 in the air phase. Decrease or increase of one component—CO_2 (air), CO_2 (dissolved), H_2CO_3, H^+, or HCO_3^-—causes a change in every component. The CO_2/HCO_3^- system is extremely important for maintaining pH homeostasis in animals. CO_2 is constantly produced in catabolic reactions in tissues and is removed by the lungs in expired air. Respiratory acidosis can be either an acute (holding one's breath) or a chronic condition (pneumonia).

Henderson–Hasselbalch Equation Defines the Relationship between pH and Concentrations of Conjugate Acid and Base

A change in concentration of any component in an equilibrium reaction necessitates a concomitant change in every component. For example, an increase in $[H^+]$ decreases the concentration of conjugate base (e.g., lactate ion) with an equivalent increase in the **conjugate acid** (e.g., lactic acid). This relationship is conveniently expressed by rearranging the equilibrium equation and solving for H^+, as shown for the following dissociation:

$$\text{Conjugate acid} \rightleftharpoons \text{conjugate base} + H^+$$

$$K_{eq}' = \frac{[H^+][\text{conjugate base}]}{[\text{conjugate acid}]} \tag{1.6}$$

Dividing Eq. 1.6 by both $[H^+]$ and K_{eq}' leads to

$$\frac{1}{[H^+]} = \frac{1}{[K_{eq}']} \cdot \frac{[\text{conjugate base}]}{[\text{conjugate acid}]} \tag{1.7}$$

Taking the logarithm of both sides gives

$$\log \frac{1}{[H^+]} = \log \frac{1}{[K_{eq}']} + \log \frac{[\text{conjugate base}]}{[\text{conjugate acid}]} \tag{1.8}$$

Since $pH = \log 1/[H^+]$ and $pK' = \log 1/K_{eq}'$, Eq. 1.8 becomes

$$\mathbf{pH = pK' + \log \frac{[conjugate\ base]}{[conjugate\ acid]}} \tag{1.9}$$

Equation 1.9, referred to as the **Henderson–Hasselbalch equation**, is a convenient way of viewing the relationship between pH of a solution and relative amounts of individual conjugate base and acid pairs present. Analysis of Eq. 1.9 demonstrates that when the ratio of [base] to [acid] is 1:1, the pH equals the pK' of the acid because $\log 1 = 0$. If pH is

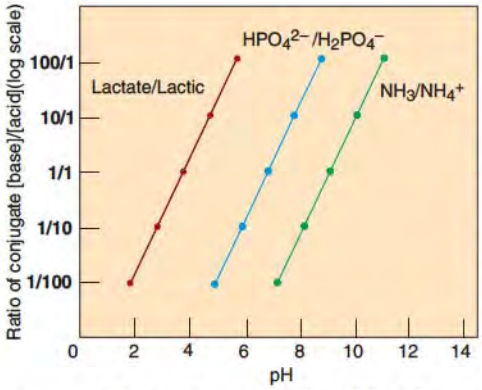

Figure 1.6 Ratio of conjugate [base]/[acid] as a function of pH. When the ratio of [base] to [acid] is 1, pH equals pK' of weak acid.

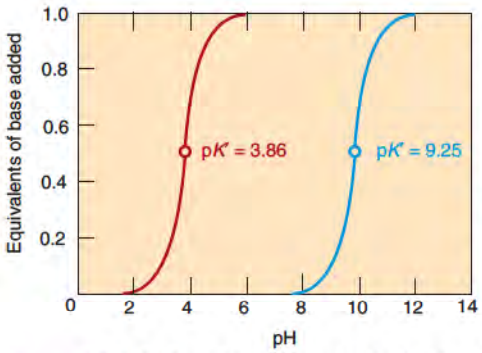

Figure 1.7 Acid–base titration curves for lactic acid (pK' 3.86) and NH_4^+ (pK' 9.25). At pH equal to respective pK' values, there will be an equal amount of acid and base for each conjugate pair.

one unit less than pK', the [base]/[acid] ratio is 1:10, and if pH is one unit above pK', the [base]/[acid] ratio is 10:1. Figure 1.6 is a plot of ratios of conjugate base to conjugate acid versus pH of several weak acids; note that ratios are presented on a logarithmic scale.

Buffering Is Important to Control pH

When NaOH is added to a solution of a weak acid, NaOH dissociates totally and the OH^- formed is neutralized by H^+ from the partially dissociated acid to form H_2O. The decrease in [H^+] causes further dissociation of the weak acid to comply with requirements of its equilibrium reaction. The amount of weak acid dissociated will be so nearly equal to the amount of OH^- added that it is considered equal. Thus, the decrease in the conjugate acid concentration is equal to the amount of conjugate base that is formed and the ratio of [conjugate base]/[conjugate acid] of the weak acid changes. The events are represented in titration curves of two weak acids presented in Figure 1.7. When 0.5 equivalent (equiv) of OH^- is added, 50% of the weak acid is dissociated and the [acid]/[base] ratio is 1.0; pH at this point is equal to pK' of the acid. Shapes of individual titration curves are similar but displaced due to differences in pK' values. There is a steep rise in pH when only 0.1 equiv of OH^- is added, but between 0.1 and 0.9 equiv of added OH^-, the pH change is only ~2. Thus, a large amount of OH^- is added with a relatively small change in pH. This is called **buffering** and is defined as the ability of a solution to resist a change in pH when an acid or base is added. If weak acid is not present, a small amount of OH^- would lead to a change to a high pH because there would be no significant source of H^+ to neutralize the OH^-.

The best buffering range for a conjugate pair is in the pH range near the pK' of the weak acid. Starting from a pH one unit below and going to a pH one unit above pK', about 82% of a weak acid in solution will dissociate, and therefore an amount of base equivalent to about 82% of original acid can be neutralized with a change in pH of 2. Maximum buffering ranges for conjugate pairs are considered to be between 1 pH unit below and 1 pH unit above pK'. The conjugate pair lactate ion/lactic acid with a pK' = 3.86 is an effective buffer between pH 3 and pH 5, with no significant buffering capacity at pH = 7.0. The $HPO_4^{2-}/H_2PO_4^-$ pair with pK' = 6.7 is an effective buffer at pH = 7.0. Thus at the pH of the cell's cytosol (~ 7.0), the lactate–lactic acid pair is not an effective buffer but $HPO_4^{2-}/H_2PO_4^-$ is.

Buffering capacity also depends on concentrations of conjugate acid and base. The higher the concentration of conjugate base, the more added H^+ with which it can react. The more conjugate acid the more added OH^- can be neutralized by dissociation of the acid. A case in point is blood plasma at pH 7.4. The pK' for $HPO_4^{2-}/H_2PO_4^-$ of 6.7 suggests that this conjugate pair would be a significant buffer in plasma. The concentration of the phosphate pair, however, is low compared to that of the HCO_3^-/CO_2 system with a

A CLOSER LOOK 1.2

pH and Buffering Problems

1. Calculate the ratio of HPO_4^{2-} to $H_2PO_4^-$ (pK' = 6.7) at pH 5.7, 6.7, and 8.7.

Solution: $$\mathbf{pH = pK' + \log \frac{[HPO_4^{2-}]}{[H_2PO_4^-]}}$$

$$5.7 = 6.7 + \log \text{ of ratio}$$

Rearranging, $5.7 - 6.7 = -1 = \log$ of ratio

The antilog of $-1 = 0.1$, or 1/10. Thus, $HPO_4^{2-}/H_2PO_4^- = 1/10$ at pH 5.7. Using the same procedure, the ratio of HPO_4^{2-} to $H_2PO_4^-$ at pH 6.7 = 1:1 and at pH 8.7 = 100:1.

2. If the pH of blood is 7.1 and the HCO_3^- concentration is 8 mM, what is the concentration of CO_2 in blood (pK' for HCO_3^-/CO_2 = 6.1)?

Solution: $$\mathbf{pH = pK' + \log \frac{[HCO_3^-]}{[CO_2]}}$$

$$7.1 = 6.1 + \log \frac{8 \text{ mM}}{[CO_2]}$$

Rearranging, $7.1 - 6.1 = 1 = \log \frac{8 \text{ mM}}{[CO_2]}$

The antilog of 1 = 10. Thus, $10 = 8 \text{ mM}/[CO_2]$. Rearranging,

$$[CO_2] = \frac{8 \text{ mM}}{10}$$

$$= 0.8 \text{ mM}$$

CLINICAL CORRELATION 1.2

Importance of Blood HCO_3^- in Metabolic Acidosis

Buffers in blood maintain the pH at about 7.40. Cellular production of acids leads to an acidification of blood where the H^+ is buffered by several different bases including HCO_3^-, hemoglobin, and HPO_4^{2-}. The pH of blood will decrease as the bases are consumed in the buffering process. If all the bases are used, there will be no further buffering capacity and the pH will decrease precipitously. The concentrations of HCO_3^- and CO_2 and pH of blood are measured in clinical practice to determine the acid/base status of patients. In a metabolic acidosis where the blood pH is less than 7.35 (Clin. Corr. 1.1, p. 7), it is important to monitor the pH as well as to evaluate the amount of HCO_3^- remaining to buffer against a continuing production of acid. Using the Henderson–Hasselbalch equation, with knowledge of two variables, the third can be calculated.

Consider the blood values of a patient with a metabolic acidosis were pH = 7.03, and $[CO_2]$ = 1.10 mM. Normal values are pH = 7.40, $[HCO_3^-]$ = 24.0 mM, and $[CO_2]$ = 1.20 mM. What is the patient's blood $[HCO_3^-]$, and how much of the normal $[HCO_3^-]$ has been used in buffering the acid causing the condition?

1. The Henderson–Hasselbalch equation is

$$pH = pK' + \log \frac{[HCO_3^-]}{[CO_2]}$$

   pK' for $[HCO_3^-]/[CO_2]$ is 6.10.
2. Substitute given values in the equation.

$$7.03 = 6.10 + \log \frac{[HCO_3^-]}{1.10\ mM}$$

   or $$7.03 - 6.10 = 0.93 = \log \frac{[HCO_3^-]}{1.10\ mM}$$

   The antilog of 0.93 = 8.5; thus,

$$8.5 = \frac{[HCO_3^-]}{1.10\ mM}$$

   or $[HCO_3^-]$ remaining in blood = 9.4 mM
3. Thus, there has been a decrease of 14.6 mmol of HCO_3^-/L of blood. If much more HCO_3^- is lost, this important buffer would be unavailable to buffer any additional acid and the pH would drop rapidly, very likely leading to death of the patient.

pK' of 6.1, which is present at a 20-fold higher concentration. The HCO_3^-/CO_2 system accounts for most of the buffering capacity even though its pK' is 1.3 pH units lower than plasma pH. Both pK' and the concentration of a conjugate pair must be taken into account when considering buffering capacity. Most organic acids are relatively unimportant as buffers in cellular fluids because their pK' values are more than several pH units lower than the pH of the cell, and their concentrations are too low in comparison to buffer systems such as $HPO_4^{2-}/H_2PO_4^-$ and HCO_3^-/CO_2.

A typical problem using the Henderson–Hasselbalch equation is presented in A Closer Look 1.2. Control of pH and buffering in humans cannot be over emphasized; Clin. Corr. 1.2 is a representative problem in clinical practice.

1.4 • EUKARYOTES: MAMMALIAN CELLS AND TISSUES

Eukaryotic cells contain subcellular structures, organelles, such as a **nucleus**, **mitochondria**, **lysosomes**, and **peroxisomes**, each enclosing a subcellular compartment that is delineated by a membrane (Figure 1.8). Membranes also form a tubular network throughout the cell, the **endoplasmic reticulum** and **Golgi apparatus**, enclosing an interconnecting space or cisternae respectively. The lipid–protein nature of all cellular membranes (p. 465) prevents rapid exchange of many molecules, including water, from one compartment to another. Specific translocation mechanisms in membranes control the concentrations of small and large, charged and uncharged molecules in the various subcellular compartments. Thus the composition of inorganic ions, organic molecules, proteins, and nucleic acids is different in the diverse organelles. Sequestering of specific substrates, cofactors, and enzymes in membrane-enclosed spaces increases metabolic efficiency and permits a greater degree of control of biological processes.

The chemical composition, activities, and functions of the various cellular compartments have been studied by using a variety of techniques. With intact cells, histochemical, immunological, and fluorescent staining methods have been employed. Methods for observations in real time of intracellular events in viable cells have been employed. Changes of

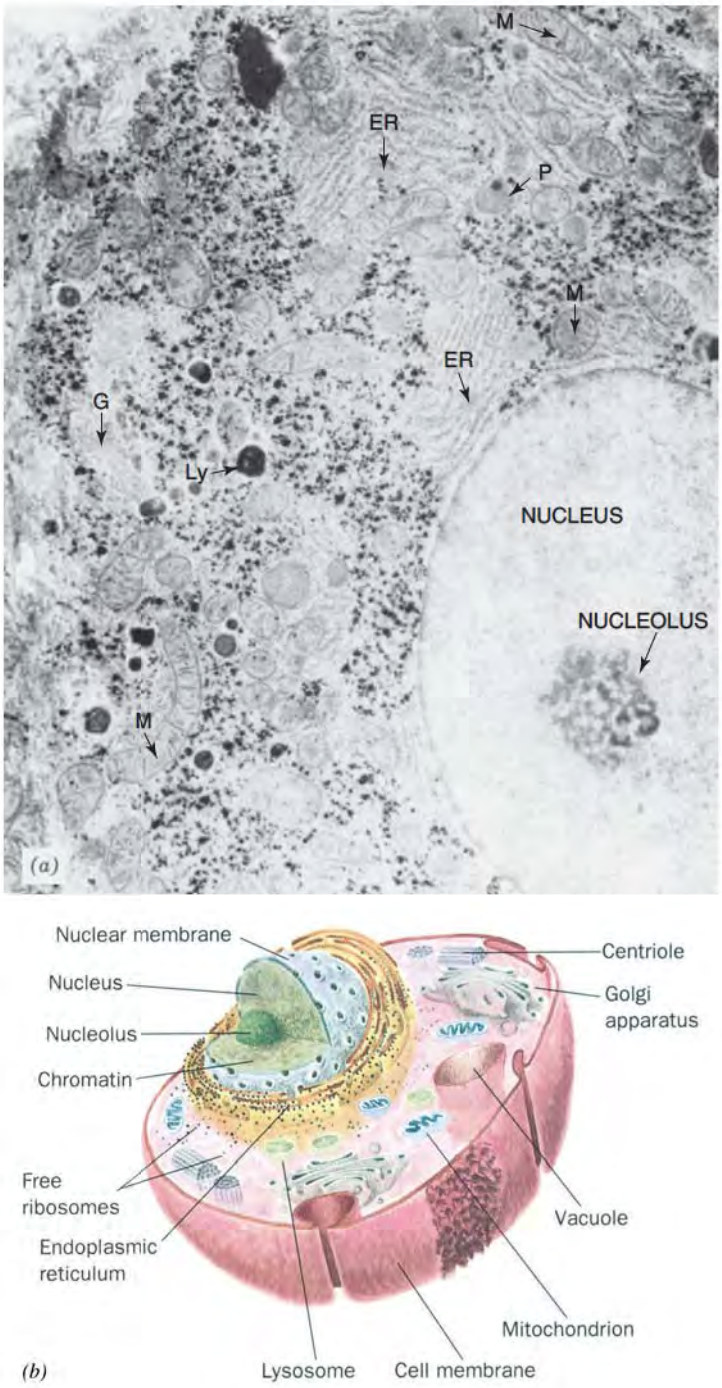

Figure 1.8 The Mammalian Cell. (*a*) Electron micrograph of a rat liver cell labeled to indicate the major structural components of eukaryotic cells. (*b*) A schematic drawing of an animal cell. Note the number and variety of subcellular organelles and the network of interconnecting membranes enclosing channels or cisternae. All eukaryotic cells are not as complex in their appearance, but most contain the major structures shown: ER, endoplasmic reticulum; G, Golgi apparatus; Ly, lysosome; P, peroxisome; and M, mitochondrion.
Photograph (*a*) reprinted with permission of Dr. K. R. Porter, from Porter, K. R., and Bonneville, M. A. In *Fine Structure of Cells and Tissues.* Philadelphia: Lea & Febiger, 1972. cytosolic pH and ionic calcium concentration are studied by use of ion-specific indicators. Cellular localization of specific proteins is determined by fluorescent antibodies. Individual organelles, membranes, and components of the cytosol can be isolated and analyzed after disruption of the plasma membrane. Techniques for disrupting the plasma membrane include use of osmotic shock, detergents, or homogenization of tissues. In the latter technique, shearing forces disrupt the plasma membrane. Differential centrifugation permits separation of cell components because of differences in their size and density. In addition, components of organelles, such as mitochondria and peroxisomes, can be isolated after disruption of the organelle membrane.

Most isolated structures and cellular fractions appear to retain the chemical and biochemical characteristics of the structure *in situ.* But biological membrane systems are subject to damage even under very mild conditions and changes in composition do occur during

isolation. Damage to a membrane alters its permeability properties and allows transfer of substances that would normally be excluded by the membrane barrier. In addition, many proteins are associated loosely with membranes and dissociate easily (p. 470).

Mammalian Cells

Mammals are one of the most complex multicellular organisms; there are over 5400 species within this class of vertebrates. They are not only multicellular, but the cells in each of the organ systems (liver, kidney, brain, etc.) are specialized to carry out specific functions. Many of the individual organs consist of a number of different cell types, each with a specialized role. There are over 200 different cell types in the human as determined by their physical and chemical attributes. These range from single cells such as leukocytes in blood to cells grouped together in organs such as neurons in the nervous system. With the exception of mature erythrocytes, which contain no DNA, all cells in an individual contain the identical genetic information in their DNA. Only the necessary information for the functions of an individual cell is expressed. In the postfertilization period of an egg, some cells, referred to as **embryonic stem cells**, have the potential to develop into every cell of every organ in the adult organism. These are **pluripotent cells**. Differentiated tissues contain **multipotent cells**, which can differentiate into a limited number of different cell types. Recent studies have demonstrated that the genome of differentiated cells can be reprogrammed to form multipotent or pluripotent cells. Thus the genetic information for development in the differentiated cell is not lost irreversibly but only suppressed.

All mammalian cells, regardless of the tissue of origin and degree of specialization, have many physical, chemical, and biochemical properties in common. Activities and components of cells of an organ of one species of mammals will be similar, if not identical, to those of the same organ of some other species. Within one mammal, including humans, the same protein or enzyme is present in cells of many different cell types (e.g., muscle and liver) but there are frequently marked differences in the quantity (e.g., concentration). A particular metabolic pathway may be very important in one cell type but less so in another. These differences are due to variations in the needs of individual specialized cells; these differences are controlled by expression of the genome in the diverse cell types.

All components of cells are in a dynamic equilibrium of being synthesized and degraded, creating a steady state of cellular concentration of these substances. This dynamic state varies between mammalian cell types. These **catabolic** (degradative) and **anabolic** (synthetic) pathways are regulated to maintain the proper balance of chemical intermediates and products. In many cases control is exerted by chemical signals generated intracellularly. Mammals also have complex and integrated chemical signaling systems for information transmission between cell types (p. 504). These pathways include synthesis and release of signal molecules from one cell type, transport to cells in another organ system, and specific recognition of the signal by target cells. In most cases, the signal molecule does not affect all cell types. An example is the role of hormones (e.g., insulin) synthesized by cells in the endocrine system altering the metabolism of glucose in the muscular system.

As indicated, a major difference between prokaryotes and eukaryotes is the presence of intracellular membrane systems and organelles in eukaryotes. This permits another level for facilitation and control of enzyme catalyzed chemical reactions. As an example, by having a metabolic pathway within the smaller space of an organelle (e.g., mitochondria), the concentration of chemical intermediates can be maximized to facilitate the output of the pathway or reaction. If this were not the case, the total amount of reactants in a cell would have to be higher to achieve the same outcome.

Chemical Composition of Mammalian Cells

The basic chemical components of biological cells are presented in Table 1.5. In different types of mammalian cells, the concentrations of intracellular inorganic ions are essentially similar but very different from those of the extracellular milieu. An approximation of the ionic composition of intracellular fluid, considered to represent primarily the **cytosol**, compared

TABLE 1.5 • Chemical Components of Biological Cells

Component	*Range of Molecular Weights*
H_2O	18
Inorganic ions Na^+, K^+, Cl^-, SO_4^{2-}, HPO_4^{2-} HCO_3^- Ca^{2+}, Mg^{2+}, etc.	23–100
Small organic molecules Carbohydrates, organic acids, lipids, nucleotides, peptides	100–1200
Macromolecules Proteins, polysaccharides, nucleic acids	6000–1,000,000

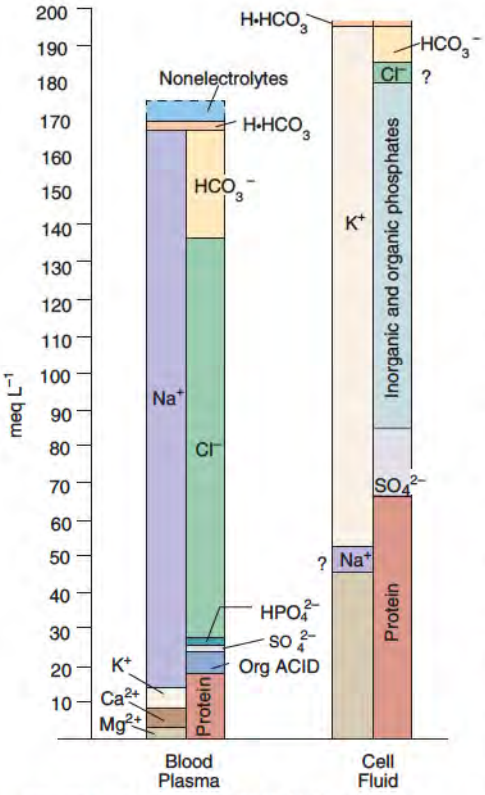

Figure 1.9 Major chemical constituents of blood plasma and cell fluid. Height of left half of each column indicates total concentration of cations; that of right half, concentration of anions. Both are expressed in milliequivalents per liter (meq/L) of fluid. Note that chloride and sodium values in cell fluid are questioned. It is probable that, at least in muscle, the cytosol contains some sodium but no chloride.

to blood plasma is presented in Figure 1.9. The volume and degree of hydration of cells are dynamic, and thus, these concentrations are only estimates of the actual concentrations. Na^+ is the major extracellular cation, with a concentration of ~140 meq/L (mM); very little Na^+ is present in intracellular fluid. K^+ is the major intracellular cation. Mg^{2+} is present in both extra- and intracellular compartments at concentrations much lower than Na^+ and K^+. The major extracellular anions are Cl^- and HCO_3^- with smaller amounts of phosphate and sulfate. Most proteins have a negative charge at pH 7.4 (p. 85), being anions at the pH of tissue fluids. Major intracellular anions are inorganic phosphate, organic phosphates, and proteins. Other inorganic and organic anions and cations are present in concentrations well below the meq/L level. Except for very small differences created by membranes and leading to the development of membrane potentials, total cation equals total anion concentration in the different fluids.

Intracellular concentrations of most small molecular weight organic molecules, such as sugars, organic acids, amino acids, and phosphorylated intermediates, are in the range of 0.01–1.0 meq/L, but some are significantly lower. Coenzymes, organic molecules required for activity of some enzymes, are in the same range of concentration. The overall cellular concentrations of substrates for enzymes are relatively low in comparison to inorganic ions; localization in specific organelles or cellular microenvironments, however, can increase their concentrations significantly.

It is not very meaningful to determine the molar concentration of individual proteins in cells. In many cases, they are localized in specific structures or in combination with other proteins to create functional units. It is in a restricted compartment that individual proteins carry out their role, whether structural, catalytic, or regulatory. It is of interest that blood plasma contains thousands of distinct proteins, ranging in concentration from about 10^{-3} M (albumin) to 10^{-13} M (parathyroid hormone), with some proteins that have even lower concentrations.

1.5 • FUNCTIONS OF SUBCELLULAR ORGANELLES AND MEMBRANE SYSTEMS IN EUKARYOTE CELLS

Organelles have very specific functions and their enzymatic activities serve as markers for the organelle during isolation. Some metabolic pathways are located in a single cellular compartment. As examples, the tricarboxylic acid cycle (p. 552) is entirely in mitochondria, glycolysis in cytosol (p. 592), and DNA replication only in nuclei and mitochondria. Some pathways are divided between two locations, with the pathway intermediates diffusing or being translocated from one compartment to another. The enzymes for heme synthesis (p. 791) are split between mitochondria and cytosol.

A summary of functions of the major structures of eukaryotic cells is presented in Table 1.6 and the structures are identified in Figure 1.8. With the ability to selectively inactivate or delete specific genes in animals (p. 292), pathological conditions and diseases have been identified involving most of the cellular organelles and structures. In many cases, however, the biochemical details that lead to the consequences of a modified gene have not as yet been determined.

Plasma Membrane Is Limiting Boundary of a Cell

The outer surface of **plasma membranes** (Figure 1.10) is in contact with a variable external environment and the inner surface with a relatively constant environment provided by the cell's cytoplasm. The protein composition of plasma membranes varies between cell types but there is a commonality in the lipid composition. Proteins and lipids are not randomly distributed throughout the membrane. The two sides of mammalian plasma membranes have a different lipid composition (p. 467).

The outer surface makes adhesive interactions with the extracellular matrix and other cells through **integrins**. These transmembrane proteins bind to the cytoskeleton inside the cell and participate in bidirectional signaling across the membrane. Through **cytoskeletal elements** the plasma membrane is involved in determining cell shape and movement. The

TABLE 1.6 • Summary of Eukaryotic Cell Compartments and Their Major Functions

Compartment	*Major Functions*
Plasma membrane	Transport of ions and small molecules
	Exo- and Endo-Cytosis
	Recognition
	Cell-Cell
	Receptors for small and large molecules
	Cell morphology and movement
Nucleus	DNA synthesis and repair
	RNA synthesis
Nucleolus	RNA processing and ribosome synthesis
Endoplasmic reticulum	Membrane synthesis
	Synthesis of proteins and lipids for some organelles and for export
	Lipid and steroid synthesis

	Cell morphology
	Cell motility
	Intracellular movements
Cytosol	Metabolism of carbohydrates, amino acids, and nucleotides; synthesis of fatty acids
	Protein synthesis

lipid nature of membranes excludes many substances, but transport mechanisms or pores allow transmembrane movement of ions, organic molecules, and water. Intercellular communication occurs by the presence of specific **protein receptors** on the outer surface of the plasma membrane for binding extracellular signals, such as hormones and neurotransmitters. The plasma membrane interacts with a variety of cytoplasmic substances to carry out endo- and exocytosis. Besides its role in the uptake of extracellular fluid, **endocytosis** has a significant role in programmed cell death, termed apoptosis (p. 1010). Details of membrane structure and biochemistry are presented in Chapter 12.

Nucleus Is Site of DNA and RNA Synthesis

The **nucleus** (Figure 1.11) is surrounded by two membranes, termed the **nuclear envelope**, with the outer membrane being continuous with membranes of the endoplasmic reticulum. The space between the membranes, the **perinuclear space**, is continuous with the lumen of the rough endoplasmic reticulum. The nuclear envelope contains numerous multi protein complexes, termed **nuclear pore** complexes, which cross the envelope and have a pore with an average diameter of about 90 Å. The complex permits controlled movement of particles and large molecules between the nuclear matrix and the cytoplasm. Transport of macromolecules requires expenditure of energy, and it is facilitated by a diverse series of cargo proteins and soluble transport factors, which cycle between the two compartments. It is now considered that the nuclear envelope plays important roles other than just as a barrier between the nuclear matrix and the

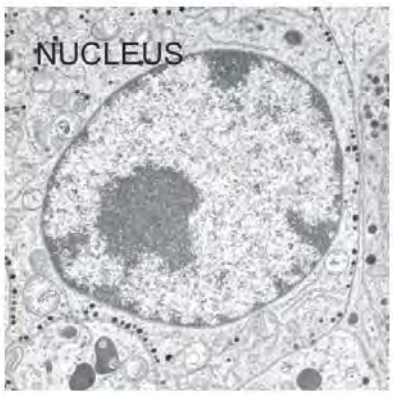

Figure 1.11 Nucleus of a mammalian cell. Electron micrograph generously supplied by Dr. John A. McNulty, Department of Cell Biology, Neurobiology and Anatomy, Stritch School of Medicine, Loyola University, Chicago.

CLINICAL CORRELATION 1.3

Accelerated Aging and the Cell Nucleus

Hutchinson–Gilford progeria syndrome (HGPS) (OMIM 17660) is a very rare condition where patients experience a rapid rate of aging beginning at birth. It is estimated that the syndrome occurs in about 1 in 4 to 8 million births. It is detected early in life with limited growth, loss of hair, distinctive facial characteristics, small fragile bodies, wrinkled skin, atherosclerosis, and cardiovascular problems, all of which are common in the elderly. Patients do not, however, have symptoms of neurodegenerative diseases. They rarely live past the early teens. The aging process in these individuals is 6 to 8 times the normal rate of aging.

A genetic change from normal has been identified in patients with HGPS. The nuclear envelope of patients appears distorted. Lamina A, a structural protein in nuclei, is involved in nuclear synthesis of DNA and RNA. It is formed from a precursor, attached to the nuclear membrane, by an enzyme-catalyzed reaction. HGPS patients have a deficit in this conversion, leading to accumulation of an abnormal lamina A in normal cells with aging. The presence of this abnormal protein causes blebbing of the nucleus, an alteration in gene expression, and interference with mitosis. At this time there is no established therapy for the condition, but by defining the causative changes, approaches to treatment may be possible. Results of studies of HGPS should also lead to unraveling details of the normal aging process.

Hutchinson-Gilford progeria syndrome, aging, and the nuclear lamina. *N. Engl. J. Med.* 358: 552, 2008; and Merideth, M. A., Gordon, L. B., Clauss, S., Sachdev, V., et al., Phenotype and course of Hutchinson-Gilford progeria syndrome. *N. Engl. J. Med.* 358: 592, 2008.

cytoplasm (Clin. Corr. 1.3). There are also intranuclear subcompartments, the major one being the **nucleolus**. A meshwork structure underlying the inner nuclear membrane, the nuclear lamina, supports the structure of the nucleus.

Deoxyribonucleic acid (DNA), the repository of genetic information, is located in the nucleus as a DNA–protein complex, **chromatin**, which is organized into chromosomes. The nucleus contains the proteins and enzymes for replication of DNA and for repair of DNA that has been damaged (p. 164). Transcription of the genetic information in DNA into a form that can be translated into cell proteins (p. 187) involves synthesis and processing of a variety of forms of **ribonucleic acid (RNA)**. The processing of RNA for assembly of ribosomes, required for protein synthesis in the cytosol, occurs in the nucleolus.

Endoplasmic Reticulum Has a Role in Protein Synthesis and Many Synthetic Pathways

The cytoplasm of eukaryotic cells contains an extensive network of interconnecting membranes that extend from the nuclear envelope to the plasma membrane, termed **endoplasmic reticulum (ER)**. It consists of membranes with a smooth (smooth ER or SER) appearance in some parts and rough (rough ER or RER) in other places (Figures 1.12 and 1.13). This dynamic organelle changes size and shape depending on the needs of the cell. The ER encloses the ER lumen, where newly synthesized proteins are modified. The rough appearance is due to the presence of **ribonucleoprotein particles**, called **ribosomes**, attached on its cytosolic side. During cell fractionation the endoplasmic reticulum network is disrupted and the membrane reseals to form small vesicles, termed **microsomes**. These vesicles are not present in cells.

A major function of ribosomes on rough endoplasmic reticulum is biosynthesis of proteins for incorporation into membranes and cellular organelles, and for export to the outside of the cell. The ER is involved in the folding of proteins; if the folding system is overwhelmed and unfolded proteins accumulate, a series of processes are induced to reduce the stress on the ER. There is some evidence that ER stress is involved in several diseases. Smooth endoplasmic reticulum is involved in lipid synthesis and contains enzymes termed cytochromes P450 (p. 426), which catalyze hydroxylation of a variety of endogenous and exogenous compounds. These enzymes are important in the biosynthesis of steroid hormones, removal of toxic substances, and drug metabolism. The endoplasmic reticulum and Golgi apparatus are also involved in formation of other cellular organelles such as lysosomes and peroxisomes and in Ca^{2+} signaling (p. 532).

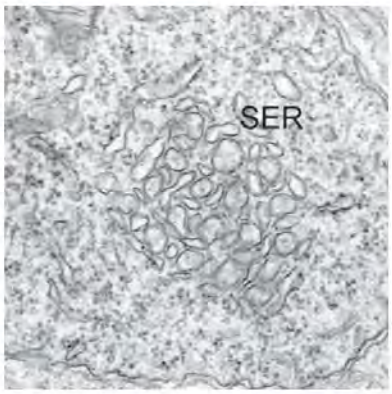

Figure 1.12 Smooth endoplasmic reticulum of a mammalian cell. SER, smooth endoplasmic reticulum.
Electron micrograph generously supplied by Dr. John A. McNulty, Department of Cell Biology, Neurobiology and Anatomy, Stritch School of Medicine, Loyola University, Chicago.

Golgi Apparatus Is Involved in Secretion of Proteins

The **Golgi apparatus** (also referred to as **Golgi complex**) (Figure 1.14) is a network of flattened smooth membrane stacks—cisternae—and vesicles. It works in consort with the endoplasmic reticulum where proteins for specific destinations are synthesized. Enzymes in Golgi membranes catalyze transfer of carbohydrate units to proteins to form glycoproteins, a process that is important in determining the proteins' eventual destination. The Golgi is the major site of new membrane synthesis and participates in formation of lysosomes and peroxisomes. Membrane vesicles shuttle proteins between the cisternae; they are pinched off one cisterna and fuse with another with the aid of a family of proteins, termed **SNARE** proteins. Vesicles originating from the Golgi apparatus transport proteins such as hormones, blood plasma proteins, and digestive enzymes to the plasma membrane for secretion. The Golgi apparatus also has a role in movement of lipids in the cell.

Mitochondria Supply Most of the Cellular Need for ATP

Mitochondria (Figure 1.15) are well established as the powerhouse of the cell, responsible for synthesis of over 90% of the required adenosine triphosphate (ATP) of cells (p. 572). They also have important roles in diverse cellular functions, including apoptosis (p. 1010), formation of reactive oxygen species (p. 583), cell signaling, and various metabolic processes. In electron micrographs, mitochondria appear as rods, spheres, or filamentous bodies, usually about 0.5–1 μm in diameter and up to 7 μm in length; some of these differences in shape may be due to the preparation of the tissue or cell for microscopic evaluation. The internal matrix of the organelle, the **mitosol**, is surrounded by two membranes, distinctly different in appearance, composition, and biochemical function. The inner membrane convolutes into the matrix to form **cristae** and contains numerous small spheres attached by stalks extending into the mitosol, which are responsible for ATP synthesis. The structure of cristae varies from tubular to lamellar depending on the tissue and functional state of the mitochondria. Mitochondria can divide by fission and fuse together; the proteins required for these processes have been identified, but many details of the actual mechanisms are not known. Exercise promotes an increase in the number of mitochondria in skeletal muscle. Components of the electron transport system and oxidative phosphorylation are part of the inner membrane (p. 559). Metabolic pathways for oxidation of pyruvate produced by glycolysis, fatty acids, and amino acids and some reactions in biosynthesis of urea and heme are located in the mitosol. The outer and inner membranes both contain mechanisms for translocation of specific proteins. There are a variety of transmembrane systems in the inner membrane for translocation of various metabolites. Mitochondria have a key role in aging; cytochrome c, a component of the mitochondrial electron transport system, is an initiator of apoptosis.

CLINICAL CORRELATION 1.4

Mitochondrial Diseases

The first disease specifically involving mitochondrial energy transduction (Lufts disease) (OMIM 238800) was reported in 1962. A 30-year-old patient had general weakness, excessive perspiration, a high caloric intake without increase in body weight, and an excessively elevated basal metabolic rate (a measure of oxygen utilization). She had a defect in the mechanism that controls mitochondrial oxygen utilization (p. 573). Since then several hundred genetic abnormalities have been identified that lead to alterations in mitochondrial enzymes, ribonucleic acids, electron transport components, and membrane transport systems. Some conditions result from mutations of mitochondrial DNA and others to mutations of nuclear DNA coding for mitochondrial proteins.

The first disease to be identified as due to a mutation of mtDNA was Leber Hereditary Optic Neuropathy (OMIM 535000), which leads to sudden blindness in early adulthood. Many mitochondrial diseases involve skeletal muscle and central nervous systems. Mitochondrial DNA damage may occur due to free radicals (superoxides) formed in the mitochondria. Abnormalities in mitochondria have been implicated in the pathophysiology of schizophrenia, bipolar disorder, and in age-related degenerative diseases, such as Parkinson disease, Alzheimer disease, and cardiomyopathies. Recently it has been suggested that a single mutation for a mitochondrial t-RNA leads to a constellation of symptoms including hypertension, high blood cholesterol, and decreased levels of plasma Mg^{2+}. The diseases caused by mutations of mtDNA are transmitted by a female to her offspring because mitochondria in the fertilized egg are derived from the ovum.

See Clin. Corrs. 6.6, page 229; 14.4, page 583; 14.5, page 583; 14.6, page 584; and 14.7, page 585, for details of specific mitochondrial diseases.

Luft, R. The development of mitochondrial medicine. *Proc. Natl. Acad. Sci. USA* 91:8731, 1994; Lin, M. T., and Beal, M. F. Mitochondrial dysfunction and oxidative stress in neurodegenerative diseases. *Nature* 443:787, 2006; Schapira, A. H. Mitochondrial disease. *Lancet* 368:70, 2006; and Pieczenik, S. R., and Neustadt, J. Mitochondrial dysfunction and molecular pathways of disease. *Exp. Mol. Path.* 83:84, 2007.

Mitochondria have a role in their own replication. They contain a number of copies of a circular DNA (**mitochondrial DNA** [**mtDNA**]), with genetic information for 13 mitochondrial proteins and some RNAs. The DNA is similar in size (16,569 base pairs) to that of bacterial chromosomes. The presence of an independent genome and the similarity to bacteria have lead to the widely accepted hypothesis that these organelles were bacteria that were taken up by a more advanced cell, and instead of being destroyed formed an endosymbiotic relationship. It is estimated that this event might have occurred some 3 billion years ago. The inheritance of mitochondria is by maternal transmission, and it has been possible to study the global movement of humans by evaluating variations in mtDNA. Mitochondria also have the requisite machinery (p. 582) to catalyze protein synthesis. Most mitochondrial proteins (over 90%) are derived from genes present in nuclear DNA and synthesized in the cytosol, then imported into the organelle. There are several hundred genetic diseases of mitochondrial function (Clin. Corr. 1.4).

Figure 1.16 Lysosomes of a mammalian cell. Electron micrograph generously supplied by Dr. John A. McNulty, Department of Cell Biology, Neurobiology and Anatomy, Strich School of Medicine, Loyola University, Chicago.

Lysosomes Are Required for Intracellular Digestion

Lysosomes (Figure 1.16) are responsible for intracellular digestion of both extracellular and intracellular substances. With a single limiting membrane, they maintain an acidic intralysosomal pH of about 5. Encapsulated in these organelles is a class of glycoprotein enzymes, **hydrolases**, which catalyze hydrolytic cleavage of carbon–oxygen, carbon–nitrogen, carbon–sulfur, and oxygen–phosphorus bonds in proteins, lipids, carbohydrates, and nucleic acids. A partial list of lysosomal enzymes is presented in Table 1.7. The enzyme content of lysosomes varies in different tissues and depends on specific tissue functions. Lysosomal hydrolases are most active at an acid pH and split complex molecules into simple low molecular weight compounds that can be reutilized. The relationship between pH and enzyme activity is discussed on page 387. Disruption of the lysosomal membrane within cells leads to cellular digestion. Various pathological conditions have been attributed to release of lysosomal enzymes, including arthritis, allergic responses, several muscle diseases, and drug-induced tissue destruction (Clin. Corr. 1.5).

Cells ingest foreign particles, such as microorganisms and viruses, by phagocytosis, fluids by **pinocytosis**, and specific proteins by **endocytosis**, a receptor mediated process. In each case material from the exterior of a cell is encapsulated in plasma membrane bound vesicles (Figure 1.17). The vesicles containing external material fuse with primary lysosomes to form secondary lysosomes, or **digestive vacuoles**, which contain material to be digested

CLINICAL CORRELATION 1.5

Lysosomal Enzymes and Gout

Catabolism of purines (p. 820), nitrogen containing heterocyclic compounds found in nucleic acids, leads to formation of uric acid, which is excreted in urine. Gout is an abnormality in which uric acid is produced in excess, leading to an increase of uric acid in blood and deposition of urate crystals in joints. Clinical manifestations include inflammation, pain, swelling, and increased warmth of some joints, particularly the big toe. Uric acid is rather insoluble, and some of the clinical symptoms of gout can be attributed to damage done by urate crystals. Crystals are phagocytized by cells in the joint, and they accumulate in intracellular digestive vacuoles that contain lysosomal enzymes. Crystals cause physical damage to the vacuoles, releasing lysosomal hydrolases into the cytosol. Even though the pH optimum of lysosomal enzymes is lower than the pH of the cytosol, they have some hydrolytic activity at the higher pH, which causes digestion of cellular components and cellular autolysis.

Weissmann, G. Crystals, lysosomes, and gout. *Adv. Intern. Med.* 19:239, 1974; and Burt, H. M., Kalkman, P. H., and Mauldin, D. Membranolytic effects of crystalline monosodium urate monohydrate. *J. Rheum.* 10:440, 1983.

and lysosomal hydrolases to carry out the digestion. They are identified microscopically by their size and often by the presence of partially digested structures. Primary lysosomes are those which have not fused with vesicles containing material to be degraded.

Cellular proteins, nucleic acids, lipid, and organelles, such as mitochondria, are in a dynamic state of synthesis and degradation. Lysosomes are responsible for hydrolysis of these cellular components by a highly regulated process termed autophagy. Substances destined to be degraded are identified and taken up by lysosomes or are first encapsulated

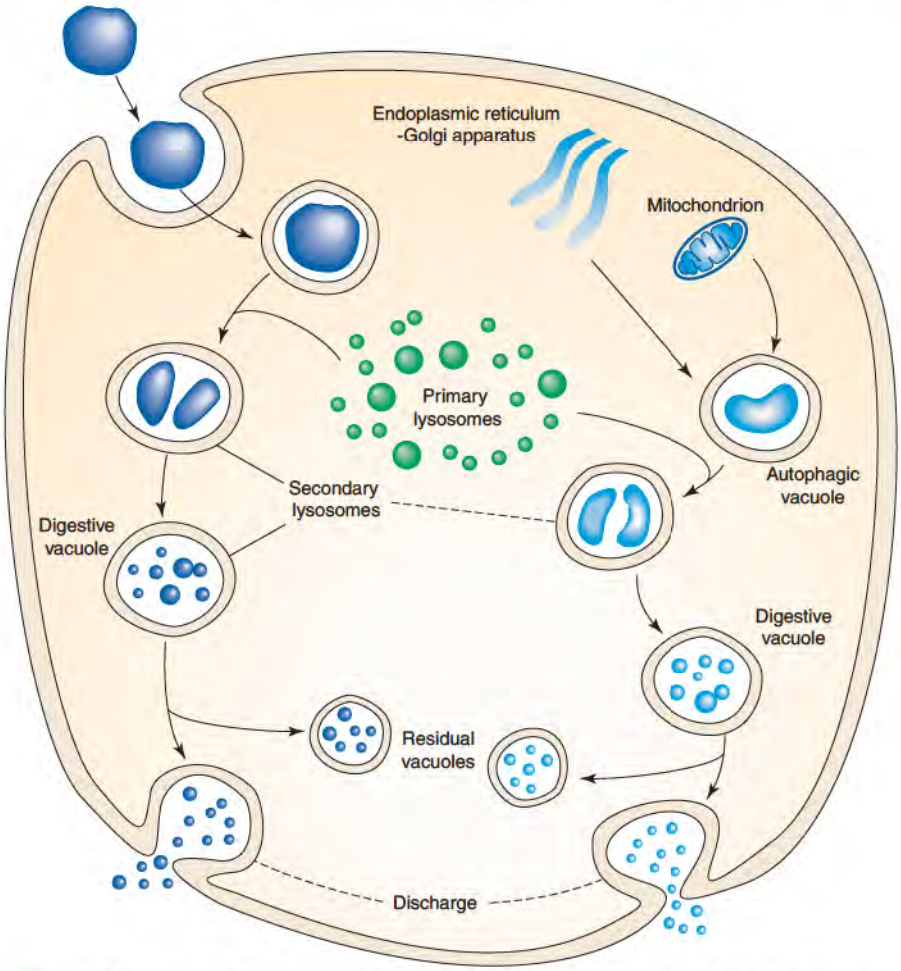

Figure 1.17 Diagrammatic representation of the role of lysosomes in intracellular digestion of substances internalized by phagocytosis (heterophagy) and of cellular components (autophagy). In both processes substances to be digested are enclosed in a membrane vesicle, followed by fusion with a primary lysosome to form a secondary lysosome where digestion occurs.

TABLE 1.7 • Representative Lysosomal Enzymes and Their Substrates

Type of Substrate and Enzyme	*Specific Substrate*
POLYSACCHARIDE HYDROLYZING ENZYMES	
α-Glucosidase	Glycogen
α-Flucosidase	Membrane fucose
β-Galactosidase	Galactosides
α-Mannosidase	Mannosides
β-Glucuronidase	Glucuronides
Hyaluronidase	Hyaluronic acid and chondroitin sulfates
Arylsulfatase	Organic sulfates
Lysozyme	Bacterial cell walls
PROTEIN-HYDROLYZING ENZYMES	
Cathepsins	Proteins
Collagenase	Collagen
Elastase	Elastin
Peptidases	Peptides
NUCLEIC ACID-HYDROLYZING ENZYMES	
Ribonuclease	RNA
Deoxyribonuclease	DNA
LIPID-HYDROLYZING ENZYMES	
Lipases	Triacylglycerol and cholesterol esters
Esterase	Fatty acid esters
Phospholipase	Phospholipids
PHOSPHATASES	
Phosphatase	Phosphomonoesters
Phosphodiesterase	Phosphodiesters
SULFATASES	
Chondroitin sulfatase	Heparan sulfate
Arylsulfatase B	Dermatan sulfate

CLINICAL CORRELATION 1.6

Lysosomal Acid Lipase Deficiency

Human lysosomal acid lipase (hLAL) hydrolyzes triacylglycerol to free fatty acids and glycerol, and cholesteryl esters to cholesterol and fatty acids. It is a critical enzyme in cholesterol metabolism, serving to make cholesterol available for the needs of cells. Cholesteryl ester storage disease (CESD) and Wolman disease (OMIM 278000) are two distinct phenotypic forms of a genetic deficiency of hLAL; both are rare autosomal recessive diseases. CESD is usually diagnosed in adulthood and is evidenced by hypercholesterolemia, hepatomegaly, and early onset of severe atherosclerosis. Affected individuals have hLAL activity but at a very low level (< 5% of normal). Apparently, this level is sufficient to hydrolyze triacylglycerol but not cholesteryl esters. Patients are homozygous for a mutation at a splice junction on both alleles leading to a catalytically defective and unstable enzyme.

Wolman disease is manifested in infants and is usually fatal by age one. There is no detectable activity of hLAL. Both triacylglycerol and cholesteryl esters accumulate in tissues. Patients are homozygous for a mutation that leads to an absence of active enzyme.

Hegele, R. A., Little, J. A., Vezina, C., et.al. Hepatic lipase deficiency: Clinical, biochemical, and molecular genetic characteristics. *Atherosclerosis and Thrombosis* 13:720, 1993; Anderson, R. A., Bryson, G. M. and Parks, J. S. Lysosomal acid lipase mutations that determine phenotype in Wolman and cholesteryl ester storage disease. *Mol. Genetics & Met.* 68:333, 1999; and Zschenker, O., Illies, T., and Ameis, D. Overexpression of lysosomal acid lipase and other proteins in atherosclerosis. *J. Biochem.* 140:23, 2006.

within membrane vesicles that fuse with primary lysosomes (Figure 1.17). Autophagy is important not only in stressed but also in normal mammalian cells; starvation and specific hormones induce autophagy.

Products of lysosomal digestion are released from lysosomes and reutilized by the cell. Indigestible material accumulates in vesicles called residual bodies whose contents are normally removed from the cell by exocytosis. Some residual bodies contain high concentrations of a pigmented substance that is chemically heterogeneous and contains polyunsaturated fatty acids and proteins. This material accumulates in cells and is termed **lipofuscin** or "age pigment" or "wear and tear pigment." Lipofuscin has been observed particularly in postmitotic neurons and muscle cells and has been implicated in the aging process.

Some lysosomal enzymes are normally secreted from the cell for digestion of extracellular material in connective tissue and prostate gland. In the genetic lysosomal storage diseases (p. 236), individual lysosomal enzymes are missing, leading to accumulation in lysosomes of the substrate of the missing enzyme. The lysosomes become enlarged with undigested material, interfering with normal cell processes (Clin. Corr. 1.6). One such is I cell disease in which the cellular mechanism for directing lysosomal enzymes into lysosomes during their synthesis is defective. Instead, the hydrolytic enzymes are exported out of the cell and damage the extracellular matrix (Clin. Corr. 6.8, p. 238).

Peroxisomes Have an Important Role in Lipid Metabolism

Most mammalian, protozoan, and plant cells have organelles, designated **microbodies** or **peroxisomes**, the latter because of their ability to produce or utilize **hydrogen peroxide** (H_2O_2). They have a single membrane and are small (0.3–1.5 μm in diameter), spherical or oval with a fine network of tubules in their matrix. The high protein concentration in the matrix of some peroxisomes leads to crystalline inclusions. They vary between cells in their enzyme composition, function, and number. Over 50 enzymes, catalyzing oxidative and biosynthetic reactions, have been identified in peroxisomes from different tissues.

Peroxisomes are essential for oxidation of very long-chain fatty acids (p. 701) and synthesis of glycerolipids, glycerol ether lipids (plasmalogens), and isoprenoids (p. 720). In mice, peroxisomes have been demonstrated to have a significant physiological role in lipid synthesis and degradation. They also contain enzymes that oxidize D-amino acids, uric acid, and various 2-hydroxy acids using molecular O_2 with formation of H_2O_2. **Catalase,** a heme enzyme (p. 587) present in peroxisomes, catalyzes the conversion of H_2O_2 to water and oxygen and oxidation of various compounds by H_2O_2 (Figure 1.18). Cells protect themselves from the toxicity of H_2O_2 by having both peroxide-producing and peroxide-utilizing enzymes in one compartment.

(1) $2H_2O_2 \longrightarrow 2H_2O + O_2$

(2) $RH_2 + H_2O_2 \longrightarrow R + 2H_2O$

Figure 1.18 **Reactions catalyzed by catalase.**

Proteins responsible for the biogenesis of peroxisomes have been identified. Several classes of **xenobiotics**, that is, foreign substances, including aspirin, lead to proliferation of peroxisomes in liver. Over 25 genetic diseases involve peroxisomes; they are grouped together as disorders of peroxisome biogenesis (Clin. Corr. 1.7).

Cytoskeleton Organizes the Intracellular Contents

Eukaryotic cells contain microtubules, intermediate filaments, and actin filaments (microfilaments) as parts of a cytoskeletal network, or scaffolding in the cytoplasm (p. 980). This dynamic structure has a role in maintenance of cellular morphology, intracellular transport of vesicles and organelles, cell motility, and cell division. The cytoskeleton includes **microtubules** consisting of multimers of **tubulin**, a protein that assembles rapidly into tubular structures and disassembles depending on the needs of cells. Actin and myosin form very important cellular filaments in striated muscle where they are responsible for muscular contraction (p. 969). Three separate super families of mechanochemical proteins—myosin, dynein, and kinesin—convert chemical energy into mechanical energy for movement of cellular components (p. 979). These molecular motors are associated with the cytoskeleton. Dynein is involved in ciliary and flagellar movement, whereas kinesin is a driving force for the movement of vesicles and organelles along microtubules, especially in neuronal axons. These motor proteins have a significant role in the pathogenesis of a variety of diseases.

Cytosol Contains Soluble Cellular Components

The least complex in structure, but not in chemistry, is the organelle-free cell sap, or **cytosol**. It is here that many reactions and pathways of metabolism (e.g., glycolysis, glycogenesis, glycogenolysis, and fatty acid synthesis) occur. Synthesis of proteins on both free ribosomes often in a polysome form and those bound to endoplasmic reticulum occurs in the cytosol, which contains all the required intermediates. Although there is no apparent structure to the cytosol, the high protein content precludes it from being a truly homogeneous mixture of soluble components, and it is believed that there are functional compartments throughout the cytosol. Many reactions are localized in selected areas where substrate availability is more favorable. The actual physicochemical state of the cytosol is poorly understood. Another complication of evaluating the composition of the cytoplasm is that some enzymes and proteins occur as soluble proteins when the cytosol is isolated, but in the intact cell may actually be loosely attached to membrane structures or to cytoskeletal components.

1.6 • INTEGRATION AND CONTROL OF CELLULAR FUNCTIONS

A eukaryotic cell is a complex structure that maintains an intracellular environment that permits many complex reactions and processes to occur simultaneously. This requires a high degree of control and integration. Cells of multicellular organisms also participate in maintaining the well-being of the whole organism by exerting influences on each other to maintain the balance between tissue and cellular activities. Very few functions operate totally independently; changes in one function can exert an influence, positive or negative, on other functions. As will be described throughout this book, the control of function is mediated at many levels, from the expression of a gene, to altering the concentration of an enzyme or a protein effector, to changes in substrate or coenzyme levels to adjust the rate of a specific enzyme reaction. The integration of many cellular processes is controlled by proteins that serve as activators or inhibitors that maintain cellular homeostasis. Many cellular processes are programmed to occur under specific conditions; for example, cell division in normal cells occurs only when the processes required for cell division are activated (p. 1004). Then and only then is there an orderly and integrated series of reactions culminating in the division of a cell into two daughter cells. Programmed cell death

CLINICAL CORRELATION 1.7

Peroxisome Biogenesis Disorders (PBD)

Peroxisomes are responsible for a number of important metabolic reactions, including synthesis of glycerol ethers, shortening very long-chain fatty acids so that mitochondria can completely oxidize them, and oxidation of the side chain of cholesterol needed for bile acid synthesis. Peroxisome Biogenesis Disorders (PBD) (OMIM 601539) comprise more than 25 genetically and phenotypically related disorders that involve enzymatic activities of peroxisomes. They are rare autosomal recessive diseases characterized by decreased levels of glycerol–ether lipids (plasmalogens), and increased levels of very long-chain fatty acids (C_{24} and C_{26}) and cholestanoic acid derivatives (precursors of bile acids). The disease can affect liver, kidney, brain, and skeletal systems. The most severe is Zellweger syndrome, which is due to the absence of functional peroxisomes; death frequently occurs by age 6 months. In this condition, the genetic defect is in the mechanism for importing enzymes into the matrix of peroxisomes. Some PBD conditions are caused by donor splice or missense mutations (p. 166); in some, there is the absence of a single metabolic enzyme or defect in a membrane transport component. In some instances the disease can be diagnosed prenatally by assay of peroxisomal enzymes or fatty acids in cells of amniotic fluid.

Peroxisome biogenesis disorders. *Biochim. Biophys. Acta.* 1763:1733, 2006.

(p. 1010) is a highly regulated process occurring in all mammalian cells but individual steps in the process vary from tissue to tissue. Many diseases are due to a failure in specific control mechanisms. As we continue to comprehend the complexity of biological cells, we are amazed that there are not many more errors occurring and many more individuals with abnormal conditions.

Thus as we proceed to study the separate chemical components and activities of cells in subsequent chapters, it is important to remember the concurrent and surrounding activities, constraints, and influences of the environment. Only by bringing together all the separate parts and activities of a cell, that is, reassembling the puzzle, will we appreciate the wonder of living cells.

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. Both prokaryotic and eukaryotic cells have all of the following except
- **A.** a plasma membrane.
- **B.** a genome of DNA.
- **C.** subcellular organelles defined by membranes.
- **D.** the ability to replicate.
- **E.** the ability to transform external sources of energy into utilizable energy.

2. Factors responsible for a water molecule being a dipole include the
- **A.** similarity in electron affinity of hydrogen and oxygen.
- **B.** tetrahedral structure of liquid water.
- **C.** magnitude of the H—O—H bond angle.
- **D.** ability of water to hydrogen bond to various chemical structures.
- **E.** difference in bond strength between hydrogen bonds and covalent bonds.

3. Hydrogen bonds can be expected to form only between electronegative atoms such as oxygen or nitrogen and a hydrogen atom bonded to
- **A.** carbon.
- **B.** an electronegative atom.
- **C.** hydrogen.
- **D.** iodine.
- **E.** sulfur.

4. Which of the following is both a Brønsted acid and a Brønsted base in water?
- **A.** $H_2PO_4^-$
- **B.** H_2CO_3
- **C.** NH_3
- **D.** NH_4^+
- **E.** Cl^-

5. Biological membranes are associated with all of the following except
- **A.** prevention of free diffusion of ionic solutes.
- **B.** release of proteins when damaged.
- **C.** specific systems for the transport of uncharged molecules.
- **D.** sites for biochemical reactions.
- **E.** free movement of proteins and nucleic acids across the membrane.

6. Analysis of the composition of the major fluid compartments of the body shows that
- **A.** the major blood plasma cation is K^+.
- **B.** the major cell fluid cation is Na^+.
- **C.** one of the major intracellular anions is Cl^-.
- **D.** one of the major intracellular anions is phosphate.
- **E.** plasma and cell fluid are all very similar in ionic composition.

Questions 7 and 8: A patient with Luft disease presented with general weakness, excessive perspiration, a high caloric intake without increase in body weight, and an excessively elevated basal metabolic rate. Luft disease was the first disease involving a defect in mitochondria to be described. It is a defect in the mechanism that controls oxygen utilization in mitochondria.

7. Components of the electron transport system and oxidative phosphorylation are found associated with the
- **A.** outer mitochondrial membrane.
- **B.** inner mitochondrial membrane.
- **C.** mitosol.
- **D.** peroxisomes.
- **E.** protein synthetic components.

8. Which of the following is a characteristic of mitochondria?
- **A.** The inner membrane forms cristae and contains small spheres attached by stalks on the inner surface.
- **B.** Only the outer membrane has transmembrane systems for translocation of metabolites.
- **C.** The mitosol is relatively inert metabolically.
- **D.** Mitochondrial DNA is similar to nuclear DNA in size and shape.
- **E.** Mitochondria have no role in apoptosis.

Questions 9 and 10: Gout is a condition in which excessive production of uric acid leads to deposition of urate crystals in joints. Clinical manifestations include inflammation, pain, and swelling of joints, especially the joint of the big toe. Crystals are phagocytosed by cells in the joint and accumulate in digestive vacuoles that contain lysosomal enzymes. Crystals cause physical damage to the vacuoles, releasing lysosomal enzymes into the cytosol.

9. Lysosomal enzymes
- **A.** are hydrolases.
- **B.** usually operate at acidic pH.
- **C.** are normally isolated from their substrates by the lysosomal membrane.
- **D.** can lead to cellular digestion if the lysosomal membrane is disrupted.
- **E.** all of the above.

10. Individual lysosomal enzymes are missing in a number of genetic diseases referred to as Lysosomal Storage diseases. In these diseases
- **A.** the defect is an inability to direct enzymes to the lysosome after synthesis.
- **B.** lysosomes of affected cells become enlarged with undigested materials.
- **C.** lipofuscin, or "wear and tear pigment," accumulates in cells.
- **D.** any material taken into the lysosome will accumulate.
- **E.** residual bodies contain the products of digestion.

11 and 12: Zellweger syndrome is one of a class called Peroxisome Biogenesis Disorders (PBD). PBDs are characterized by abnormalities of the liver, kidney, brain, and skeletal system. Zellweger syndrome is particularly severe and death usually occurs by age 6 months. There is an absence of functional peroxisomes.

11. Peroxisomes have a role in all of the following except
- **A.** oxidation of very long chain fatty acids.
- **B.** synthesis of glycerolipids.
- **C.** hydrolysis of cholesteryl esters.
- **D.** oxidation of D-amino acids.
- **E.** oxidation of uric acid.

12. One of the roles of peroxisomes is to render H_2O_2 nontoxic by
- **A.** oxidizing amino acids with O_2.
- **B.** the action of the enzyme catalase.
- **C.** transporting H_2O_2 from blood into peroxisomes.
- **D.** the action of cathepsins.
- **E.** shortening of a fatty acid chain.

Problems

13. If a weak acid is 91% neutralized at pH 5.7, what is the pK' of the acid?

14. If normal plasma pH is 7.4 and normal [CO_2] is 1.2 mM, what is the normal [HCO_3^-]? The pK' for this system is 6.1.

Answers

1. C The intracellular milieu of prokaryotes is organized into functional compartments, but they are not defined by membranes. A, B, D, and E: These are features that prokaryotes and eukaryotes have in common.

2. C Water is a polar molecule because the bonding electrons are attracted more strongly to oxygen than to hydrogen. The bond angle gives rise to asymmetry of the charge distribution; if water were linear, it would not be a dipole. A: Hydrogen and oxygen have very different electron affinity. B and D are consequences of water's structure, not factors responsible for it.

3. B Only hydrogen atoms bonded to one of the electronegative elements (O, N, or F) can form hydrogen bonds. A hydrogen participating in hydrogen bonding must have an electronegative element on both sides of it.

4. A $H_2PO_4^-$ can donate a proton to become HPO_4^{2-}. It can also accept a proton to become H_3PO_4. B and D are Brønsted acids; C is a Brønsted base. The Cl^- ion in water is neither.

5. E These molecules are too large to cross the membrane freely unless the membrane is damaged (B). A: Ionic solutes do not cross the lipid membrane readily. C: Most substances require transport across the membrane. D: Different membranes have different reactions.

6. D Phosphate and protein are the major intracellular anions. A, B, and E: plasma and cell fluid are strikingly different. The Na^+ ion is the major cation of plasma. C: Most chloride is extracellular.

7. B The electron transport and oxidative phosphorylation proteins are part of the inner membrane. D: Peroxisomes are separate organelles, not part of mitochondria. E: Mitochondria produce some of their own proteins but this is a separate process and not part of electron transport or oxidative phosphorylation.

8. A The cristae are the site of ATP synthesis. B: The outer membrane is relatively freely permeable; it is the inner membrane that is not and has multiple transport systems. C: The mitosol has numerous metabolic pathways–oxidation of pyruvate, fatty acids, and amino acids, for example. D: Mitochondrial DNA (mtDNA) is small and circular. E: Cytochrome c is an initiator of apoptosis.

9. E A: There are hydrolases for all classes of macromolecules. B and D: Lysosomal pH is usually about 5 but the enzymes retain some activity at higher pH. C: Substrates and enzymes are brought together by phagocytosis or pinocytosis.

10. B Engorgement interferes with normal cell processes. A: This is I cell disease and affects all of the lysosomal enzymes exported out of the cell. C: This is a normal process. Lipofuscin is a chemically heterogeneous pigmented substance and not caused by a missing lysosomal enzyme. D: Each Lysosomal Storage disease affects a single enzyme so only substrates of that enzyme would be affected. E: Residual bodies contain indigestible material.

11. C This occurs in lysosomes.

12. B H_2O_2 is converted to O_2 and H_2O. A and E: These produce H_2O_2. C: H_2O_2 is produced and utilized within peroxisomes. D: These are enzymes of lysosomes.

13. If a weak acid is 91% neutralized, 91 parts are present as conjugate base and 9 parts remain as the undissociated acid. Thus the conjugate base/acid ratio is 10:1. Substituting this ratio into the Henderson–Hasselbalch equation gives $5.7 = pK' + \log(10/1)$. Solving the equation for pK' gives an answer of 4.7. The acid could be β-hydroxybutyric acid, an important physiological acid, which has this pK'.

14. In this system CO_2 is the conjugate acid and HCO_3^- the conjugate base. Substituting the values in the Henderson–Hasselbalch equation would give

$$7.4 = 6.1 + \log(x/1.2)$$

The antilog of $1.3 = 20$. Therefore, $[HCO_3^-] = 20 \times 1.2 = 24$ mM. The ability to solve for any value in this equation given three of the terms is very important in assessing the acid–base status in the blood.

Key Concepts

- The central dogma of molecular biology holds that biological information specified by nucleic acid sequences in DNA and RNA determines protein sequences, and therefore, protein properties.
- The structures of nucleic acids are determined by the chemical properties of their constituent parts: phosphate, sugar, and nucleobase.
- Cellular DNAs are typically double-stranded polymers of 2′-deoxyribonucleoside 5′ monophosphates.
- Complementarity between the bases in the double helix allows DNA to function as a cellular genetic material.
- The length of a DNA molecule is much greater than the dimensions of a cell; therefore, DNA adopts higher-order structures that greatly compact the molecule into chromatin.
- The nucleotide sequence of DNA determines its function.
- Cellular RNAs are single-stranded polymers of ribonucleoside 5′ monophosphates.
- RNA tertiary structure is determined by intramolecular hydrogen bonding.
- Cellular RNAs have roles in information transfer, and catalytic and regulatory roles.

2.1 • NUCLEIC ACIDS AND BIOLOGICAL INFORMATION

Central Dogma of Molecular Biology

One of the hallmarks of living organisms is their ability to reproduce. The information that makes each individual life form unique must be preserved and passed on to progeny. All life on Earth uses **nucleic acids** for the storage of genetic information. With the exception of some viruses, the biomolecule utilized for information storage is **deoxyribonucleic acid (DNA)**. This molecule is remarkably well suited for its task because of its chemical stability and its ability to encode vast amounts of information using a simple four-letter code. However, DNA is only a part of the core architecture of life. **Ribonucleic acid (RNA)** and protein play equally important roles. The interrelationship of these three classes of molecules constitutes the "**central dogma of molecular biology**" (Figure 2.1), which holds that DNA stores information that determines the sequence of RNA which in turn determines the structure of protein. Much of the structure and biochemistry of cells is due to the properties of their constituent proteins. These properties are determined by portions of the sequence of DNA. Information, however, cannot flow directly from DNA to protein, but depends on RNA to transport the information. Genetic information is transmitted from DNA to RNA by **transcription.** The sequence of RNA is then **translated** into a protein sequence at the ribosome. DNA also plays an essential role in heredity by serving as the template for its own **replication.** Several discoveries have blurred the distinct roles of each of these biomolecules in the central dogma. For example, RNA can act as a catalyst **(ribozyme)** in biochemical reactions and constitutes the active component of ribosomes, the protein synthesis machinery of the cell. RNA can serve as a template for DNA synthesis, reversing the normal flow of information **(reverse transcription).** Some disease can be transmitted by proteins in the absence of nucleic acids. Nevertheless, nucleic acids play central roles in the storage and transmission of biological information.

DNA Can Transform Cells

Prior to the 1950s, the general view held that nucleic acids were substances of limited cellular importance. The first evidence that DNA is the genetic material was found during the 1920s, but the definitive demonstration of DNA's role was not accomplished until 1944. The key experiments involved two strains of pneumococcus, a bacterium that causes a form of pneumonia. When cultured, one strain formed smooth colonies and the other formed rough colonies; these were labeled the S- and R-forms, respectively. The S-form is virulent while the R-form is nonvirulent, and the two forms are genetically distinct and cannot interconvert spontaneously. Treatment of R-form bacteria with pure DNA extracted from the S-form resulted in their **transformation** into the S-form. The transformation was inherited permanently by subsequent generations. This demonstrated that DNA was the transforming agent and the material responsible for transmitting genetic information from one generation to the next. Clin. Corr. 2.1 describes vaccines based on transformation of mammalian cells with DNA.

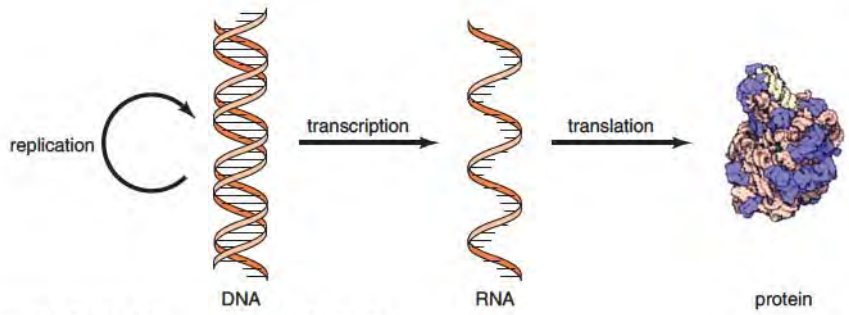

Figure 2.1 **Central dogma of molecular biology.**

Information Capacity of DNA Is Enormous

A striking characteristic of DNA is its ability to encode an enormous quantity of biological information. For example, a human cell contains information for the synthesis of about 20,000 to 25,000 proteins. This information is stored in the cell nucleus, a package roughly 0.00001 m in diameter. Despite this compactness, information in DNA is readily accessed and duplicated on command. The ability to store large amounts of information on molecules and to access it readily is still far beyond modern information technology. The capacity of nucleic acids to maintain and transmit the archived information efficiently arises directly from their chemical structure.

2.2 • STRUCTURAL COMPONENTS OF NUCLEIC ACIDS: NUCLEOBASES, NUCLEOSIDES, AND NUCLEOTIDES

Nucleic acids are linear polymers of **nucleotide** units. Each nucleotide consists of a phosphate ester, a pentose sugar, and a heterocyclic nucleobase. In RNA, the sugar is **D-ribose**; in DNA, it is the closely related sugar, **2-deoxy-D-ribose**. In either case, the base is attached to the 1-position of the sugar through a β-*N*-glycosidic bond. Two classes of major nucleobases are found in nucleic acids: **purines** and **pyrimidines** (Figure 2.2). The major purines are **guanine** and **adenine**, which occur in both DNA and RNA and are attached to the sugar at N-9. The three major pyrimidine nucleobases are **cytosine**, **uracil**, and **thymine**. Cytosine is present in both DNA and RNA. However, uracil is generally found only in RNA, and thymine is generally found only in DNA. Each pyrimidine is linked to the sugar through the N1-position. A nucleobase glycosylated with either pentose sugar is a **nucleoside.** Nucleosides that contain ribose are **ribonucleosides** (Figure 2.3) whereas those with **deoxyribose** are **deoxyribonucleosides** (Figure 2.4). Four ribonucleosides are commonly found in RNA—**adenosine (A), guanosine (G), cytidine (C),** and **uridine (U)**—and four deoxyribonucleosides in DNA—**deoxyadenosine (dA), deoxyguanosine (dG), deoxycytidine (dC), and deoxythymidine (dT)**. In addition, more than 80 minor nucleosides have been found in naturally occurring nucleic acids.

Nucleotides are phosphate esters of nucleosides (Figure 2.5). Any of the hydroxyl groups on their sugars can be phosphorylated, but the bases are not. Nucleotides that contain a phosphate monoester are nucleoside monophosphates. For example, the 5′-nucleotide of deoxycytidine is deoxycytidine 5′-monophosphate (5′-dCMP). More than one phosphate

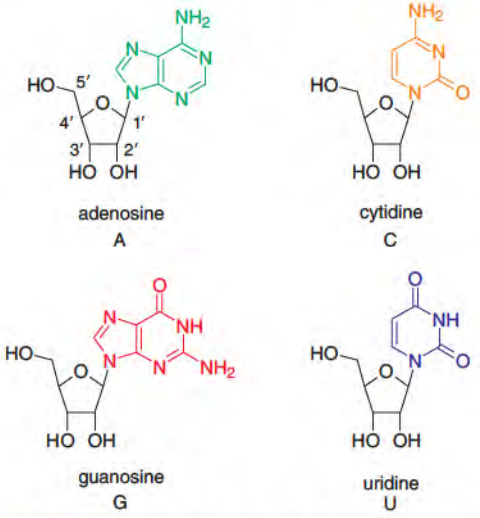

Figure 2.3 Structures of ribonucleosides. Shown are one-letter abbreviations for each compound. These abbreviations are also used for the corresponding bases and nucleotides and, in some instances, for the deoxyribonucleosides.

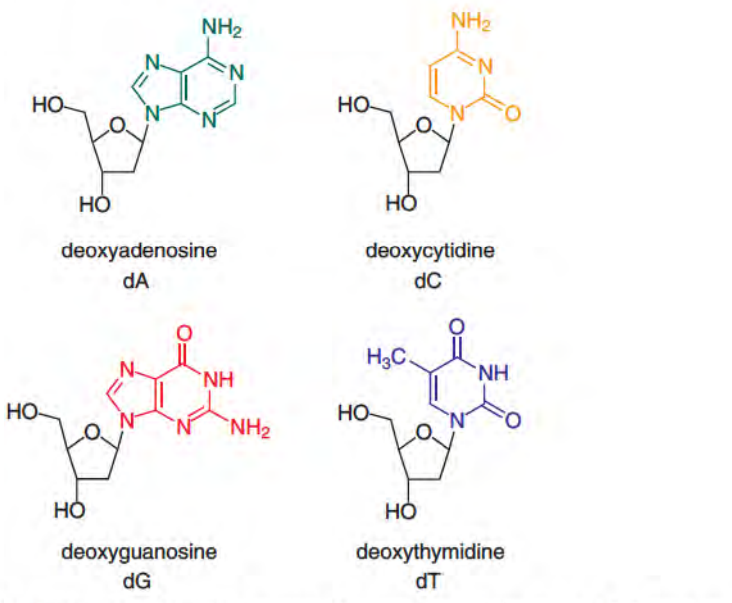

Figure 2.4 Structures of deoxyribonucleosides. Presence of 2-deoxyribose is denoted by a "d" preceding the one-letter notation. Note that thymidine (T) is often used interchangeably with deoxythymidine (dT).

CLINICAL CORRELATION 2.1

DNA Vaccines

Traditional procedures of vaccination have used components of infectious organisms, dead organisms, or attenuated intact cells to elicit production of specific antibodies that can provide individuals with active immunity. Such vaccines have successfully provided protection against diseases such as polio, smallpox, whooping cough, typhoid fever, and diphtheria. However, the development of immunizations against infectious pathogens such as HIV and malaria has proven to be difficult. The enormous worldwide impact of these pathogens, the potential bioterror uses of others, and the worsening problems of antibiotic resistance have prompted the efforts to produce new vaccines.

A recent approach to immunization has used DNA containing a sequence of the pathogen's genome. This DNA is typically a bacterial plasmid engineered to include the sequence of an antigenic protein from the pathogen. This DNA can enter a number of cell types, and it can be expressed there using cellular transcription and translation machinery. In this respect, DNA vaccines act much like viruses. However, these DNAs contain only a very limited amount of genetic information and cannot become infectious. The mechanisms of uptake and induction of the immune response are not yet clear. However, promising results have been observed against viruses, bacteria, and parasitic microorganisms. This approach holds great promise for the development of effective vaccines against intractable diseases including HIV/AIDS, tuberculosis, and malaria.

DNA vaccines may also be useful for vaccination against cancers. Although the antigens presented by tumor cells are only weakly immunogenic, model studies using plasmid DNA have shown promising results. Mice vaccinated by oral delivery of plasmids grown within attenuated *Salmonella* bacteria were able to slow or completely stop the growth of a lethal dose of carcinoma cells. Death of the bacteria presumably releases large numbers of the plasmids that are taken up by antigen-presenting cells of the immune system. Extension of this work to humans is currently under investigation.

can be linked by an anhydride linkage, resulting in the corresponding di-, tri-, and tetraphosphate esters. The 5′-triphosphate of guanosine is guanosine 5′-triphosphate (GTP). **Phosphate diesters** are also possible including the important second messengers—adenosine-3′, 5′-cyclic monophosphate (cAMP) and guanosine-3′, 5′-cyclic monophosphate (cGMP).

Physical Properties of Nucleosides and Nucleotides

To varying degrees, nucleobases, nucleosides, and nucleotides are soluble in water over a wide range of pHs. At biologically relevant pHs (pH 6–8), nucleobases and nucleosides are neutral species. The first p*Ka*s of phosphate mono- and diesters are ~1; thus, nucleotides carry a negative charge at physiological pHs. The second p*Ka* of a phosphate monoester is ~6.5, and an equilibrium exists between the monoanion and the dianion at neutral pHs. Nucleotides with di- and triphosphates carry multiple negative charges. The presence of charged phosphate groups on nucleotides provides sites for electrostatic interactions with positively charged sites on proteins and metal ions.

Nucleosides and nucleotides are stable over a wide range of pHs. Under strongly basic conditions, hydrolysis of phosphate esters slowly occurs. *N*-Glycosidic bonds of nucleosides and nucleotides are stable under these conditions, but under acidic conditions they are considerably more labile. At elevated temperatures, protonation of purine bases (G and A) results in rapid scission of the bond between the sugar and the base. Pyrimidine (C, T, and U) nucleosides and nucleotides are much more resistant to acid treatment. Conditions that break the glycosidic bond (e.g., 60% perchloric acid at 100°C) also lead to destruction of the sugar.

Molecules that contain purine or pyrimidine bases strongly absorb UV light. Purines and purine-containing nucleosides and nucleotides have higher molar extinction coefficients (absorb light more strongly) than pyrimidine derivatives. The UV wavelength where maximum absorption occurs varies but is usually near 260 nm. Because of the high extinction coefficients of nucleobases and their high concentration in nucleic acids, the absorbance at 260 nm can be used to accurately quantitate the amount of nucleic acid (DNA or RNA) present in a sample. Further analysis and separation of nucleobases, nucleosides, nucleotides, and nucleic acids can be accomplished by use of a variety of techniques, including high-performance liquid chromatography (HPLC), thin-layer chromatography (TLC), paper chromatography, and electrophoresis.

Structural Properties of Nucleosides and Nucleotides

A striking feature of nucleosides and nucleotides is the considerable number of possible conformations that they can adopt. Unlike six-membered rings, five-membered rings are highly flexible. The five-ring atoms in a pentose sugar are not coplanar; typically one or two of the atoms of the ring twist out of plane. In cyclopentane rings, there are several envelope and half-chair conformations that rapidly interconvert. Because of the asymmetric substitution pattern of the pentose ring in nucleosides, two conformations are preferred (Figure 2.6). These modes of **sugar puckering** are defined by the displacement of the 2′- and 3′-carbons above the plane of the C1′–O4′–C4′ atoms. By convention, above is the direction in which the base and C5′ project from the ring and is termed the endo face of the pentose. If C2′ is displaced above the pentose ring, the conformation is C2′-endo. In the second common pucker, C3′ is displaced toward the endo face and is called C3′-endo. Notably, the groups attached to the sugar have very different orientations in each of these conformations. For example, 5′- and 3′-phosphate groups are much farther apart in the C2′-endo pucker than in the C3′-endo pucker. The orientation of the glycosidic bond also changes significantly in the two conformations. C2′-endo and C3′-endo conformations are in rapid equilibrium. An electronegative substituent at the 2′-position of the pentose favors the C3′-endo conformation. Thus, ribonucleosides in RNA prefer this sugar pucker because they have a 2′-hydroxyl group. The 2′-deoxynucleosides of DNA contain a hydrogen in place of the 2′-OH group, and the C2′-endo conformation is preferred.

The bases in nucleosides are planar. Although free rotation around the glycosidic bond is possible, two orientations of the base with respect to the sugar predominate (Figure 2.7). In purines, the **anti conformation** places H8 over the sugar, whereas the **syn conformation** positions this atom away from the sugar and the bulk of the bicyclic purine over the sugar. Purines rapidly interconvert between the two conformations but favor the anti orientation. However, guanine 5′-nucleotides are exceptions. In these cases, favorable interactions between the 2-NH_2 group and the 5′-phosphate group stabilize the syn conformation. 2′-Deoxyguanosine 5′-monophosphate (dGMP), for example, prefers the syn glycosidic conformation. This preference has also been observed in double-stranded DNA with sequences of alternating Gs and Cs. The syn conformation of the G residues in such DNA results in formation of an unusual left-handed helix, termed Z-DNA (p. 38). In pyrimidines, the H6 atom is above the pentose ring in the anti conformation, and the larger O2 atom is above the ring in the syn glycosidic conformation. Pyrimidines, therefore, show a large preference for the less sterically hindered anti conformation.

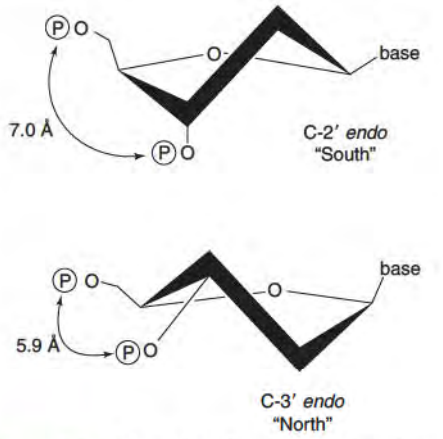

Figure 2.6 Preferred conformations of pentose sugars. The two conformations produce variations in relative orientation of the base (with respect to the sugar) and in the distance between 3′- and 5′-phosphate groups (P). Ultimately, these differences effect overall conformation of the double-helical complex.

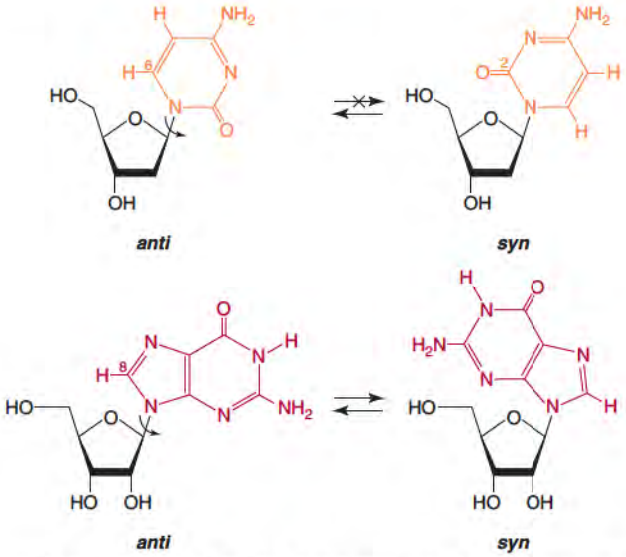

Figure 2.7 Glycosidic conformations of purines and pyrimidines. In pyrimidines, steric clashes between the sugar and the O2 of the base strongly disfavor the *syn* conformation. In purines, the *anti* and *syn* conformations readily interconvert, with *anti* being more stable in most cases. The *syn* conformation is stabilized in guanosine 5′-phosphates because of favorable interactions between the 2-NH_2 group and the phosphate oxygens.

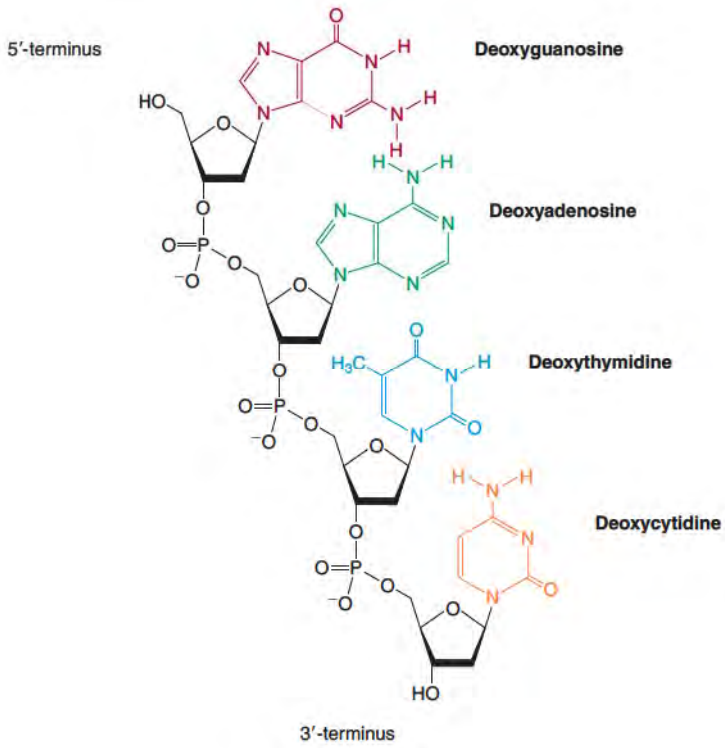

Figure 2.8 Structure of a DNA polynucleotide. Shown is a tetranucleotide. Generally, nucleic acids less than 50 nucleotides long are referred to as oligonucleotides. Longer nucleic acids are called polynucleotides.

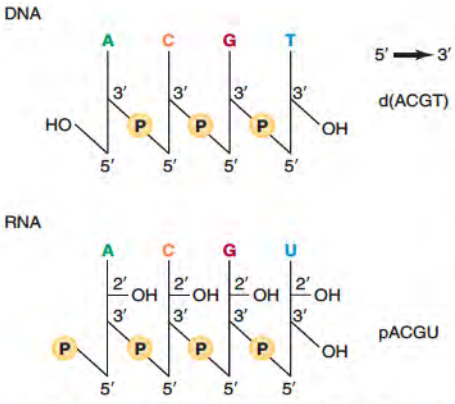

Figure 2.9 Shorthand notations for structures of oligonucleotides. The convention used in writing the structure of an oligo- or polynucleotide is a perpendicular bar represents the sugar moiety, with the 5′-OH position of the sugar located at the bottom of the bar and the 3′-OH (and 2′-OH, if present) at a midway position. Bars joining 3′- and 5′-positions represent the 3′→5′-phosphodiester bond, and the P on the left or right side of the perpendicular bar represents a 5′-phosphate or 3′-phosphate ester, respectively. The base is represented by its initial placed at the top of the bar. An alternative shorthand form is to use the one-letter initials for the bases written in the 5′→3′ direction from left to right. Internal phosphodiester groups are assumed, and terminal phosphates are denoted with a "p". Oligonucleotide sequences containing deoxyribose sugars are preceded by a "d".

2.3 • STRUCTURE OF DNA

Polynucleotide Structure and Properties

Nucleic acids are strands of nucleotides linked by **phosphodiester** bonds (Figure 2.8). The length of these strands varies considerably, ranging from two residues to hundreds of millions of residues. Typically, strands of nucleic acids containing 50 or fewer nucleotides are called **oligonucleotides,** whereas those that are longer are called **polynucleotides.** The phosphodiester bond links the 5′-hydroxyl group of one residue to the 3′-hydroxyl group of the next. Linkages between two 5′-OHs or two 3′-OHs are not seen in naturally occurring DNA. The **directionality** of this bond means that linear oligo- and polynucleotides have one end that terminates in a 5′-OH and another that terminates in a 3′-OH. These ends are the **5′-terminus** and **3′-terminus,** respectively. Circular polynucleotides have no free termini, and they are formed by joining the 5′-terminus of a linear polynucleotide with its own 3′-terminus through a phosphodiester bond. In both linear and circular polynucleotides, the sugar–phosphodiester backbone is highly uniform, and chemical diversity arises primarily from the bases. The **sequence** of bases provides each molecule with a unique chemical identity (Figure 2.9). This arrangement is analogous to that in polypeptides and proteins (p. 80) where variations in chemical structure primarily arise from the identity of the amino acid side chains.

Polynucleotide Conformations

The bases are largely responsible for the conformations of polynucleotides. The edges of the bases contain nitrogen and oxygen atoms (—NH_2, =N-, and =O groups) that can interact with other polar groups or surrounding water molecules. The faces of the rings, however, cannot participate in such interactions and tend to avoid contact with water. Instead they interact with one another, producing a stacked conformation. **Base stacking** reduces the hydrophobic surface area that must be solvated by polar water molecules. Release of these water molecules into the bulk solvent is entropically favorable. The stacked arrangement of bases is further stabilized by favorable electronic interactions (van der Waals forces). Like other aromatic systems, the bases possess highly delocalized π-orbitals above and below the planes of their rings. This electron density can be polarized by nearby dipoles.

The resulting induced dipole can then favorably interact with the polarizing group. These weak interactions are further enhanced by attractive London dispersion forces (induced dipole-induced dipole). Because the strength of these electronic interactions is strongly dependent on distance, no empty space remains between the stacked bases.

Polynucleotides adopt conformations that maximize favorable stacking interactions between neighboring bases. The constraints imposed by the structure of the sugar-phosphodiester backbone favor helical structures (Figure 2.10). The overall stability of these helical structures is dependent on factors that include sequence-dependent base stacking, pH, salt concentration, and temperature. For example, some synthetic polynucleotides, including poly(C) and poly(A), form right-handed helices in which the bases are highly stacked. Many other polynucleotides remain in a largely disordered **random-coil** conformation. Large polynucleotides may have both helical and disordered regions depending on the local sequence. The characteristics of the solution also determine whether polynucleotides adopt stacked conformations. For example, high concentrations of cations, especially polyvalent ions such as Mg^{2+}, stabilize the helical conformation by shielding the charges of the phosphodiester groups in the backbone. Without this shielding, the negative charges on the phosphates would destabilize the helix by electrostatic repulsion.

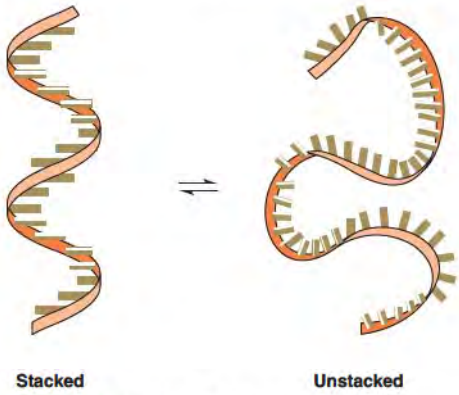

Figure 2.10 Stacked and random-coil conformations of a single-stranded polynucleotide. The helical band represents the sugar–phosphate backbone of the polynucleotide. Bases are shown in a side view as lines in contact with their neighbors. Unstacking of bases leads to a more flexible structure with bases oriented randomly.

Stability of the Polynucleotide Backbone

Polynucleotides are relatively stable in aqueous solutions near neutral pH. It has been estimated that the half-life for the spontaneous hydrolysis of phosphodiester linkages in DNA is about 200 million years. This high stability makes DNA suitable for the long-term storage of genetic information. In contrast, RNA is much more prone to hydrolysis. The presence of the 2′-OH group provides an internal nucleophile for transesterification of the 3′, 5′-phosphodiester linkage (Figure 2.11). The result is scission of the polynucleotide backbone, leaving a 2′, 3′-cyclic phosphate diester on one fragment and a free 5′-OH group on the other. The greater hydrolytic lability of RNA makes it less suitable as a genetic material than DNA.

While the DNA backbone is relatively stable to hydrolysis, numerous enzymes (**nucleases**) catalyze phosphodiester scission. These nucleases are characterized by the types of polynucleotides they hydrolyze and the specific bonds that are broken. Exonucleases cleave the last nucleotide residue at either the 5′- or 3′- terminus of a polynucleotide. Stepwise removal of individual nucleotides from one end of a polynucleotide can result in its complete degradation. Endonucleases cleave phosphodiester bonds located in the interior of polynucleotides. They do not require a free terminus; therefore, they can also cleave circular polynucleotides. Endonucleases such as DNase I and DNase II hydrolyze DNA with little sequence selectivity. The **restriction endonucleases** recognize and cleave very specific sequences. Nucleases also exhibit specificity with respect to the

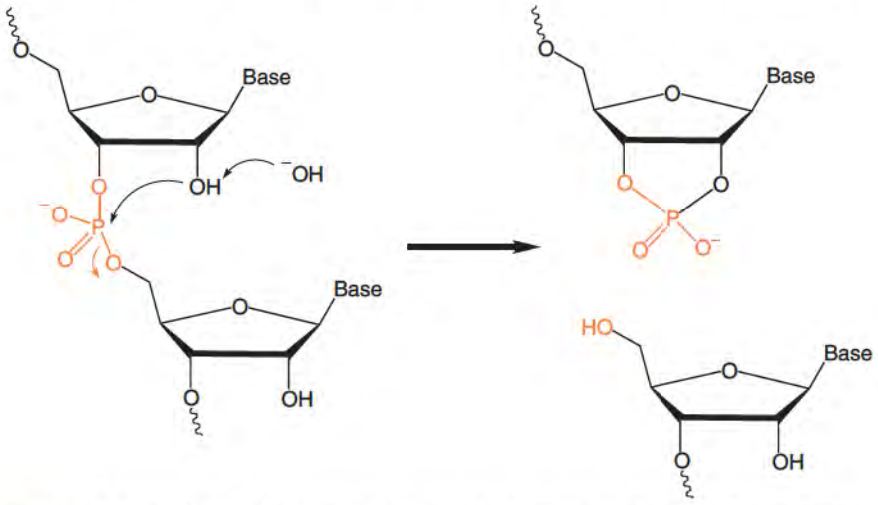

Figure 2.11 Hydrolysis of RNA is accelerated by participation of the 2′-OH group. Intramolecular nucleophilic attack by the 2′-OH group of ribose greatly increases the rate of hydrolytic cleavage of the phosphodiester backbone, especially under basic conditions. The resulting 2′, 3′-cyclic phosphodiester can subsequently react with water or hydroxide to a mixture of 2′- and 3′-phosphate monoesters.

overall structure of polynucleotides. For instance, some nucleases act on both single- and double-stranded polynucleotides, whereas others discriminate between these two structures. Some exclusively act on either DNA or RNA, whereas others are active toward only one type of polynucleotide.

Double-Helical DNA

With the recognition in the early- and mid-twentieth century that DNA served as the carrier of genetic information, work to establish the structural basis for information storage intensified.

Synthetic and X-ray diffraction experiments led to the acceptance of a linear polynucleotide structure for DNA. Three key pieces of information were necessary for deduction of the three-dimensional structure of DNA. The first was the determination that DNA did not contain equal amounts of the four nucleosides, but variable amounts in different organisms. However, it was found that the abundance of deoxyadenosine always equaled that of deoxythymidine and the abundance of deoxyguanosine always equaled that of deoxycytidine. This led to the consideration of structures with the nucleosides specifically paired together (dA with dT and dG with dC). The second was that X-ray diffraction data suggested that DNA contained **double-helical** structures, and symmetry suggested that the two polynucleotide strands were oriented **antiparallel** to each other. The third was the suggestion that the nucleobases were in the keto and amino **tautomeric** forms rather than enol and imino forms. Tautomers are isomers of a molecule that differ only in the position of a hydrogen atom. Each of the four nucleobases has two or more possible tautomeric forms that are in equilibrium (Figure 2.12). The incorrect assignment of the predominant tautomeric structures

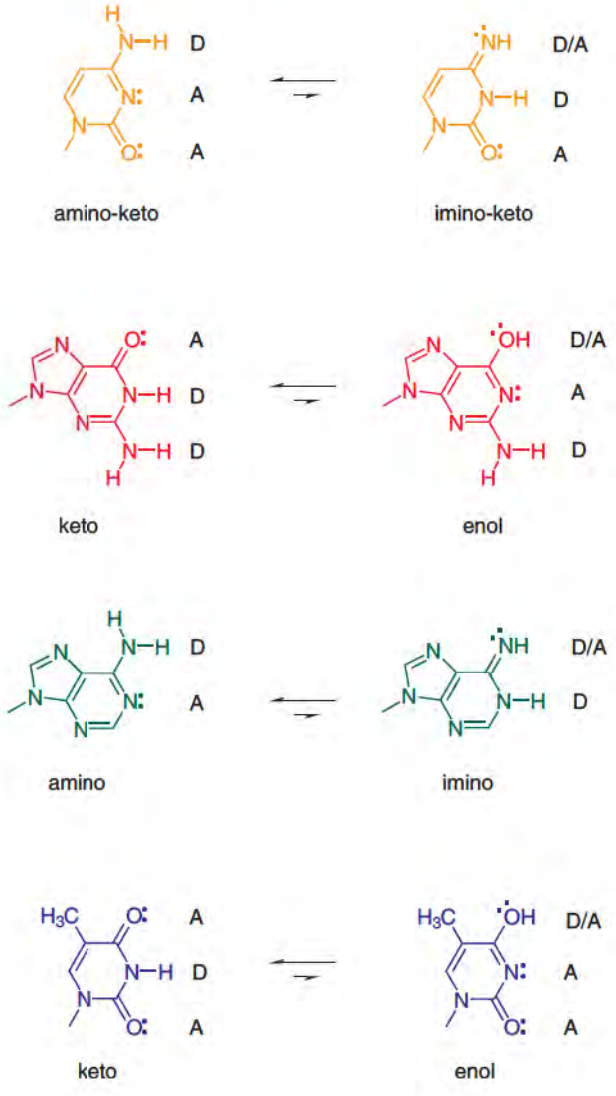

Figure 2.12 Tautomeric forms of nucleobases. The pattern of hydrogen bonding donating (D) and accepting (A) groups changes depending on the tautomer of the base that is present. Shown are predominant tautomeric forms (left) and one of the alternate forms (right) for each base. The hydrogen bonding pattern for each tautomer is also shown; ambiguity at the —OH and =NH positions of the minor tautomers arises from rotation or isomerism of these groups. The equilibrium ratio of the predominant form to all others is greater than 99:1.

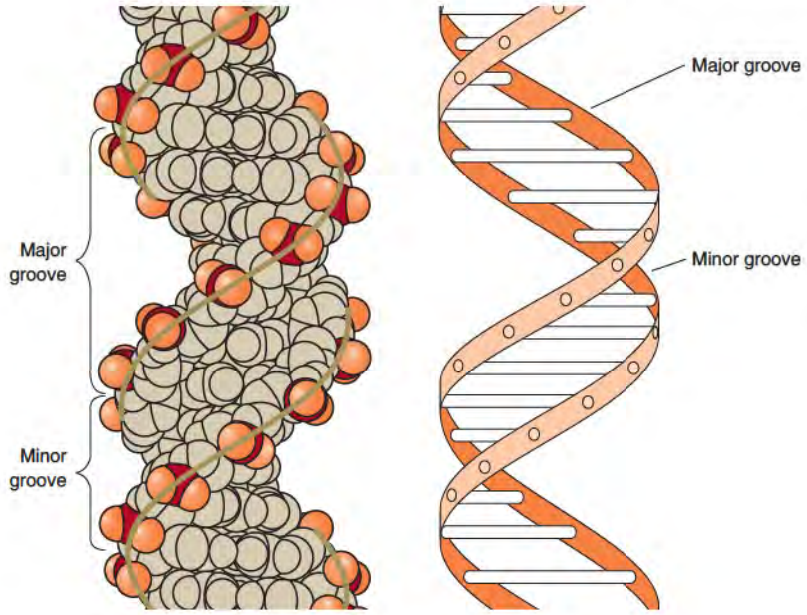

Figure 2.13 Watson–Crick model of DNA. On the left is a space-filling model of DNA; on the right is an idealized ribbon model. Bases are stacked in the interior of the helix, whereas hydrophilic sugar–phosphodiester backbone is located on the exterior.
Redrawn from Rich, A. J. *Biomol. Struct. Dyn.* 1:1, 1983.

meant that researchers were attempting to form base pairs using incorrect hydrogen-bonding patterns. With the correct tautomers, a model for DNA rapidly fell into place.

The structure that **Watson and Crick** proposed in 1953 for double helical DNA was attractive because of its simplicity and symmetry (Figure 2.13). Moreover, it explained all of the available structural data for DNA and immediately led to hypotheses regarding a mechanism for storage and replication of genetic information. The Watson–Crick double helix can be visualized as the interwinding of two right-handed helical polynucleotide strands around a common axis. The strands achieve contact through hydrogen bonds formed at the hydrophilic edges of the bases. The N—H groups of the nucleobases are good hydrogen bond donors, and the electron pairs on the sp^2-hybridized oxygens of the C=O groups and nitrogens of the =N– groups are good hydrogen bond acceptors. Pairing occurs when an acceptor and a donor are in a position to form a hydrogen bond. These bonds extend between purine residues in one strand and pyrimidine residues in the other, and the matching of hydrogen bond donors and acceptors results in two types of **base pairs:** adenine–thymine and guanine–cytosine (Figure 2.14). A direct consequence of these hydrogen-bonding specificities is that **double-stranded DNA (dsDNA)** must contain ratios of nucleosides that agree with experimental observations (dA = dT and dG = dC). Finally, the geometries of the dA/dT and dG/dC base pairs result in similar C1′–C1′ distances (~10.6 Å) and glycosidic bond orientations. This **structural isomorphism** means that any of the four possible base pairs (dA-dT, dT-dA, dG-dC, and dC-dG) can be placed into the double helix without significantly changing the structure of the backbone; note how this leads to the possible replacement of one base pair by any other, a key to understanding how DNA information can change, or **mutate.**

The relationship between bases on opposing strands within the double helix is described as **complementarity.** Bases are complementary because every nucleobase of one strand is matched by shape and hydrogen bonding to a complementary base on the other strand (Figure 2.15). For instance, for each adenine projecting toward the axis of the double helix, a thymine must be projected from the opposite strand to hydrogen-bond and exactly fill the space between the strands. Neither cytosine nor guanine fits precisely in the available space across from adenine in a manner that allows formation of hydrogen bonds across strands. These hydrogen-bonding specificities ensure that the entire base sequence of one strand is complementary to that of the other strand.

The exterior of the double helix consists of the sugar–phosphate backbones of its component strands. The two strands are aligned in opposite directions; if two adjacent nucleobases in the one strand, for example, thymine and cytosine, are connected in the 5′→3′ direction, their complementary nucleobases on the other strand, adenine and guanine, will

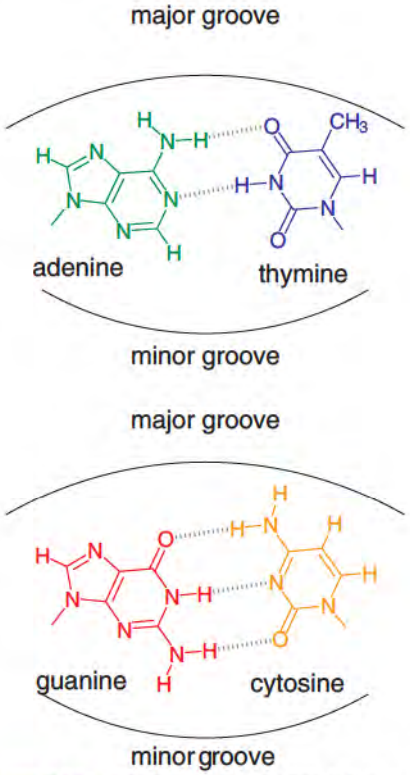

Figure 2.14 Watson–Crick base pairs. Selective base pairs are formed between adenine and thymine and between guanine and cytosine. Note the formation of two hydrogen bonds in an A-T base pair and three in a G-C base pair.

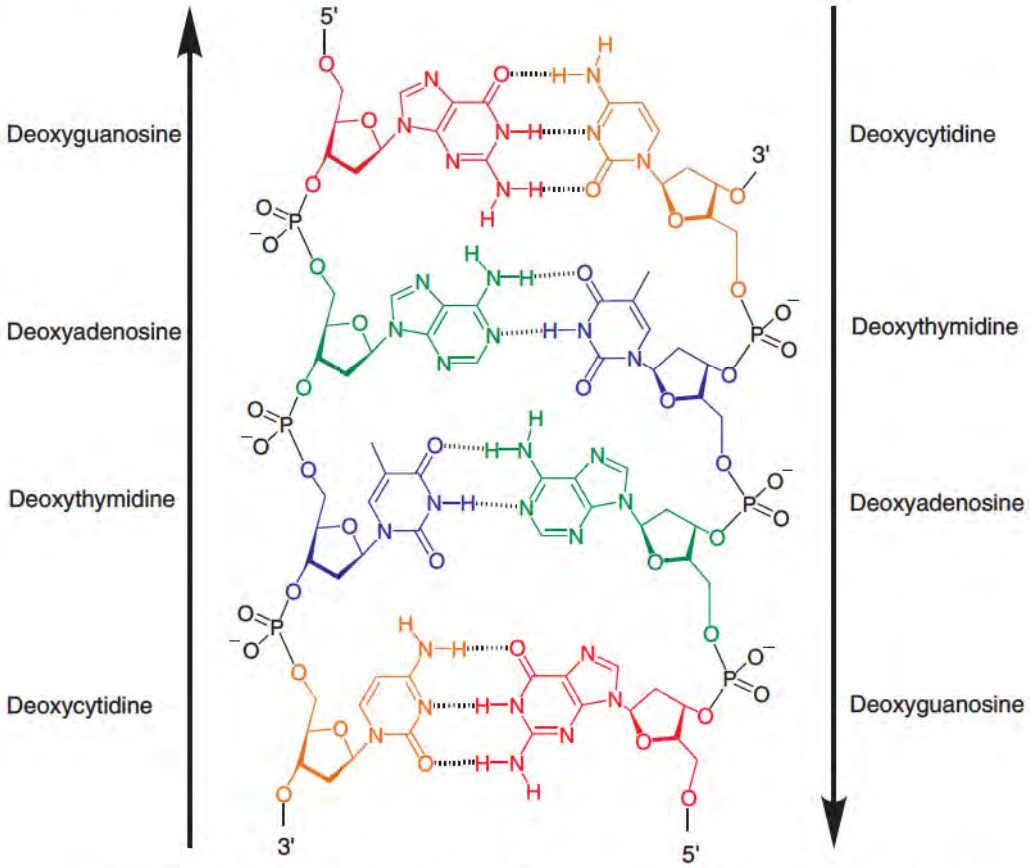

Figure 2.15 Formation of hydrogen bonds between complementary bases in double-stranded DNA. Interaction between polynucleotide strands is highly selective. Complementarity depends not only on the geometric factors that allow the proper fitting between the complementary bases of the two strands but also on the formation of specific hydrogen bonds between complementary bases. Note the antiparallel orientation of the strands of a double-stranded DNA. The geometry of the helices does not prevent a parallel alignment, but such an arrangement is not found in DNA.

be linked in the 3′→ 5′ direction. This antiparallel alignment produces a stable association between strands to the exclusion of the alternate parallel arrangement.

Interwinding of the two antiparallel strands produces a structure that has two distinct helical grooves between the sugar–phosphate backbones (Figures 2.13 and 2.14). The **major groove** is much wider than the **minor groove**. This disparity arises from the geometry of the base pairs: The glycosidic bonds between the bases and the backbone pentose are not arranged directly opposite to each other but are displaced toward the minor groove. Significantly, the nucleotide sequence of DNA can be discerned without dissociating the double helix by looking inside these grooves. Each base always displays the same atoms into each of the grooves on the double helix. These atoms then constitute an important means of sequence-specific recognition of DNA by proteins and small molecules. For example, N7 of purines is always displayed in the major groove, and it can serve as a hydrogen bond acceptor in interactions with donor groups on proteins (Figure 2.14). Similarly, the exocyclic 2-NH_2 group of guanine always projects into the minor groove and can form a steric blockade to the binding of small molecules.

Factors That Stabilize Double-Helical DNA

Stacking interactions that stabilize the helical structures of single-stranded polynucleotides are also instrumental in stabilizing the double helix. The separation between the hydrophobic core of the stacked nucleobases and the hydrophilic exterior of the charged sugar–phosphate groups is even more pronounced in the double helix than in single-stranded helices. The stacking tendency of single-stranded polynucleotides can be viewed as resulting from a tendency of the bases to reduce their contact with water. The double-stranded helix is a more

TABLE 2.1 • Base-Pair Stacking Energies

favorable arrangement, essentially removing the nucleobases from the aqueous environment while permitting the hydrophilic phosphate backbone to be highly solvated by water.

Stacking interactions, a combination of hydrophobic forces and van der Waals interactions, are 16–61 kiloJoules per mole (kJ/mol; 4–15 kilocalories per mole [kcal/mol]) of stabilization energy for each adjacent base pair (Table 2.1). Additional stabilization of the double helix results from extensive networks of cooperative hydrogen bonds. Generally, these bonds are weak 10–30 kJ/mol (3–7 kcal/mol), and they are even weaker in DNA 8–12 kJ/mol (2–3 kcal/mol) because of geometric constraints within the double helix. It might appear that hydrogen bonds between nucleobases could cumulatively provide substantial stabilization for the double helix. However, the hydrogen bonds in a double helix merely replace energetically similar ones between the nucleobases and water in single-stranded polynucleotides. Therefore, hydrogen bonding is not the glue that maintains double-helical structures. Yet, in contrast to stacking forces, hydrogen bonds are highly directional and help discriminate between correct and incorrect base pairs. Because of their directionality, hydrogen bonds tend to orient the nucleobases to favor stacking. Therefore, the contribution of hydrogen bonds is indirectly vital for the stability of the double helix.

The relative importance of stacking interactions versus hydrogen bonding in stabilizing the double helix was not always appreciated. Experiments with reagents that reduce the stability of the double helix (denaturants) illustrate the greater relative importance of stacking interactions (Table 2.2). These results show that the destabilizing effect of a reagent is not related to its ability to break hydrogen bonds but is determined by the solubility of the

[a]The destabilizing effect of the reagents listed on the double helix is independent of the ability of these reagents to break hydrogen bonds. Rather, the destabilizing *effect* is determined by the solubility of adenine. Similar results would be expected if the solubilities of the other bases were examined.

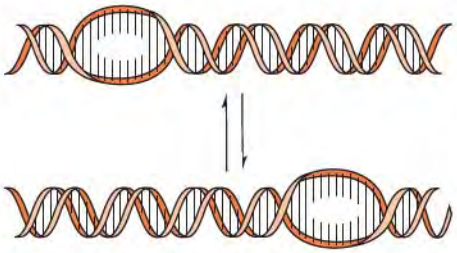

Figure 2.16 Migration of bubbles through double-helical DNA. DNA contains short open-stranded sections of DNA that can "move" along the helix.

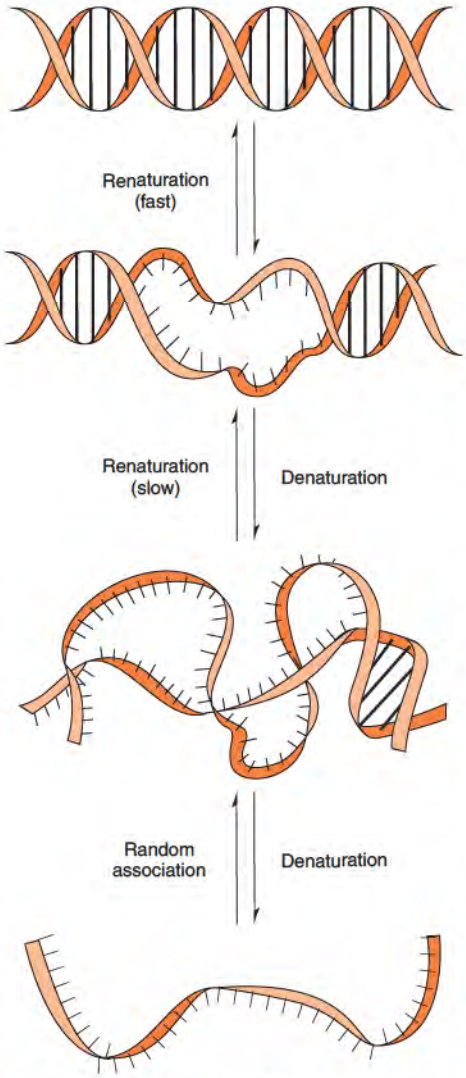

Figure 2.17 Denaturation of DNA. At high temperatures the double-stranded structure of DNA is completely disrupted, with eventual separation of strands and formation of single-stranded open coils. Denaturation also occurs at extreme pH ranges or at extreme ionic strengths.

free bases in the reagent. As the reagent becomes a better solvent for the bases, the driving force for stacking diminishes, and the double helix is destabilized.

Electrostatic forces also have an effect on the stability and conformation of the double helix. Phosphodiester groups are ionized at physiological pH; thus, the exterior of the double helix carries two negative charges per base pair. The interstrand electrostatic repulsion between negatively charged phosphates is destabilizing and tends to separate the complementary strands. In distilled water, DNA strands separate at room temperature. However, cations such as Mg^{2+}, spermine^{4+} (a tetramine), and basic amino acid side chains in proteins can shield the phosphate groups and decrease repulsive forces.

Denaturation and Renaturation

The double helix is disrupted during almost every important biological process in which DNA participates, including DNA replication, transcription, repair, and recombination. The forces that hold the two strands together are adequate for providing stability but weak enough to allow facile strand separation. The double helix is stabilized relative to the single strands by about 4 kJ/mol (1 kcal/mol) per base pair so that a relatively minor perturbation can produce a local disruption in a short section of the double helix. These base pairs can close up again, releasing free energy that can then cause the adjacent base pairs to unwind. In this manner, minor disruptions of the double helix can migrate along its length (Figure 2.16). Thus, at any particular moment, the large majority of bases remain hydrogen bonded, but all bases can transiently pass through the single-stranded state. The ability of the DNA double helix to breathe is an essential prerequisite for its biological functions.

Separation of DNA strands can be studied by increasing the temperature of a solution. At relatively low temperatures a few base pairs are disrupted, creating one or more open-stranded bubbles (Figure 2.17). These bubbles form initially in sections that contain relatively higher proportions of adenine–thymine pairs because of the lower stacking energies of such pairs. As the temperature is raised, the size of the bubbles increases, and the thermal motion of the polynucleotides eventually overcomes the forces that stabilize the double helix. At even higher temperatures, the strands separate and acquire a random-coil conformation. The process is most appropriately described as a helix-to-coil transition, but is commonly called denaturation or **melting**.

Denaturation is accompanied by several physical changes in the DNA-containing solution including an increase in buoyant density, a reduction in viscosity, a change in ability to rotate polarized light, and changes in absorbance of UV light. The last are frequently used to follow the process of denaturation experimentally (Figure 2.18). Because of the strong absorbance by the purine and pyrimidine bases, DNA absorbs strongly in the UV region with a maximum near 260 nm. However, the absorbance by individual bases is reduced by electronic interactions between stacked bases. The total absorbance may be reduced by as much as 40% compared to that in an unstacked state. This reduction in the extinction coefficient of the aggregate bases is termed **hypochromicity**. Stacking interactions decrease gradually as the ordered structure of the double helix is disrupted by increasing temperatures. Therefore, a completely disordered polynucleotide approaches an absorbance comparable to the sum of the absorbances of its purine and pyrimidine constituents.

Measurement of the absorbance of a DNA complex at 260 nm while slowly increasing the temperature provides a means to observe denaturation. In a thermal denaturation experiment monitored using absorption spectroscopy; the polynucleotide absorbance typically changes very slowly at first, and then rises rapidly to a maximum value. Before the rise, the DNA is double stranded. In the rising section of the curve an increasing number of base pairs are interrupted. Complete strand separation occurs at temperatures corresponding to the upper plateau of the curve. The midpoint temperature of this transition, the melting temperature ($\mathbf{T_m}$), is characteristic of the base content of DNA under standard conditions of concentration and ionic strength. The higher the guanine–cytosine content, the higher the transition temperature between double-stranded helix and single strands. This difference in T_m values is attributed to the increased stability of guanine–cytosine pairs, which arises from more favorable stacking interactions.

DNA becomes denatured at pH >11.3 as the N–H groups on the bases become deprotonated, preventing them from participating in hydrogen bonding. Alkaline denaturation is often used to prevent damage to the DNA that can occur at a high temperature or low pH. Denaturation can also be induced at low ionic strengths, because of enhanced interstrand repulsion between negatively charged phosphates and by various denaturing agents (compounds that can effectively hydrogen bond to the bases while disrupting hydrophobic stacking interactions). A complete denaturation curve similar to that shown in Figure 2.18 is observed at a relatively low constant temperature by variation of the concentration of an added denaturant such as urea.

Complementary DNA strands, separated by denaturation, can reform a double helix if appropriately treated. This is called **renaturation** or **annealing**. If denaturation is not complete and a few nucleobases remain hydrogen bonded between the two strands, the helix-to-coil transition is rapidly reversible. Annealing is possible even after complementary strands have been completely separated. Under these conditions the renaturation process depends on the DNA strands meeting in a manner that can lead to reformation of the original structure. Not surprisingly, this is a slow, concentration-dependent process. As renaturation begins, some of the hydrogen bonds formed are extended between short tracts of polynucleotides that may have been distant in the original native structure. These randomly base-paired structures are short lived because the bases that surround the short complementary segments cannot pair and, thus, cannot form a stable, fully hydrogen bonded structure. Once the correct nucleobases begin to pair by chance, the double helix is rapidly reformed over the entire DNA molecule.

Sudden onset of denaturation or renaturation reveals the all-or-none nature of helix-to-coil or coil-to-helix transitions. The renaturation process requires formation of a short double-helical region to initiate formation of the double helix (Figure 2.19). This begins with the formation a single base pair that is rather unstable. However, the formation of a second neighboring base pair is enhanced because the process is now less entropically unfavorable. As new base pairs begin to form a stacked structure, the formation of subsequent base pairs is further facilitated. Unpaired nucleotides of each strand begin to stack on the growing helix, positioned optimally for base pairing. After formation of a double helix with four to five base pairs, a stable double helix forms, and the remainder of the complex will rapidly and spontaneously "zip up." After formation of the initial base pair, stacking and base pairing are not independent events but are influenced by the neighboring pairs. Such a process is called **cooperative.** The presence of a short double helix serves as a nucleation site for annealing by facilitating the formation of subsequent base pairs. Denaturation is the same process in reverse: A bubble serves as an initiation site for unstacking of the nucleobases and rapid unzipping of the helix.

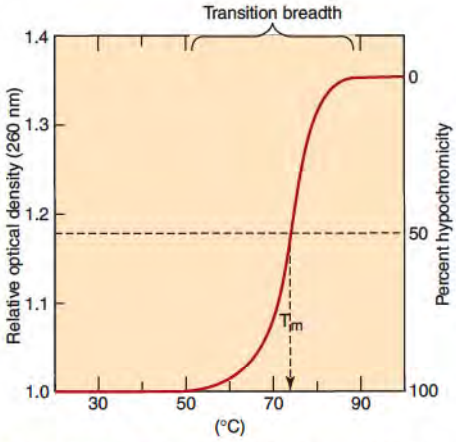

Figure 2.18 Temperature-optical density profile for DNA. When DNA is heated, the absorbance at 260 nm increases with rising temperature. A graph in which absorbance versus temperature is plotted is called a melting curve. Relative optical density is the ratio of the absorbance at any temperature to that at low temperatures. The temperature at which one-half of the maximum optical density is reached is the midpoint temperature T_m.

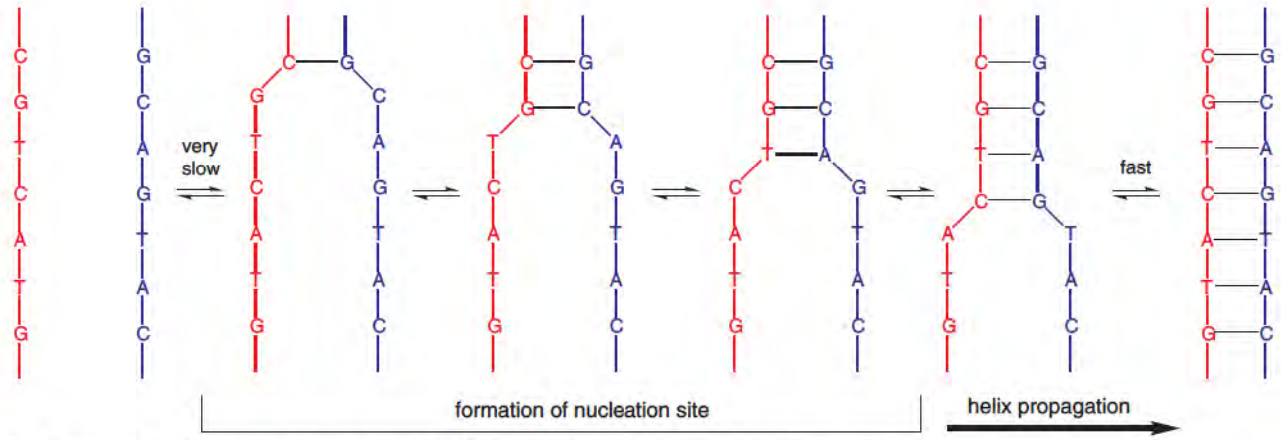

Figure 2.19 Cooperativity of renaturation/denaturation of DNA double helices. During renaturation, formation of the first correct base pair is very slow. Annealing of neighboring pairs is facilitated, especially after formation of a 3- to 5-bp nucleation site. Denaturation follows a similar course, but the order of steps is reversed.

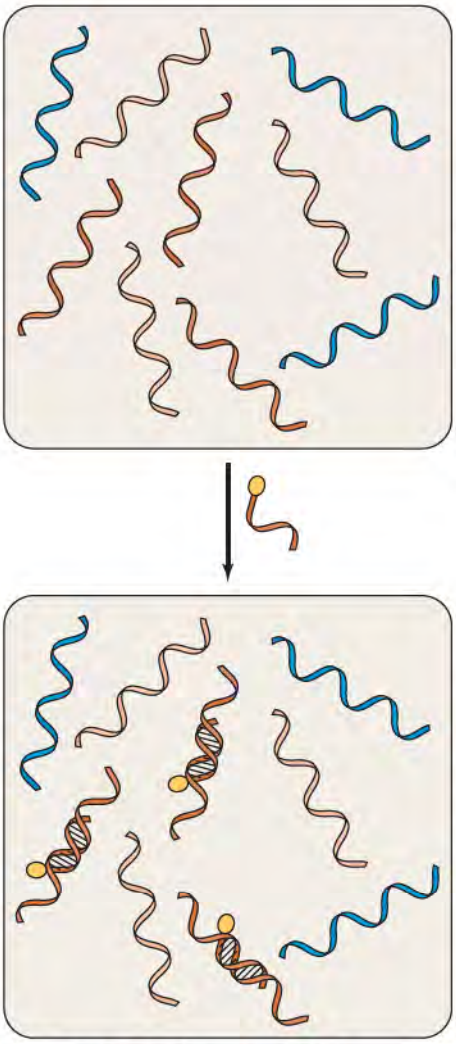

Figure 2.20 General representation of hybridization experiments. A mixture of denatured DNAs is treated with a DNA probe bearing a label. The probe can hybridize with those DNAs with complementary sequences. Detection of the double-helical complexes allows for detection and quantitation of DNA that contains the sequence of interest. Specific applications often feature steps to separate and immobilize the different DNAs in the mixture to be probed.

Hybridization

A technique based on the association of complementary polynucleotide strands, **hybridization** has been developed for the detection and quantitation of specific sequences of target nucleic acid. These are important basic tools in contemporary molecular biology and are being used for determining (a) whether a certain sequence occurs in the DNA of a particular organism, (b) a genetic or evolutionary relatedness between different organisms, (c) the number of genes transcribed in a particular mRNA, and (d) the location of any given DNA sequence. They are based on annealing a complementary polynucleotide, called a **probe,** which is appropriately tagged for easy detection of the hybrid double helix.

In a typical experiment, DNA or RNA to be tested for hybridization is denatured and immobilized by binding to a suitable insoluble matrix. Labeled DNA probes are then allowed to hybridize to complementary sequences bound to the matrix (Figure 2.20). Probes are short single-stranded RNA or DNA oligonucleotides that are complementary to specific sequences of interest. Under the proper conditions probes interact only with the segment of interest, indicating whether it is present in a particular sample of DNA. Probe molecules are generally >20 nucleotides long. Appropriate labels include radioactive elements, fluorescent chromophores, and biotin. Because the double-helical complex containing the hybridized probe is usually bound to an insoluble matrix, unhybridized probes can be washed away. Detection of bound labels allows direct quantitation of the sequence of interest. Determination of the maximum amount of DNA that can be hybridized can establish the degree of homology between the DNAs of different species since the base sequences in each organism are unique. The observed homologies serve as indices of evolutionary relatedness and have been particularly useful for defining phylogenesis in prokaryotes. Hybridization studies between DNA and RNA have provided very useful information about the biological role of DNA, particularly the mechanism of transcription. Arrays of probes are useful for definitive and rapid diagnosis of genetic disorders, infectious disease, and cancer, as described in Clin. Corr. 2.2.

Conformations of Double-Helical DNA

The early X-ray diffraction studies showed that there was more than one conformation of DNA (Figure 2.21). One of these, **A-DNA,** was found under conditions of low humidity and high salt concentration. Adding organic solvents such as ethanol reduced the humidity of these aqueous solutions. A second distinct form, B-DNA, appeared under conditions of high humidity and low salt concentration and was the basis of the Watson–Crick structure. Eleven distinct conformations of double-helical DNA have since been described. They vary in orientation of the bases relative to the helix and to each other and in other geometric parameters of the double helix. One form, Z-DNA, incorporates a left-handed helix rather than the usual right-handed variety.

The structural polymorphism of double-helical DNA depends on the base composition and on physical conditions. The local structure of DNA is sufficiently flexible to allow for changes in conformation that maximize stacking while minimizing unfavorable steric interactions. The stacking preferences of bases can favor one conformation over others. For example, consecutive guanines on one strand favor A-DNA–like conformations. The solution conditions also play a key role in determining the favored conformation. Water molecules interact differently with double helices in different conformations. For example, the phosphate groups in B-DNA are more accessible to water molecules than those in A-DNA. Also, polar groups on the bases are better hydrated in a B-DNA conformation. In fact, in AT-rich sequences, an ordered array of water molecules occupies the narrow minor groove of B-DNA (Figure 2.22*a*). With a decrease in humidity, the available water molecules solvate the highly polar phosphate groups in preference to the bases. The major groove narrows allowing water molecules to bridge the phosphates (Figure 2.22*b*), and thus stabilizing the A-DNA conformation.

The different conformations of DNA can be grouped into three families: A-DNA, **B-DNA,** and **Z-DNA.** The parameters for these conformations, listed in Table 2.3, have been determined by X-ray diffraction methods. It must be emphasized that the average overall structure of DNA in living organisms is believed to be B-DNA–like. Notably, the B-conformation, unlike the A- and Z-forms, is highly flexible. In native B-DNA, considerable local variation in conformation of individual nucleotides may occur. Such variations

CLINICAL CORRELATION 2.2

Diagnostic Use of DNA Arrays in Medicine and Genetics

With completion of the Human Genome Project, a wealth of genetic information is rapidly becoming available. Application of this knowledge to medicine requires the development of new techniques to monitor gene expression and to analyze rapidly genes for mutations. Oligonucleotide arrays consist of a number of gene-specific oligonucleotide probes immobilized at specific sites on a solid matrix (chip). They can contain thousands of unique probe molecules, each within a spatially fixed address. Gene chips can then be treated with labeled target nucleic acids (DNA or RNA) derived from cells of an organism. Hybridization of the targets with complementary probe sequences allows for immobilization of the label at specific sites on the chip. The presence of specific sequences can be determined, and the amount of labeled target hybridized to a site can be quantitated.

Such techniques may lead to diagnostics for rapid screening of genomic DNA for disease-associated mutations. For example, high-density DNA arrays with thousands of oligonucleotide probes has been used to detect mutations leading to ataxia telangiectasia, a recessive disease characterized by neurological disorder, recurrent respiratory infection, and dilated blood vessels in the skin and eyes. Similar studies have examined mutations in the hereditary breast and ovarian cancer gene BRCA. Comparable assays can be used to identify accurately pathogens present in a clinical sample. The ability to quantitate the amounts of mRNAs in various cells allows for the profiling of gene expression. This may lead to techniques to evaluate illnesses such as cancer and select individualized treatments.

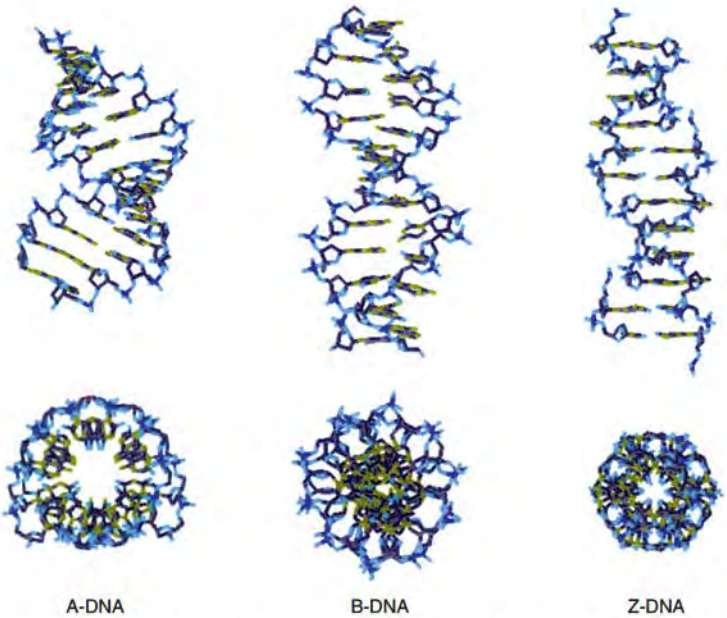

Figure 2.21 The varied geometries of double-helical DNA. Depending on conditions and base sequence, the double helix can acquire various distinct geometries. There are three main families of DNA conformations: A, B, and Z. The right-handed forms, B-DNA and A-DNA, differ in sugar pucker; this leads to differing helical structures. The A-form is underwound compared to the B-form, and the resulting helix is shorter and fatter. The Z-DNA structure is a left-handed helix with a zigzagging backbone. The sugar puckers and glycosidic conformations alternate from one residue to the next, producing a local reversal in chain direction.

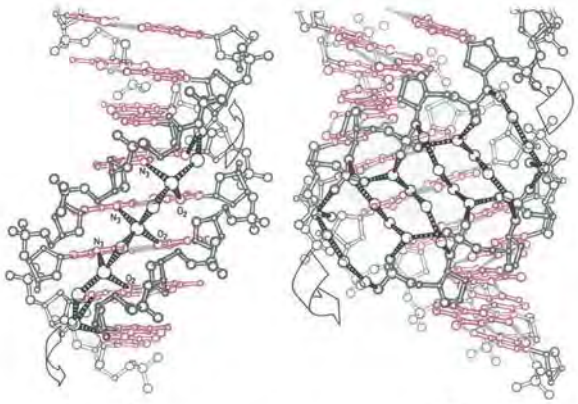

(a) (b)

TABLE 2.3 • Structural Features of A-, B-, and Z-DNA

Features	*A-DNA*	*B-DNA*	*Z-DNA*
Helix rotation	Right-handed	Right-handed	Left-handed
Base pairs per turn (crystal)	10.7	9.7	12
Base pairs per turn (fiber)	11	10	—
Base pairs per turn (solution)	—	10.5	—
Pitch per turn of helix	24.6 Å	33.2 Å	45.6 Å
Proportions	Short and broad	Longer and thinner	Elongated and thin
Helix packing diameter	25.5 Å	23.7 Å	18.4 Å
Rise per base pair (crystal)	2.3 Å	33 Å	3.7
Rise per base pair (fiber)	2.6	3.4 Å	—
Helix axis	Major groove	Through base pairs	Minor groove
Sugar ring conformation (crystal)	C3′ *endo*	Variable	Alternating
Sugar ring conformation (fiber)	C3′ *endo*	C2′ *endo*	—
Glycosyl bond conformation	*anti*	*anti*	*anti* at C, *syn* at G

may be important in regulation of gene expression, since they can influence the extent of DNA binding with various types of regulatory proteins.

DNA conformations in the B-family feature base pairs that are nearly perpendicular to the helical axis, which passes through the base pairs. The major and minor grooves are roughly the same depth, and the minor groove is relatively narrow. The helix is long and thin, with approximately 10 base pairs per helical turn. The rise per residue is 3.4 Å, the approximate thickness of the bases. In contrast, the A-DNA structure is shorter and thicker. There are about 11 base pairs per helical turn with a vertical rise of 2.56 Å per residue. In order to accommodate the thickness of the bases, the base pair is tilted 20° from the plane perpendicular to the helical axis. The helical axis is displaced to the major groove side of the base pairs. This results in a very deep major groove and a shallow minor groove and forms a hole ~3 Å in diameter that runs through the center of the helix. Low humidity favors the A-DNA structure that exposes more hydrophobic surface to the solvent than the B-DNA structure.

Z-DNA is a radically different left-handed, double-helical conformation for double-stranded DNA. It is generally observed in sequences of alternating purines and

pyrimidines, particularly d(GC)*n*. The designation Z was chosen because the phosphodiester backbone assumes a zigzag arrangement compared to the smooth conformation that characterizes A-DNA and B-DNA. The Z-DNA structure is longer and much thinner than that of B-DNA and completes one turn in 12 base pairs. The minor groove is very deep and contains the helical axis. The base pairs are displaced so far into the major groove that a distinct channel no longer exists. These changes place the stacked nucleobases on the outer part of Z-DNA rather than in their conventional positions in the interior of the double helix.

Some evidence exists that suggests that Z-DNA influences gene expression and regulation. Apparently small stretches of DNA that contain alternating purines and pyrimidines are more commonly found at the 5′-ends of genes, regions that regulate transcriptional activities. Also, methylation of either guanine residues in the C8 and N7 positions or cytosine residues in the C5 position (Figure 2.23) stabilizes the Z-form. Sequences that are not strictly alternating purines and pyrimidines may also acquire the Z conformation because of methylation. The suggestion that Z-DNA may have a role in gene regulation is supported by modifications in methylation patterns that accompany the process of gene expression. However, Z-DNA has not yet been detected in DNA *in vivo*.

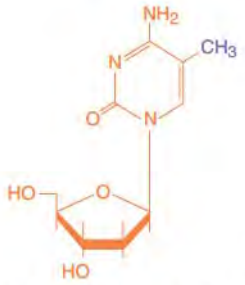

Figure 2.23 Structure of 5-methylcytidine.

Noncanonical DNA Structures

A-, B-, and Z-DNA are associated mainly with variation in the conformation of the nucleotide constituents of DNA. It is now recognized that even canonical B-DNA is not a straight, monotonous, and uniform structure. Instead, DNA bends and forms unusual structures such as cruciforms or triple-stranded arrangements as it interacts with certain proteins. Such variations in DNA conformation appear to be an important recurring theme in the process of molecular recognition of DNA by proteins and enzymes. Variations in DNA structure or conformation are favored by specific DNA sequence motifs such as inverted repeats, palindromes, mirror repeats, and direct repeats (Figure 2.24), as well as homopurine–homopyrimidine sequences, phased A tracts, and G-rich regions. AT-rich sequences, which are prone to easy strand separation, exist near the origins of DNA replication. The human genome is rich in homopurine–homopyrimidine sequences and alternating purine–pyrimidine tracts.

Bent DNA

DNA sequences with runs of 4 to 6 adenines separated by 10 base-pair (bp) spacers produce bent conformations. Structural studies have indicated that minor grooves of these sequences are compressed. However, it is not clear whether bending arises from this feature or from the boundary between this unusual conformation and normal B-DNA. DNA bending appears to be a fundamental element in the interaction between DNA sequences and proteins that catalyze central processes, such as replication, transcription, and site-specific recombination. Bending induced by interactions of DNA with enzymes and other proteins,

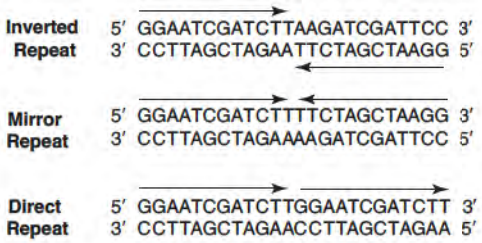

Figure 2.24 Symmetry elements in DNA sequences. Three types of symmetry elements for double-stranded DNA sequences are shown. Arrows illustrate the special relationship of these elements in each one of these sequences. In inverted repeats, or palindromes, each DNA strand is self-complementary within the inverted region that contains the symmetry elements. A mirror repeat is characterized by the presence of identical base pairs equidistant from a center of symmetry within the DNA segment. Direct repeats are regions of DNA in which a particular sequence is repeated. The repeats need not be adjacent to one another.

CLINICAL CORRELATION 2.3

Antitumor Antibiotics That Change the Shape of DNA

The local three-dimensional structure of DNA is important in interactions with proteins involved in repair, transcription, recombination, and chromatin condensation. It has been proposed that antibiotics can induce formation of DNA structures that can recruit these proteins with cytotoxic results. The best-studied example is the antitumor drug cisplatin, a tetracoordinate platinum complex (cis-$Pt(NH_2)_2Cl_2$). Cisplatin is used alone or in combination with other antitumor agents to treat a variety of tumors including testicular, ovarian, bone, and lung cancers. It forms inter- and intrastrand cross-links in double-stranded DNA with the latter adduct comprising 90% of DNA lesions. These bonds arise from displacement of chloride ligands on platinum by N7 atoms of two neighboring guanines. Structural studies on intrastrand cross-linked DNA adduct show that the double helix is strongly bent toward the major groove. In figure below, (a) Normal DNA, and (b) DNA adduct.

Bent structures of the cisplatin-DNA adduct are specifically recognized by several DNA-binding proteins such as nucleotide excision repair (NER) proteins and nonhistone DNA-binding proteins such as HMG-1. The cytotoxicity of cisplatin adducts is a complicated process mediated by specific interactions with these proteins. Cellular processes such as transcription and apoptosis are also affected by the formation of cisplatin–DNA adducts. The lesions themselves and the adduct–protein complexes are likely to interfere with transcription. NER proteins are recruited to repair the lesion, but excision repair is prone to produce DNA strand breaks. Accumulation of these breaks will ultimately induce apoptosis as the DNA becomes too damaged to function. Interactions of the cisplatin–DNA adduct with HMG proteins may also contribute to its cytotoxicity. Binding of HMG proteins may incorrectly signal that the damaged region of DNA is transcriptionally active and prevent condensation into folded chromatin structures. These complexes also perpetuate the lesion by shielding the cisplatin–DNA adducts from repair.

(*a*) (*b*)

such as **histones**, does not require the nucleotide sequence conditions that are needed for bending of protein-free DNA. Bending also occurs because of photochemical damage or mispairing of bases and serves as a recognition signal for initiation of DNA repair. Antitumor antibiotics that produce bent structures are discussed in Clin. Corr. 2.3.

Cruciform DNA

Disruption of hydrogen bonds between the complementary strands and formation of intrastrand hydrogen bonds within the region of an inverted repeat produce a cruciform structure (Figure 2.25). The loops generated by cruciform formation require the unpairing of 3 to 4

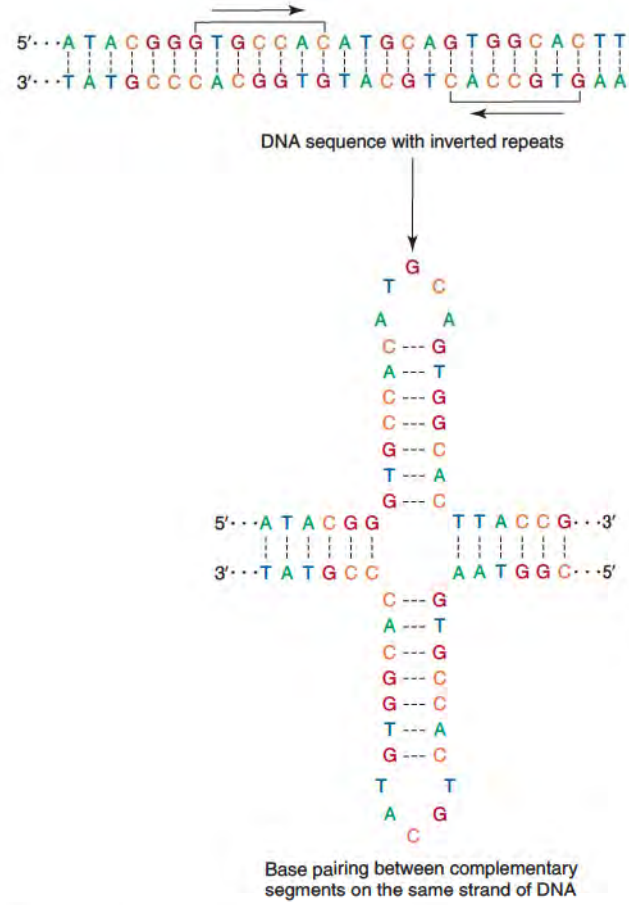

Figure 2.25 Formation of cruciform structures in DNA. The existence of inverted repeats in double-stranded DNA is a necessary but not a sufficient condition for the formation of cruciform structures. In relaxed DNA, cruciforms are not likely to form because the linear DNA accommodates more hydrogen-bonded stacked base pairs than the cruciform structure, making the formation of the latter thermodynamically unfavored. Unwinding is followed by intrastrand hydrogen bond formation between the two symmetrical parts of the repeat to produce the cruciform structure. Formation of cruciform structures is not favored at DNA regions that consist of mirror repeats because such cruciforms would be constructed from parallel rather than antiparallel DNA strands. Instead, certain mirror repeats tend to form triple helices.

bases at the end of the "hairpin." Depending on the sequence, these structures may be only slightly destabilizing because residues in the loop can remain stacked at the end of the helix.

It has been speculated that inverted repeats may function as molecular switches for replication and transcription. Inverted repeats are quite widespread within the human genome and often occur near putative control regions of genes or at origins of DNA replication. Cruciform structures at origins of DNA replication in mammalian cells have been shown to recruit cruciform-binding proteins that function during the initiation of DNA synthesis.

Triple-Stranded DNA

Some polynucleotides such as poly(dA) and poly(dT) combine to form triple-stranded complexes rather than the expected double helices. The stoichiometries of these complexes require that one strand contain a homopurine sequence while the other two have homopyrimidine sequences. Even when participating in Watson–Crick base pairing, purines possess two potential hydrogen-bonding sites in the major groove: N7 and O6 for guanine, and N7 and 6-NH_2 for adenine. Nucleobases appropriately positioned in the major groove can form specific **Hoogsteen** base triplets (Figure 2.26). For example, a thymine can selectively form two Hoogsteen hydrogen bonds to the adenine of an A-T pair. Likewise, a protonated cytosine can form two Hoogsteen H bonds with the guanine of a G-C pair, resulting in a base triplet isomorphous to the T-A-T. The pK_a' of cytidine is approximately 4.5, and triple helices containing C-G-C triplets show a strong dependence on pH. However, the templating effect of the triplet raises the apparent pK_a' of the cytosine, making it possible to form triple helices even in solutions that are only mildly acidic (pH 6). The unique Hoogsteen hydrogen-bonding patterns of guanine and adenine provide for specificity similar to the Watson–Crick pairs. Changing the orientation of the third-strand nucleobases in the major groove allows for the formation of **reverse-Hoogsteen** triplets (Figure 2.26). Selective triplets can be formed between an adenine and the A-T pair as well as between a guanine and a G-C pair. A reversed-Hoogsteen triplet can also be formed between thymine and A-T, but

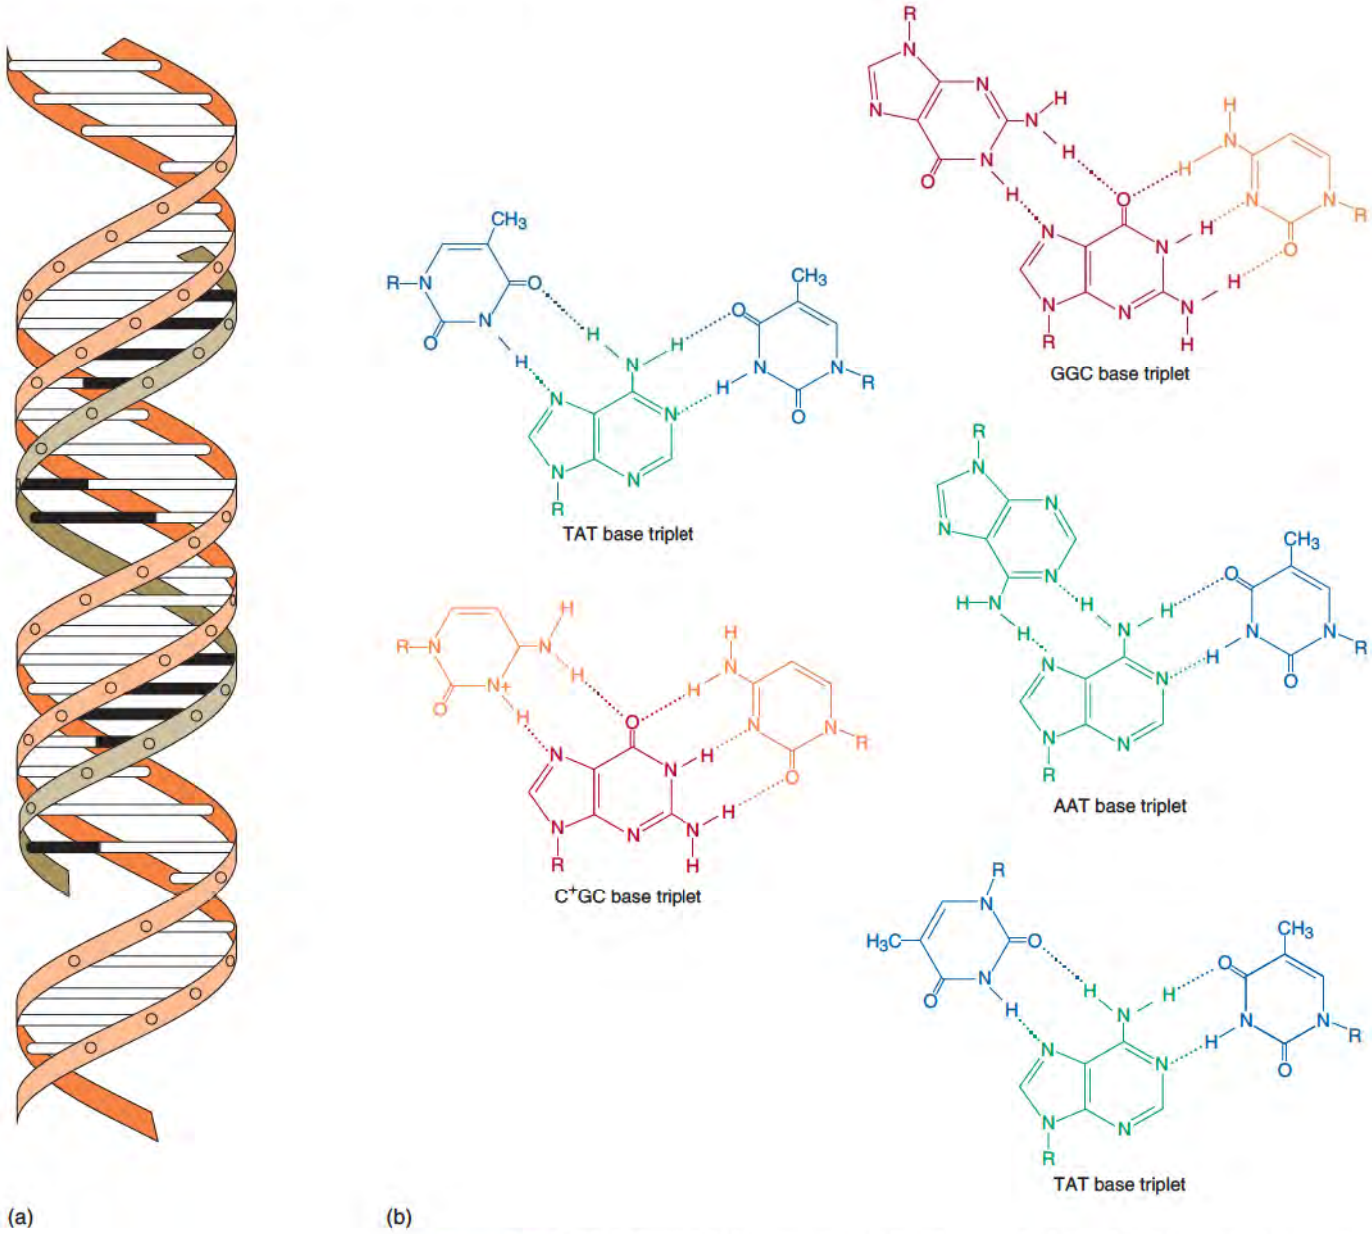

Figure 2.26 Triple helices. (*a*) Hoogsteen triple helix. Hoogsteen hydrogen bonds between a homopurine strand of a double helix and a parallel homopyrimidine strand in the major groove. The resulting isomorphous base triplets TAT and C+GC provide for sequence selective binding. (*b*) Reverse Hoogsteen triple helix. Triple helices can be formed by antiparallel binding of an oligonucleotide in the major groove to the homopurine strand of a Watson–Crick double helix. Reverse Hoogsteen hydrogen bonding produces three possible triplets: GGC, AAT, and TAT. The last triplet is not isomorphous with the others because the sugars (represented by R) are positioned differently with respect to the Watson–Crick base pair.

the resulting triplet is not isomorphous to the pu•pu•py triplets. However, the backbone is able to accommodate the distortions that result from incorporation of these triplets.

As in double-helical complexes, base stacking plays the key role in stabilizing the triplex structure. However, bringing three negatively charged backbone strands together increases electrostatic repulsion. Thus, the triple-helical complex is less stable than the associated Watson–Crick double helix. The presence of Mg^{2+} or other multivalent cations stabilizes the triple helix by shielding the phosphate charges.

Intramolecular triple helices can be formed by disruption of double-helical DNA with polypurine sequences in mirror repeats. A mirror repeat is a region such as AGGGGA that has the same base sequence when read in either direction from a central point. Refolding generates a triple-stranded region and a single-stranded loop in a structure called **H-DNA**

(Figure 2.27). Even though the formation of H-DNA is thermodynamically unfavorable because of a reduction of stacking interactions, intramolecular triple helices have been detected in cellular DNA when under **superhelical stress.** DNA **supercoiling** provides the energy to drive the unwinding of DNA that is necessary for the formation of the triple helix. Triple-strand formation produces a relaxation of negative supercoils. Also, the binding of proteins to the single-stranded DNA may further stabilize the H-DNA structure and prevent degradation of the loop by nucleases.

Many sequences in eukaryotic genomes have the potential to form triple-stranded DNA structures. Such regions occur with much higher frequency than expected from probability considerations alone. Polypurine tracts over 25 nucleotides long constitute as much as 0.5% of some eukaryotic genomes. These potential triple-helical regions are especially common near sequences involved in gene regulation. Because of this, it has been proposed that H-DNA may play a role in the control of RNA synthesis (Clin. Corr. 2.4). Other potential biological tasks have been proposed for triple-helical DNA, including possible roles in initiation and termination of replication and recombination. The abilities of triple-helical DNA to interfere with transcription have also led to efforts to use intermolecular triple helices to control artificially RNA synthesis and subsequent protein synthesis.

Figure 2.27 Intramolecular triple helices: H-DNA. Polypurine–polypyrimidine regions of DNA with a mirror repeat symmetry can form an intramolecular triple helix in which the third strand lies in the major groove, whereas its complementary strand acquires a single-stranded conformation.
Redrawn based on figure in Sinden, R. R. *DNA Structure and Function.* New York: Academic, 1994.

Four-Stranded DNA

Guanine nucleotides and highly G-rich polynucleotides form novel tetrameric structures called **G-quartets** that contain a planar array of guanines connected by Hoogsteen hydrogen bonds (Figure 2.28). Polynucleotides can interact to form **tetraplexes** where G-quartets stack on each other to form a multilayered structure (Figure 2.29). These structures are stabilized by Na^+ and K^+, which interact with guanine oxygens (O6) in the center of the quartet plane or between two adjacent planes. These cations stabilize the complex both electrostatically by balancing out the negative charges on the four polynucleotide strands and entropically by releasing a large number of water molecules into the bulk solution.

While G-tetraplexes have been observed by X-ray diffraction and NMR spectroscopy, their existence *in vivo* has not been proven. However, the ends of eukaryotic **chromosomes** (**telomeres**) contain repetitive G-rich sequences. Human telomeres contain 800–2400 copies of the hexameric repeat sequence $d(TTAGGG)_n$ and terminate in a single-stranded overhang that is roughly 150 nucleotides long. *In vitro,* oligonucleotides with this sequence can form tetraplex structures. The role tetraplexes play in telomere functions is unknown.

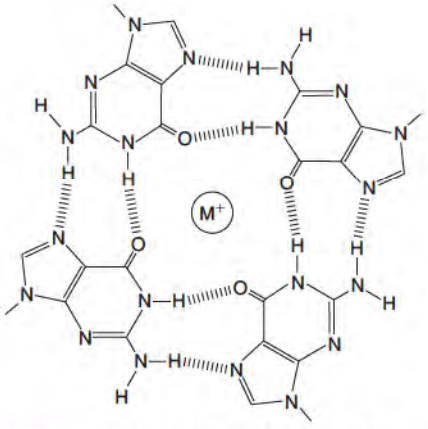

Figure 2.28 The structure of a G-quartet. The four coplanar guanines form a tetrameric structure by formation of Hoogsteen hydrogen bonds. The cavity in the center of the quartet can accommodate a sodium or potassium ion with coordination by the four O-6 oxygens.

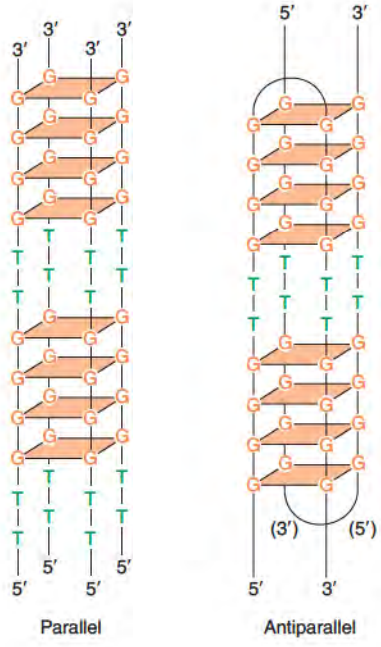

Figure 2.29 G-Quadruplex DNA. Four-stranded structures can arise from stacking of G-quartets. Quadruplex structures may be parallel or antiparallel (one possible arrangement shown). The latter may be formed by the G-rich sequences of telomeric DNA.
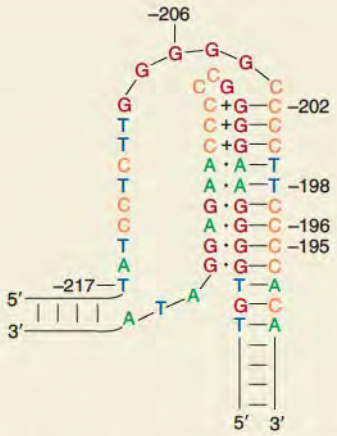
Redrawn based on figure in Sinden, R. R. *DNA Structure and Function.* New York: Academic, 1994.

CLINICAL CORRELATION 2.4

Hereditary Persistence of Fetal Hemoglobin

Hereditary persistence of fetal hemoglobin (HPFH) (OMIM 141749) is a group of conditions in which fetal hemoglobin synthesis is not terminated at birth but continues into adulthood. The homozygous form of the condition is extremely uncommon, being characterized by changes in red blood cells similar to those found in the genetic blood disorder β-thalassemia. HPFH, in either the homozygous or the heterozygous state, is associated with mild clinical or hematologic abnormalities. Mild musculoskeletal pains may occur infrequently, but HPFH patients are frequently asymptomatic.

The condition results from failure to stop transcription of human $^{G}\gamma$- and $^{A}\gamma$-globin genes, leading to elevated levels of fetal hemoglobin. The formation of an intramolecular DNA triple-helical structure located about 200 bp upstream from the initiation site for transcription of the γ-globin genes (between positions –194 and –215) acts as a brake for their expression. Hemoglobin genes of patients contain mutations in one or more positions in this region, decreasing the stability of the triple helix and reducing its ability to inhibit the protein synthesis.



Ulrich, M. J., Gray, W. J., and Ley, T. J. An intramolecular DNA triplex is disrupted by point mutations associated with hereditary persistence of fetal hemoglobin. *J. Biol. Chem.* 267:18649, 1992; and Bacolla, A., Ulrich, M. J., Larson, J. E., Ley, T. J., and Wells, R. D. An intramolecular triplex in the human gamma-globin 5'-flanking region is altered by point mutations associated with hereditary persistence of fetal hemoglobin. *J. Biol. Chem.* 270:24556, 1995.

However, telomeres are attracting attention as targets for new anticancer chemotherapies (Clin. Corr. 2.5). In addition, G-tetraplexes have been implicated in recombination of immunoglobulin genes and in dimerization of double-stranded genomic RNA of the human immunodeficiency virus (HIV).

Slipped DNA

DNA regions with direct repeat symmetry can form slipped, mispaired DNA (SMP-DNA). Their formation involves unwinding of the double helix, realignment, and subsequent pairing of one copy of the direct repeat with an adjacent copy on the other strand. This generates two single-stranded loops. Two isomeric structures of an SMP-DNA are possible (Figure 2.30). Although SMP-DNA has not yet been identified *in vivo*, genetic evidence suggests that it is involved in spontaneous frameshift mutations that result in base addition or deletion within runs of single bases (Figure 2.31). Deletions and duplications of DNA segments

CLINICAL CORRELATION 2.5

Telomerase as a Target for Anticancer Agents

Telomeres, the ends of linear eukaryotic chromosomes, are critical for maintaining the stability of the genome. They are progressively shortened during each cycle of cell division and, on reaching a critical length, trigger apoptosis. Telomerase acts to maintain or lengthen the telomeres but is not active in normal somatic cells. Telomerase activity present in most tumor cell lines may be responsible for their immortalization and, when increased, correlates to poorer clinical prognosis.

Two approaches are being examined for selective inhibition of telomerase. The first involves targeting of the RNA-containing portion of the enzyme. This RNA serves as the template for extension of the telomeric repeat sequence. Nucleic acids with chemically modified sugar–phosphate backbones bind to telomerase RNA in immortal human cells, inhibit activity, and ultimately cause cell death. Modified nucleic acids were used to resist nuclease degradation and provide high affinity for forming double-helical complexes with RNA. A second approach involves drugs that bind to G-quadruplex DNA. Large aromatic molecules such as porphyrins and anthraquinones selectively bind and stabilize G-quadruplex DNA structures.

Herbert, B.-S., Pitts, A. E., Baker, S. I., Hamilton, S. E., et al. Inhibition of human telomerase in immortal human cells leads to progressive telomere shortening and cell death. *Proc. Natl. Acad. Sci. USA* 96:14276, 1999; Parkinson, E. K., and Minty, F. Anticancer therapy targeting telomeres and telomerase. *Biodrugs* 21:375, 2007; and Cuesta, J., Read, M. A., and Neidle, S. The design of G-quadruplex ligands as telomerase inhibitors. *Mini-Rev. Med. Chem.* 3:11, 2003.

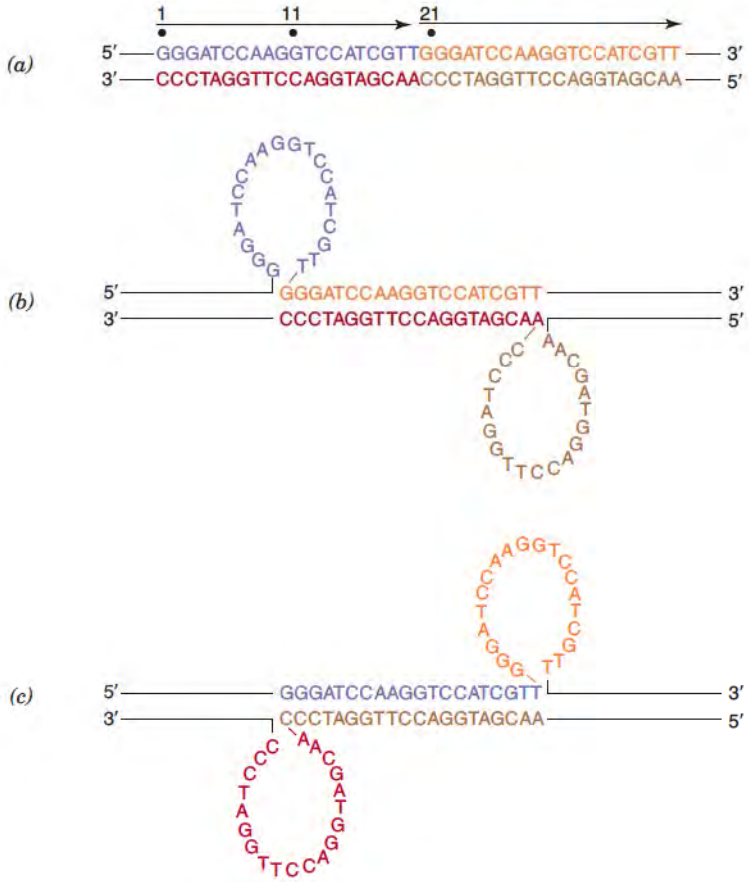


Figure 2.30 Slipped, mispaired DNA. (*a*) The presence of two adjacent tandem repeats can give rise to two isomers of slipped, mispaired DNA. (*b*) The second copy of the direct repeat in the top strand pairs with the first copy of repeat on the bottom strand. (*c*) The pairing of the first copy of the direct repeat in the top strand with the second copy of the direct repeat in the bottom strand. Two single-stranded loops are generated in each isomer.

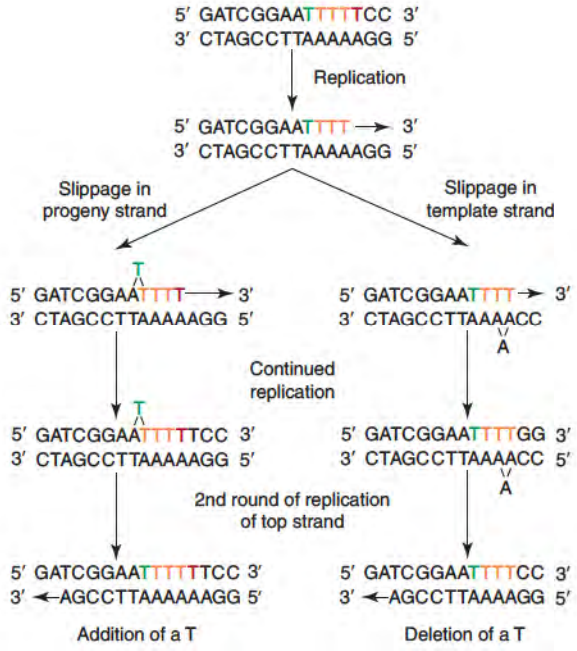

Figure 2.31 Frameshift mutagenesis by DNA slippage. DNA replication within a run of a single base can produce a single-base frameshift. In this example, a run of five As is replicated and, depending on whether a slippage occurs in progeny strand or template strand, a T may be added or deleted from the DNA.

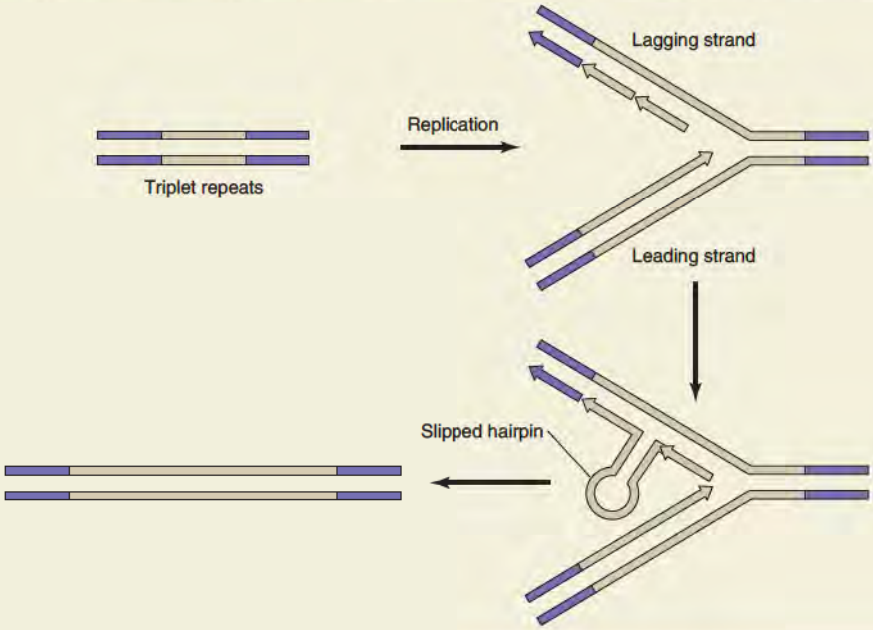
CLINICAL CORRELATION 2.6

Expansion of DNA Triple Repeats and Human Disease

The presence of reiterated three-base-pair DNA sequences occurs in a number of human genetic diseases including fragile X syndrome (OMIM 300624), myotonic dystrophy (OMIM 160900), X-linked spinal and bulbar muscular atrophy (Kennedy syndrome), Friedrich ataxia, and Huntington disease (OMIM 143100). These diseases are associated with the expansion of nucleotide triplet repeats that appear within or near specific genes. Kennedy's disease was found to contain a CAG repeat in the first exon of the androgen receptor gene. Triplet repeats can also be found within untranslated regions of the gene: in Friedrich ataxia, a repeated GAA is found within an intron and, in myotonic dystrophy, a CTG repeat is found in the 3'-untranslated region of its gene. Fragile X syndrome, a leading cause of mental retardation, is characterized by expansion of a GCC triplet on the 5'-side of the FMR-1 gene. This repeat expands from 30 copies to thousands of copies. The disease develops when the normal expression of the FMR-1 gene is turned off by methylation of CpG sites. In all cases expansion of the triplet interferes with normal functioning of the related protein. Often, there is a loss of protein function, but occasionally, a gain of a deleterious function occurs. These diseases are characterized by an increase in severity of the disease with each successive generation, which is known as anticipation.

Triplet expansion may result from slipped mispairing during DNA synthesis. Because of massive amplification that characterizes these diseases, repeated or multiple slippages would have to be involved to explain the high degree of expansion. One possible mechanism involves slippage of nascent DNA during lagging strand synthesis. This process may be aided by formation of a stable hairpin structure by the slipped loop. Repetition of this process leads to accumulation of large numbers of triplet repeats.

Mirkin, S. Expandable DNA repeats and human disease. *Nature* 447:932, 2007; and Patel, P. I., and Isaya, G. Friedrich Ataxia: from GAA triplet-repeat expansion to frataxin deficiency. *Am. J. Hum. Genetics.* 69:15, 2001.



that are longer than a single base can occur during DNA replication between direct repeats, causing slipped-looped structures. Duplication of certain simple triplet repeats that are the basis of several human genetic diseases (Clin. Corr. 2.6) can also occur by this mechanism.

2.4 • HIGHER-ORDER STRUCTURE OF DNA

With the exception of RNA-containing viruses, all life on Earth uses DNA to store genetic information. The length of DNA varies from species to species and ranges from a few thousand base pairs for small viruses, to millions of base pairs in bacteria, and to billions of base pairs in plants and animals. In all organisms, the **contour length** (length of the DNA assuming a B-form double helix) of genomic DNA is usually much larger than the size of the cell

that contains it. For example, a medium-sized virus, such as λ-phage, contains 4.8×10^4 bp of DNA which is 16.5 μm long. However, the viral particle is only 0.19 μm long. The common bacterium *Escherichia (E.) coli* is approximately 2 μm long and has a single chromosome with 4.6×10^6 bp with a contour length of 1.5 mm. A single diploid human cell contains 6×10^9 bp of chromosomal DNA packaged in 46 chromosomes. The contour length of this DNA approaches 2 m, which is packed within a nucleus about 10 μm in diameter. It is clear that the DNA of all organisms must be exquisitely packaged.

Genomic DNA May Be Linear or Circular

With the exception of some small bacteriophages such as φX174 that can acquire a single-stranded form, most DNAs exist as double-helical complexes. Depending on the source, the complexes can be linear or circular. For example, DNAs of several small viruses are linear double-stranded helices. Some of these DNAs contain naturally occurring interior single-stranded breaks. The double-helical structure is maintained because the breaks in one strand are generally in different locations from those in the complementary strand. DNAs in most higher organisms are also linear. Each of the 46 **chromosomes** in a diploid human cell is a linear double-helical DNA complexed with proteins.

Circular DNA results from the formation of phosphodiester bonds between the 3′- and 5′-termini of linear polynucleotides. The circular nature of the single-stranded phage φX174 DNA was suspected from studies that showed that no ends were available for reaction with exonucleases. In addition, endonuclease cleavage at a single site yielded only one polynucleotide. These results were later confirmed by direct observation with electron microscopy.

Some organisms have DNAs that are either linear or circular at different points in their life cycles. Before entering *E. coli,* the λ-phage DNA is linear with single-stranded overhangs on the 5′-termini. These overhangs are approximately 20 nucleotides long and have complementary sequences. On infection, circularization occurs by hybridization of the ends to each other. Formation of phosphodiester bonds between the 3′- and 5′-ends of each strand by **DNA ligase** produces a covalently closed circle (Figure 2.32). The strands of a circular DNA cannot be irreversibly separated by denaturation because they exist as intertwined closed circles. The absence of 3′- or 5′-termini endows the circular DNA with complete resistance toward exonucleases, improving the longevity of DNA.

Most DNA in bacteria exists solely as closed circles. This includes the bacterial chromosomes and the smaller extrachromosomal **plasmid** DNAs. The latter are a few thousand base pairs long and encode accessory genes such as those for antibiotic resistance. Plasmids are maintained and replicated separately from chromosomal DNA and may number in the hundreds within a bacterium. Circular DNA exists in higher organisms too. Yeasts can also carry circular plasmids. Mitochondria and chloroplasts in higher eukaryotic cells contain circular DNAs 200–1500 $\times 10^3$ bp long which encode unique proteins used by the organelles (p. 582). The presence of an independent genome and a marked similarity to cyanobacteria has led to the hypothesis that these organelles arose billions of years ago from a symbiotic relationship between protoeukaryotic cells and bacteria.

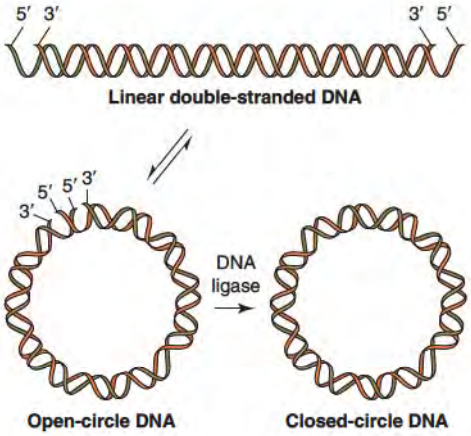


Figure 2.32 Circularization of λ DNA. DNA of bacteriophage λ exists in linear and circular forms, which are interconvertible. Circularization of λ DNA is possible because the 5′-overhangs of the linear form are complementary sequences.

DNA Is Superhelical

Circular double-stranded DNA formed by ligating the free termini of a linear DNA is **relaxed**; that is, it has the thermodynamically favored structure of B-DNA. This relaxed DNA has greatly reduced activity in replication, translation, and recombination. The biologically active form of DNA is **superhelical**, a topologically strained isomer created by underwinding or overwinding the double helix. Before circularization of a linear B-form DNA, the double helix contains about 10.5 base pairs per complete turn. If the DNA is untwisted before sealing the circle, the resulting structure will be strained (Figure 2.33). Untwisting reduces the total number of helical turns present in the circular structure. The underwinding of the helix can be accommodated by disrupting the base pairing over a small region to produce a pair of single-stranded loops in a relaxed circular structure. Loss of base stacking in this structure is energetically unfavorable. However, if all base stacking

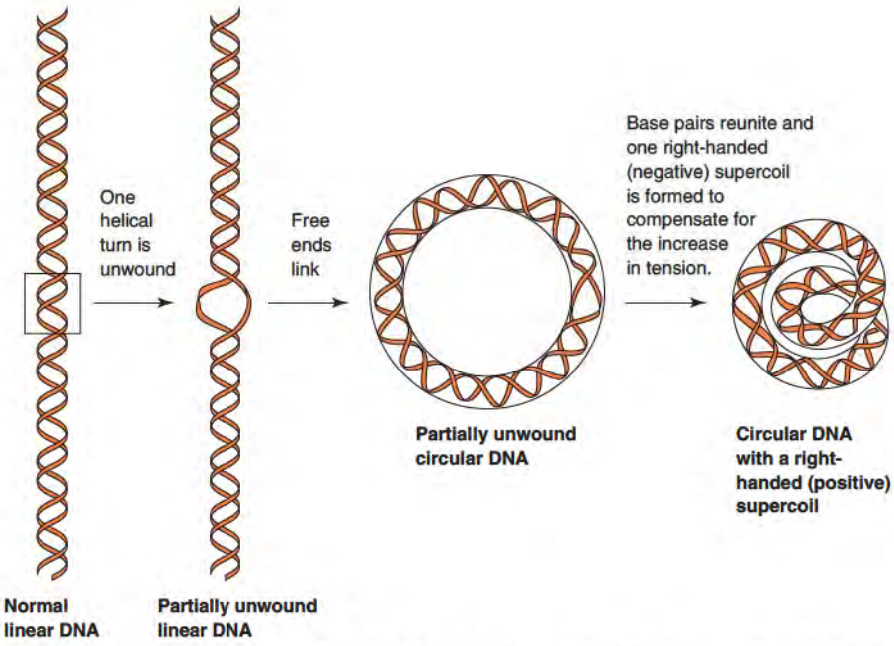

Figure 2.33 Negative DNA supercoiling. Right-handed supercoils (negatively supercoiled DNA) are formed if relaxed DNA is partially unwound. Unwinding may lead to a disruption of hydrogen bonds or may produce negative supercoils. The negative supercoils are formed to compensate for the increase in tension that is generated when disrupted base pairs are reformed.
Redrawn from Darnell, J., Lodish, H., and Baltimore, D. *Molecular Cell Biology.* New York: Freeman, 1986.

is maintained, the underwinding generates a torsional strain in the backbone of the double helix. Twisting the entire circular DNA in the direction opposite to the original rotation relieves the strain. This results in the formation of a coiled coil, better known as a superhelix. Underwound DNA is said to be negatively supercoiled, and the resulting superhelix is right handed (Figure 2.34). Conversely, overwound DNA is positively supercoiled and forms a left-handed superhelix.

Although the closed-circular form of DNA is ideal for acquiring a superhelical structure, any segment of double-stranded DNA that is immobilized at both ends can be superhelical. The DNA of eukaryotic cells, for instance, can acquire a superhelical form because its

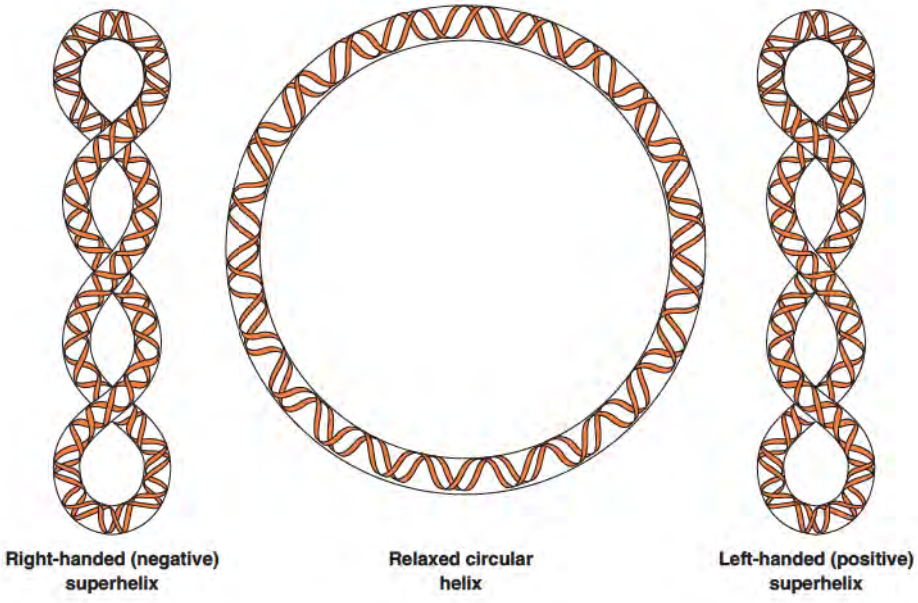

Figure 2.34 Relaxed and supercoiled DNA. Relaxed DNA can be converted to either right- or left-handed superhelical DNA. Right-handed DNA (negatively supercoiled DNA) is the form normally present in cells. Left-handed DNA may be transiently generated as DNA is subjected to enzyme-catalyzed transformations (replication, recombination, etc.) and is present in certain bacteria species. The distinctly different patterns of folding for right- and left-handed DNA superhelices are apparent in this representation.

anchoring by nuclear proteins creates numerous closed **topological domains**. A topological domain is defined as a DNA segment contained in a manner that restrains rotation of the double helix (Figure 2.35).

Overall, whether DNA is circular or linear, the existence of negative superhelicity appears to be an important feature. Supercoiling promotes packaging of DNA within the confines of the cell by facilitating formation of compact structures. Superhelices also possess a tendency to generate regions with disrupted hydrogen bonding (bubbles), which may be instrumental in facilitating the process of localized DNA strand separation during DNA repair, synthesis, and recombination.

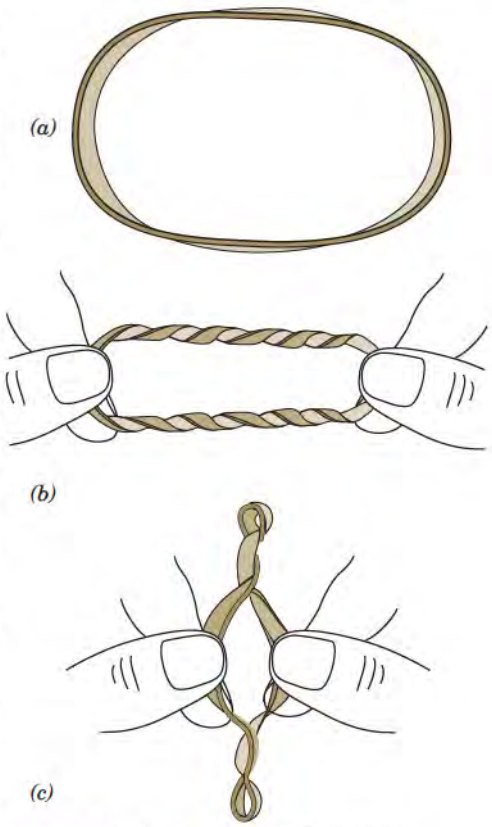

Figure 2.35 Superhelical model for DNA. A rubber band can demonstrate the topological properties of double-stranded circular DNA. (*a*) The relaxed form of the band. (*b*) The band can be twisted to generate two distinct topological domains, separated by the pair of "thumb-forefinger anchors". Left-handed (counterclockwise) turns are introduced into the upper section of the band, with compensating right-handed (clockwise) turns formed in the bottom section. (*c*) When the "anchors" are brought into close proximity with each other, the upper section that contained the left-handed turns forms a right-handed superhelix. The bottom section produces a left-handed superhelix. Superhelicity is not the property of a DNA molecule as a whole but rather a property of specific DNA domains. Redrawn from Sinden, R. R., and Wells, R. D. DNA structure, mutations, and human genetic disease. *Curr. Opin. Biotech.* 3:612, 1992.

Topoisomerases

Topoisomerases regulate the formation of superhelices. These enzymes catalyze the concerted breakage and rejoining of DNA strands, producing a DNA that is more or less superhelical than the original (Table 2.4). The precise regulation of the cellular level of DNA superhelicity is important to facilitate protein interactions with DNA. The cellular ATP-to-ADP ratio may play a role in this process, because it influences the activity of some topoisomerases. Compounds that inhibit topoisomerases and gyrases are effective antibacterial and antitumor agents (Clin. Corr. 2.7).

Topoisomerases I make transient single-strand breaks in a negatively supercoiled DNA double helix; passage of the unbroken strand through the gap eliminates one supercoil from DNA (Figure 2.36). During the reaction, the enzyme remains bound to DNA by a covalent bond between a tyrosyl residue and a phosphoryl group at the incision site. This conserves the energy of the interrupted phosphodiester bond for the subsequent repair of the nick. The two subclasses of topoisomerase I differ in the formation of 5′-phosphotyrosine (class IA) or 3′-phosphotyrosine (class IB) bonds.

TABLE 2.4 • Properties of DNA Topoisomerases

Topoisomerase	*Type*[a]	*Functions*
E. coli topoisomerase I *(topA)*[b]	IA	Relaxes negatively supercoiled DNA
E. coli topoisomerase III *(topB)*	IA	Relaxes negatively supercoiled DNA, decatenation (unlinking) activity.
Eukaryotic topoisomerase III *(top3)*	IA	Possible role in recombination and/or chromosome decatenation?
Archaeal reverse DNA gyrase	IA	Introduces positive supercoils in DNA.
Eukaryotic DNA topoisomerase I *(top1)*	IB	Relaxes either negatively or positively supercoiled DNA.
Vaccinia (poxvirus) DNA topoisomerase	IB	Relaxes either negatively or positively supercoiled DNA; binds supercoiled DNA sequence specifically.
E. coli DNA gyrase *(gyrA, gyrB)*	II	Introduces negative supercoils in DNA, relaxes either negatively or positively supercoiled DNA.
E. coli topoisomerase IV *(parC, parE)*	II	Decatenation of chromosomes during replication; relaxes negatively supercoiled DNA.
Eukaryotic DNA topoisomerase II *(top2)*	II	Decatenation of linked chromosomes; relaxes either negatively or positively supercoiled DNA.

[a]Type I topoisomerases use Mg^{2+} as a cofactor, but do not require ATP. Type II topoisomerases require both Mg^{2+} and ATP.

[b]The name of the gene coding for the topoisomerase is shown in italics.

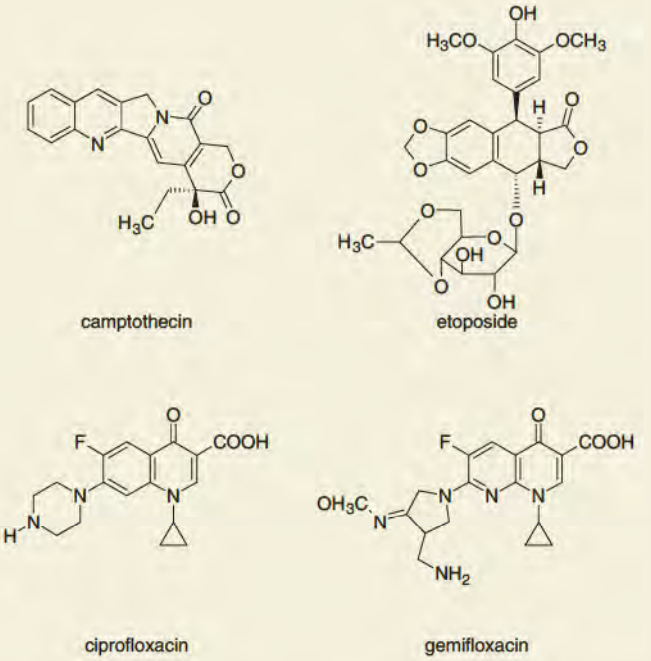
CLINICAL CORRELATION 2.7

Topoisomerases in the Treatment of Disease

Topoisomerases are important targets of antimicrobial and antineoplastic agents. These drugs do not inhibit overall activity of the enzyme, as is the case with most enzyme-targeting drugs. Instead, they trap the immediate complex between topoisomerase and DNA. This may result in degradation of DNA, introduction of mutations, or inhibition of translation and replication.

In the treatment of cancers, both topoisomerases I and II can be targeted. Camptothecin and its derivatives act on topoisomerase I. An excellent correlation has been noted between antitumor activity of various camptothecin derivatives on murine leukemia and their interference with topoisomerase activity. They may cause potentially lethal lesions by forming drug-stabilized covalent DNA cleavage complexes. Subsequent DNA replication may be a prerequisite for cell toxicity. The efficacy of camptothecin derivatives may be improved by increased levels of topoisomerase I in tumor cells such as advanced colon cancers. Two other potent antineoplastic agents, amsacrine and etoposide, act selectively on topoisomerases II and indicate that these clinically useful drugs stabilize covalent topoisomerase IIDNA cleavage complexes. Indirect evidence suggests that these drugs may stimulate formation of these complexes. Topoisomerase II-mediated DNA breaks can exert their cytotoxic effect in the absence of ongoing DNA synthesis, probably by inducing recombination and mutation at sites of formation of drug-induced topoisomerase II–DNA complexes. Many anticancer agents including anthracyclines (including adriamycin and doxorubicin), synthetic intercalators, ellipticines, and podophyllotoxins also target topoisomerases II. Hematologic neoplasms, such as lymphoid and nonlymphoid leukemias, high-grade non-Hodgkin lymphomas, and Hodgkin disease, are treated mostly with combinations of topoisomerase II inhibitors with or without additional cytotoxic agents.

Ciprofloxacin (Cipro®) gained considerable media attention for its use in the treatment of inhalation anthrax. It is a representative of the quinolones, a class of powerful broad-spectrum antibacterial activities. These antibiotics selectively inhibit bacterial DNA gyrase and topoisomerase IV. Quinolones bind to the complexes formed by these enzymes with DNA-inhibiting replication. Ultimately, cell death occurs due to the accumulation of lethal double-stranded breaks in the bacterial DNA. Because these enzymes are not found in eukaryotic cells, quinolone drugs are highly selective in their cytotoxic action. Fluoroquinolones such as ciprofloxacin show good activity against both Gram-positive and Gram-negative bacteria whereas newer drugs show even broader activities. For example, gemifloxacin (Factive®) is especially useful for the treatment of respiratory infections including those by multidrug-resistant *Staphylococcus pneumoniae, Mycoplasma, and Legionella.*



Potmesil, M., and Kohn, K. W. (Eds.). *DNA Topoisomerases in Cancer.* New York: Oxford University Press, 1991; Pommier, Y. Topoisomerase I inhibitors: camptothecins and beyond. *Nature Rev. Physician* 65:455, 2002.

Topoisomerases II are dimeric proteins that bind to a double-helical DNA and cleave both strands (Figure 2.37). Passage of another double-helical DNA segment through the break removes or adds two supercoils. All eukaryotic and many prokaryotic topoisomerases II only relax supercoiled DNA. ATP hydrolysis is required for the turnover of the enzyme, but not actually for the relaxation reaction. The **gyrases**, a subset of type II topoisomerases, are the only enzymes that add negative supercoils into DNA. They occur only in bacteria; eukaryotes use the wrapping of DNA around chromosomal proteins for the introduction of negative supercoils. The gyrase reaction requires the hydrolysis of ATP as an energy source and can add negative supercoils at a rate of about 100 per minute. Gyrases bind to DNA in a conformation that introduces a positive and negative superhelical loop, leaving the topological state of the DNA unchanged. Double-strand breakage and passage of DNA through the gap introduces two negative supercoils.

Topoisomerases also catalyze other topological isomerizations. Bacterial type III topoisomerases have type I topoisomerase properties; that is, they relax supercoils without the

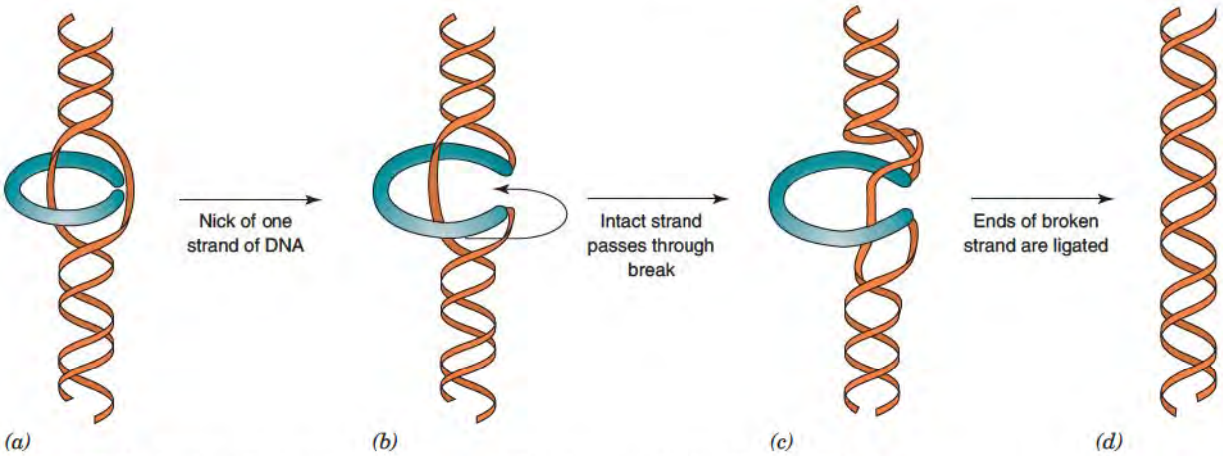


Figure 2.36 Mechanism of action of topoisomerases I. Topoisomerases I relax DNA by (*a*) binding and locally separating the complementary strands; then (*b*) nicking one strand and binding to the newly generated termini; and (*c*) passing the intact strand through the gap generated by the nick and closing the gap by restoring the phosphodiester bond. This gives rise to a relaxed structure (*d*).

requirement of an energy source, such as ATP hydrolysis. These topoisomerases may specialize in the resolution of interlocking circular DNA products (catenates) that are generated just prior to the completion of DNA replication. Reverse gyrases, members of an unusual class of topoisomerases, were first isolated from archaebacteria. These gyrases introduce positive supercoils into DNA that may protect from the denaturing conditions of high temperature and acidity under which these bacteria exist.

Packaging of Prokaryotic DNA

In prokaryotic cells, the single chromosome is a supercoiled double-stranded circular DNA. Bacterial chromosomes are dynamic structures reflecting the need for rapid DNA synthesis, cell division, and transcription. However, in a common bacterium such as *E. coli,* the contour length of the DNA is some 750 times longer than the length of the cell. Thus, DNA must be packaged in a highly condensed form to fit inside the cell. Bacterial chromosomes are organized into compacted structures, called **nucleoids**, by interaction of **HU** and **H-NS** proteins and participation of various cations, **polyamines** (such as spermine, spermidine, putrescine, and cadaverine), RNA, and nonhistone proteins (Figure 2.38). HU is an 18-kDa heterodimer of two nearly identical subunits (HU-1 and HU-2). On binding, HU changes the shape and supercoiling of the DNA. HU binding *in vitro* compacts DNA

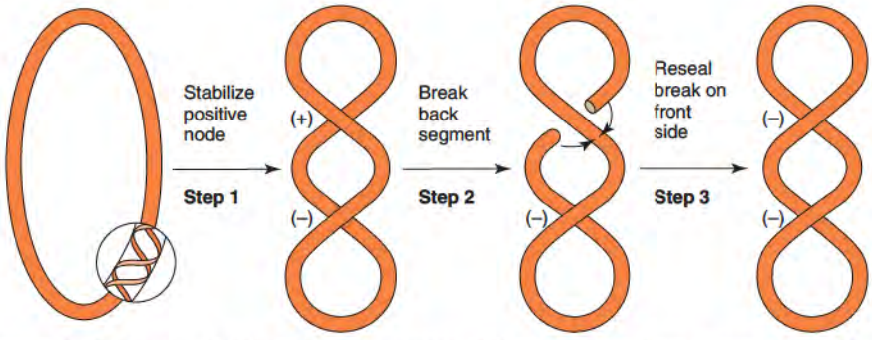

Figure 2.37 Mechanism of action of topoisomerases II. Topoisomerases II can relax or, in case of gyrases, introduce negative superhelices into DNA. The mechanism of action of gyrase is illustrated using the conversion of a relaxed DNA molecule to a molecule that contains first two supercoils, one positive and one negative (step 1). Passage of a DNA segment through the positive supercoil shown on the rightmost part of the figure (step 3) produces a molecule that contains two negative supercoils. This reaction requires the hydrolysis of ATP as an energy source.
Redrawn from Brown, P. O., and Cozzarelli, N. R. *Science* 206:1081, 1979.

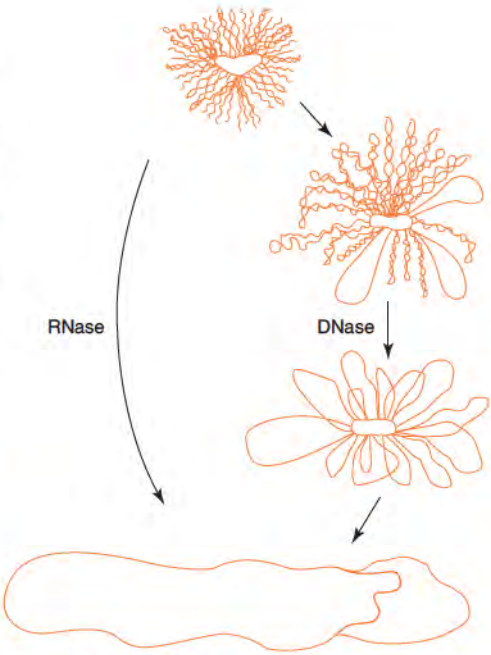

Figure 2.38 Bacterial chromosomes are packaged in nucleoids. The circular chromosome of a bacterium is compacted into about 40–50 loops of supercoiled DNA organized by a central RNA–protein scaffold. DNase relaxes the structure progressively by opening individual loops, one at a time. RNase completely unfolds the chromosome in a single step by disrupting the nucleoid core.
Redrawn from Worcel, A., and Burgi, E. *J. Mol. Biol.* 71:127, 1972.

and restrains supercoils in a concentration-dependent manner. At an equimolar ratio, the interaction of DNA with HU prevents topoisomerases I from relaxing negatively supercoiled DNA in the DNA–HU complex. Higher concentrations of HU do not result in additional supercoils. It appears that HU bends DNA sharply into a tight circle and is primarily responsible for the formation of a beaded nucleoid structure. In the nucleoid, a single supercoiled DNA molecule is organized into about 40 loops, each approximately 10^5 bp in size, that merge into a scaffold rich in protein and RNA. A role for RNA in chromosome packing is unique to prokaryotes. As a result of formation of a nucleoid, the bacterial genome can easily fit into a cell.

Organization of Eukaryotic Chromatin

The enormous length of the genome of most eukaryotes necessitates the division of genetic information into several independent chromosomes. Human cells contain 23 pairs of chromosomes with an average length of 1.3×10^8 bp, or approximately 43 mm. Each human chromosome consists of a DNA molecule varying in size from 263×10^6 bp for chromosome 1 to less than 50×10^6 bp for the Y chromosome. For this amount of DNA to fit within a cell nucleus with a diameter of approximately 10–20 μm requires a condensation ratio over five orders of magnitude (Figure 2.39).

DNA in eukaryotic cells is associated with numerous proteins to form **chromatin.** In nondividing (interphase) cells, chromatin is amorphous and dispersed throughout the nucleus. Just prior to cell division (metaphase), it becomes organized into highly compacted structures called **chromosomes.** Each chromosome is characterized by a **centromere,** which is the site for attachment to proteins that link the chromosome to the mitotic spindle. **Telomeres** define the termini of linear chromosomes. Chromosomes also contain sequences required for initiation of DNA replication (**origin of replication**).

Histones are the most numerous proteins in chromatin. There are five classes of these proteins: **histones H1, H2A, H2B, H3,** and **H4.** Because of their unusually high content of the basic amino acids lysine and arginine, histones are highly cationic and interact with the polyanionic phosphate backbone of DNA to produce uncharged nucleoproteins. The amino acid sequences of the histones are very highly conserved between species. Histones H4 from peas and cows differ by only two amino acids, although these species diverged more than a billion years ago. Histones H3 are also very highly conserved, whereas the nonbasic regions of histones H2A and H2B are less highly conserved. H1 is larger, more basic, and by far the most tissue-specific and species-specific histone. In some cell types of vertebrates, a sixth histone, H5, functions as a replacement for H1. A heterogeneous group of proteins with high species and organ specificity is also present in chromatin. These nonhistone proteins consist of several hundred members, most of which are present in trace

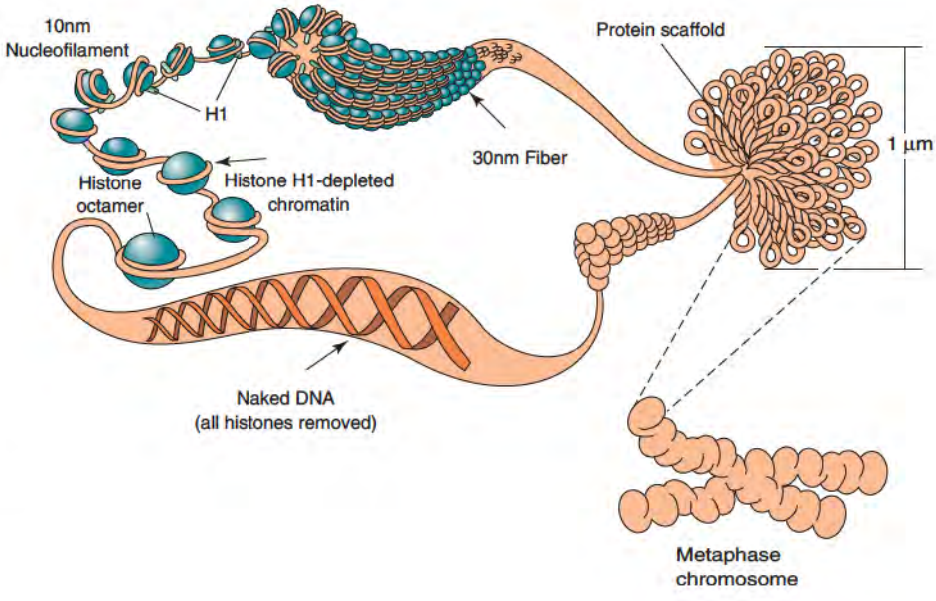

Figure 2.39 Organization of DNA into chromosomes. A drawing showing the stepwise condensation of DNA into chromatin. The DNA initially wraps around the histones of the nucleosome core. Condensation with histone H1 produces the 10-nm nucleofilament, which is subsequently packaged into a twisted, looped structure attached to a protein scaffold within the chromosome.

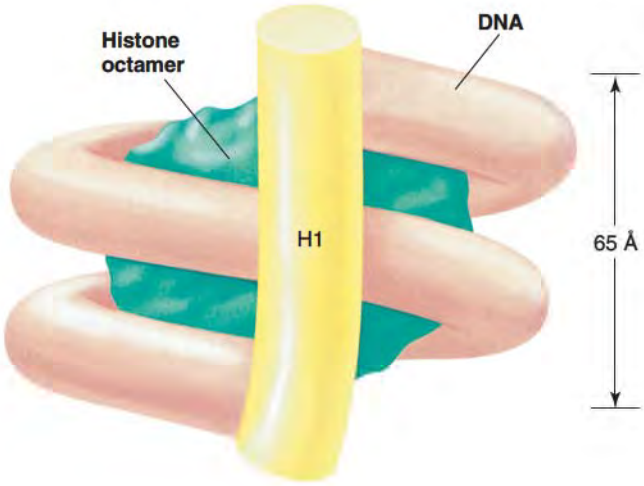

Figure 2.40 Models of the nucleosome complex. The nucleosome consists of approximately 146 bp of DNA corresponding to 1¾ superhelical turns wound around a histone octamer. The chromatosome consists of about 166 bp of DNA (two superhelical turns). The H1 histone is associated with the linker DNA. Reprinted with permission from Voet, D., and Voet, J. G. *Biochemistry.* 3d ed. New York: Wiley, 2004. © (2004) Donald and Judith Voet.

amounts. Many of them are associated with functions of chromosomes such as replication, gene expression, and chromosome organization.

Nucleosomes and Polynucleosomes

Histones interact with DNA to form a periodic beads-on-a-string structure, called a polynucleosome, in which the elementary unit is a **nucleosome** (Figure 2.40). Each nucleosome is disk shaped, about 11 nm in diameter and 6 nm in height, and consists of a DNA segment and a histone cluster composed of two molecules each of H2A, H2B, H3, and H4 histones. Each octameric cluster consists of the tetramer $(H3)_2$–$(H4)_2$ with two H2A–H2B dimers. Each histone is characterized by a central nonpolar domain, which forms a globular structure and is responsible for histone–histone interactions. The neighboring N-terminal regions contain most of the positively charged amino acid residues that provide favorable electrostatic interactions with DNA. These tail sequences appear to extend radially out from the histone core and may be involved in interactions between nucleosomes. The DNA is wrapped around the octamer with the $(H3)_2$-$(H4)_2$ core interacting with the central 70–80 bp of the surrounding DNA (Figure 2.41). Approximately 146 bp of DNA wraps around the histone octamer. The histones are in contact with the minor groove of DNA and leave the major groove available for interaction with proteins that regulate gene expression and other DNA functions. The structure of the nucleosome core explains why eukaryotic cells lack gyrases that can underwind relaxed DNA. Negative superhelicity is introduced because

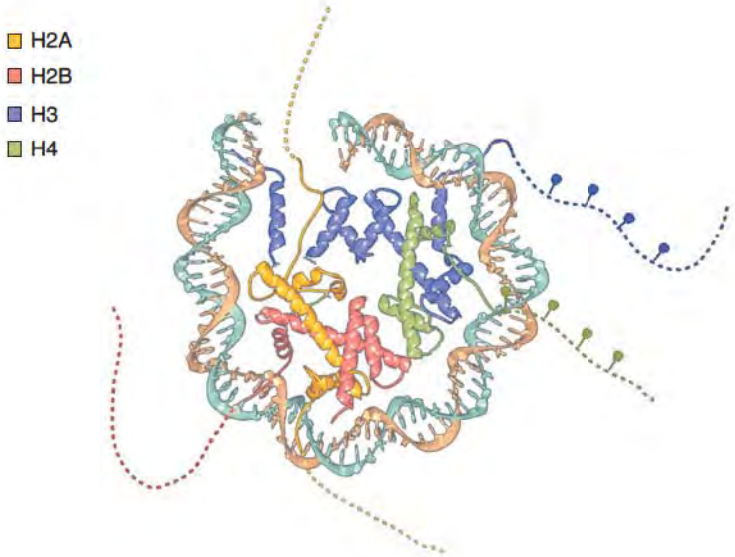

Figure 2.41 X-ray structure of the nucleosome core. The disk of the nucleosome core has been split in half to show one turn of DNA wrapped around four histone molecules. The dashed lines represent unstructured parts of the histone tails. Reproduced with permission from Kornberg, R. D., and Lorch, Y. *Cell* 98: 285, 1999.

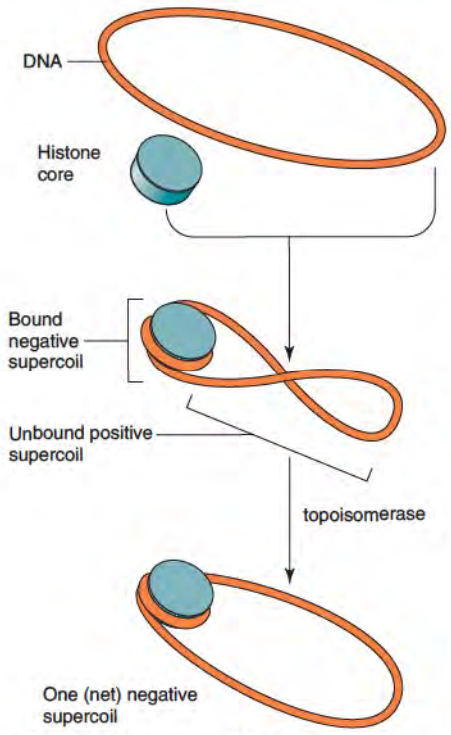

Figure 2.42 Generation of negative supercoiling in eukaryotic DNA. The binding of a histone octamer to a relaxed, closed-domain DNA forces the DNA to wrap around the octamer, generating a negative supercoil. In the absence of any strand breaks, the domain remains intact and a compensating positive supercoil must be generated elsewhere within the domain. The action of a eukaryotic topoisomerase subsequently relaxes the positive supercoil, leaving the closed domain with one net negative supercoil.

of DNA forming a coil around the histone core (Figure 2.42). Such wrapping removes approximately one helical turn from DNA, generating a negative supercoil within the region wrapped around the histone core and a compensating positive supercoil elsewhere in the molecule. Subsequent relaxation of the positive supercoil by eukaryotic topoisomerases leaves one net negative supercoil within the nucleosomal region.

Between nucleosomes is 20 to 90 bp of **linker DNA.** It is associated with histone H1 that locks the coiled DNA in place; the resulting complex is a **chromatosome** (Figure 2.40). The periodicity of nucleosome distribution along the polynucleosome structure has been determined by controlled digestion by a nuclease that preferentially attacks linker DNA. The distribution of nucleosomes is not random with respect to the DNA base sequence. DNA does not bend uniformly but rather bends gently and then more sharply around the histone octamers. This suggests that DNA binding is sequence dependent and that the positioning of nucleosomes may be influenced by the DNA sequence. In fact, nucleosomes tend to form preferentially in certain DNA regions. DNA that contains long A tracts or G-C repeats does not usually form nucleosomes. In contrast, certain bent DNA regions, for instance, periodically phased A tracts, associate strongly with histones. Histone octamers can migrate along the DNA strand. This mobility allows access to the DNA by polymerases and other proteins necessary for transcription and replication.

Polynucleosome Packing into Higher Structures

Wrapping of DNA around histones to form nucleosomes results in a 10-fold reduction of the apparent length of DNA and the formation of a **10-nm nucleofilament.** Condensation of 10-nm nucleofilaments into a **solenoid** arrangement involving six to seven chromatosomes per turn forms **30-nm fibers** (Figure 2.43). Histone H1 molecules bind to one another cooperatively, bringing the neighboring nucleosomes closer together in 30-nm fibers. At physiological salt concentrations, the 30-nm fibers form spontaneously, but at low ionic strength they dissociate into 10-nm nucleofilaments. Formation of polynucleosomes and their condensation into 30-nm fibers provides for a DNA compaction ratio of up to two orders of magnitude. The 30-nm fibers form only over selected regions of DNA that are characterized by the absence of binding with other sequence-specific nonhistone proteins. The presence of these and their effects on formation of 30-nm fibers may depend on the transcriptional status of the regions of DNA involved.

Models of the higher levels of packing of 30-nm fibers are based on indirect evidence obtained from the lampbrush chromosomes of vertebrate oocytes and polytene chromosomes of fruit fly giant secretory cells. These chromosomes are exceptional in that they maintain precisely defined higher-order structures in interphase, that is, when cells are in a resting (nondividing) state. By extrapolation, the structural features of interphase lampbrush chromosomes have led to the proposal that chromosomes in general are organized as a series of looped, condensed domains of 30-nm fibers of variable size for different organisms. These loops may contain 5,000 to 120,000 bp with an average of about 20,000. Thus, the haploid human genome would contain about 60,000 loops. A loop may contain a few linked genes. The loops are bound to a protein scaffold consisting of H1 histone and several nonhistone proteins, including two major scaffold proteins, Sc1 (a topoisomerase II)

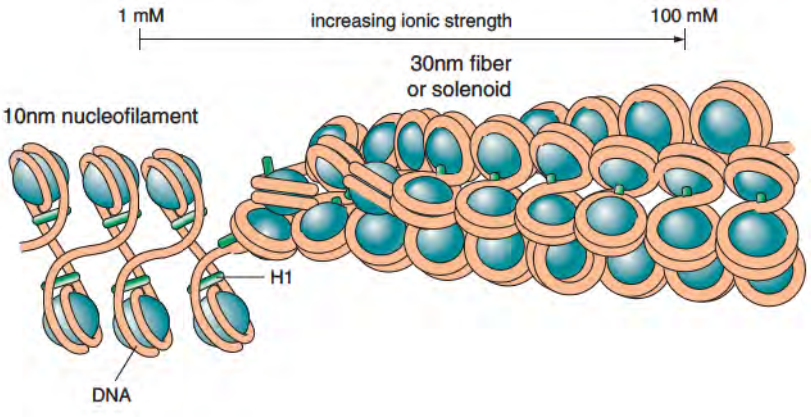

Figure 2.43 Nucleofilament structure. Histone H1 attached to the linker regions between nucleosomes results in condensation into 10-nm fibers. At higher ionic strengths the nucleofilament forms a very compact helical structure or a helical solenoid. The H1 histones interact strongly with one another in this structure.
Adapted from Kornberg, R. D., and Klug, A. *The Nucleosome.* San Diego, CA: Academic, 1989.

and Sc2. They are fixed at their bases and can therefore accumulate supercoils. Specific AT-rich regions known as scaffold attachment regions (SARs) are preferentially associated with the scaffold. SARs also contain topoisomerase II binding sites. The presence of the topoisomerases suggests that changes in supercoiling within these domains are biologically important. Formation of looped domains may account for an additional 200-fold condensation in the length of DNA and an overall packing ratio of more than four orders of magnitude. Each loop can be coiled and then supercoiled into 0.4 μm of a 30-nm fiber. Since a chromosome is about 1 μm in diameter, packing of the 30-nm fiber into a chromatid would require just one more order of folding. Further packing may be achieved by arranging the loops of 30-nm fiber into tightly stacked helical coils. **Chromatids,** the two linked arms of replicated DNA in the highly condensed metaphase chromosomes, may consist of helically packed loops of 30-nm fibers.

Packing changes at various stages of the cell cycle appear to be controlled in part by covalent modification of the core histones (**histone remodeling**). Reversible acetylation on the ε-amino groups of lysine and phosphorylation of serine and threonine residues are involved in regulating the activity of nucleosomal DNA. These modifications reduce the numbers of positive charges on the histones, causing them to bind less tightly to DNA. The resultant unraveling of 30-nm fibers and decondensation of chromatin produces loosely packed **euchromatin,** the transcriptionally active form of DNA. Methylation of basic amino acid side chains (lysine and arginine) promotes the opposite effect and, when accompanied by decreased acetylation, characterizes a highly condensed, inactive form of chromatin called **heterochromatin.** Throughout the cell cycle, permanently repressed genes and other untranscribed regions such as centromeres, telomeres, and " junk" DNA remain condensed.

The pattern of covalent modifications (the **histone code**) provides a highly tunable means of regulating gene expression (Clin. Corr. 2.8). While this code does not involve changes in the sequence of DNA (it is **epigenetic**), it is heritable due to coordination between histone modification and methylation of DNA at the 5-position of deoxycytidine (Figure 2.23; p. 41).

CLINICAL CORRELATION 2.8

Epigenetic Treatments for Cancer

Progression toward cancer can involve epigenetic alterations that affect processes including cell-cycle progression, repair of DNA damage, and programmed cell death (apoptosis). One such alteration, chromatin remodeling, has drawn attention as a target for cancer treatment. Histone deacetylases, enzymes responsible for the reversal of lysine and arginine acetylation, are overexpressed in a number of cancers including colon, prostate, breast, and cervical. Hydroxamic acids such as tricostatin A and suberoylanilide hydroxamic acid (SAHA) bind to a zinc ion in the enzyme-active site and block deacetylation of histone lysines and arginines. These compounds inhibit tumor cell growth and block cell-cycle progression. Notably, SAHA is currently approved for the treatment of cutaneous T cell lymphoma under the name Zolinza®. Other modifications of the histone code such as serine phosphorylation play roles in repair and chromosome stability and may also provide targets for antiproliferative drugs.

There is also a potential dietary component to the epigenetic control of cancer. Short-chain fatty acids such as butyrate are generated by bacterial flora of the large intestine and show a weak ability to regulate epithelial cell mitosis, differentiation, and apoptosis. Experiments have shown that butyrate increases the levels of histone acetylation, presumably from inhibition of histone deacetylase. These data suggest that the nutritional state of an individual can affect the histone code and its role in cancer.

2.5 • SEQUENCE AND FUNCTION OF DNA

The size and average base composition of DNA vary widely between species. What makes the DNA of a species unique is the nucleotide sequence. Until recently, direct determination of nucleotide sequences in genomic DNA was an intimidating undertaking. The technology developed in connection with the Human Genome Project has accelerated the rate at which DNA sequences are determined. DNA sequences of over 1000 species have already become available for analysis.

Restriction Endonucleases and Palindromes

One key event that enabled the development of methods to sequence genomic DNA was the discovery of bacterial **restriction endonucleases.** These cleave double-stranded DNA at a specific sequence by cutting each strand (Figure 2.44). Bacteria developed restriction enzymes as a defense against infection by phages. Cleavage exposes the viral DNA to eventual degradation by nonspecific bacterial exonucleases. Bacterial DNA can be protected from cleavage by sequence-specific methylation. The recognition sites for restriction methylases correspond to those of the endonucleases. Methylation of specific bases within the recognition site prevents cleavage by the cognate nuclease. The most common sites for base methylation are the 5-position of cytosine and the 6-NH_2 group of adenine. Notably, base methylation is also critical in gene regulation in higher organisms.

Hundreds of restriction endonucleases have been purified. With few exceptions, they recognize sequences four to six nucleotides long. Rare cutters, endonucleases with unusually long recognition sites, are valuable because of the relative infrequency of cleavage of very large DNAs such as eukaryotic chromosomes. Not I, for example, has an eight-nucleotide recognition sequence. The recognized sequences are often symmetrical inverted repeats or palindromes; the order of the bases is the same when the two complementary strands of the palindrome are read 5′ → 3′. For EcoR1 from *E. coli,* the sequence is 5′-GAATTC-3′. Restriction endonucleases types I and III cut in the vicinity of the recognition site, whereas type II specifically cleaves DNA within the recognition sequence.

Restriction endonucleases recognize specific sequences that can have relatively low frequencie; they fragment DNA very selectively. For example, a typical bacterial DNA with 3×10^6 bp will be cleaved into a few hundred fragments. Plasmid DNAs may have few or no cutting sites at all for a particular restriction endonuclease (Figure 2.45). Thus, a particular restriction enzyme generates a unique family of fragments, or restriction digest, for any given DNA molecule. The availability of restriction enzymes and development of gel electrophoresis techniques for separating DNA fragments have made determination of sequences a simple matter (p. 259).

Most Prokaryotic DNA Codes for Specific Proteins

In prokaryotes a large percentage of the DNA codes for specific proteins. The entire *E. coli* genome consists of about 4.6×10^6 bp of DNA and contains ~4200 genes. Not all of the genes code for proteins. For example, 80 genes code for tRNA molecules, and some may

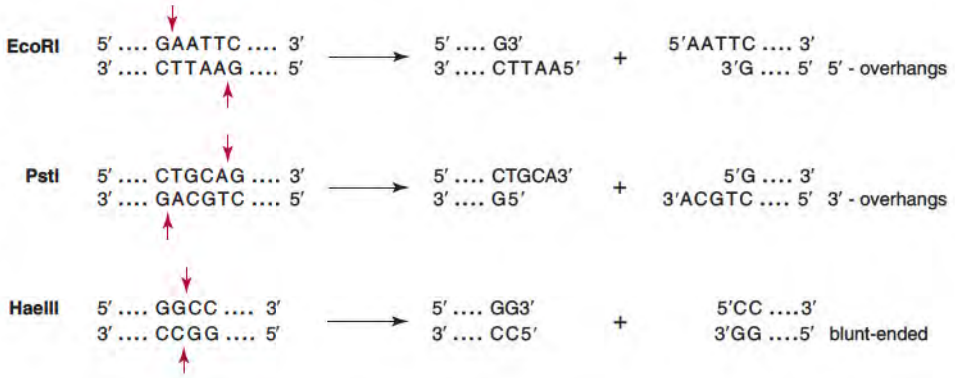

Figure 2.44 Types of products generated by type II restriction endonucleases. Enzymes exemplified by EcoRI and PstI nick on both sides of the center of symmetry of the palindrome, generating single-stranded overhangs. Many commonly used enzymes generate 5′-overhangs, although some produce ends with 3′-overhangs as shown for PstI. Other restriction nucleases cut across the center of symmetry of the recognition sequence, to produce flush or blunt ends, as exemplified by HaeIII.

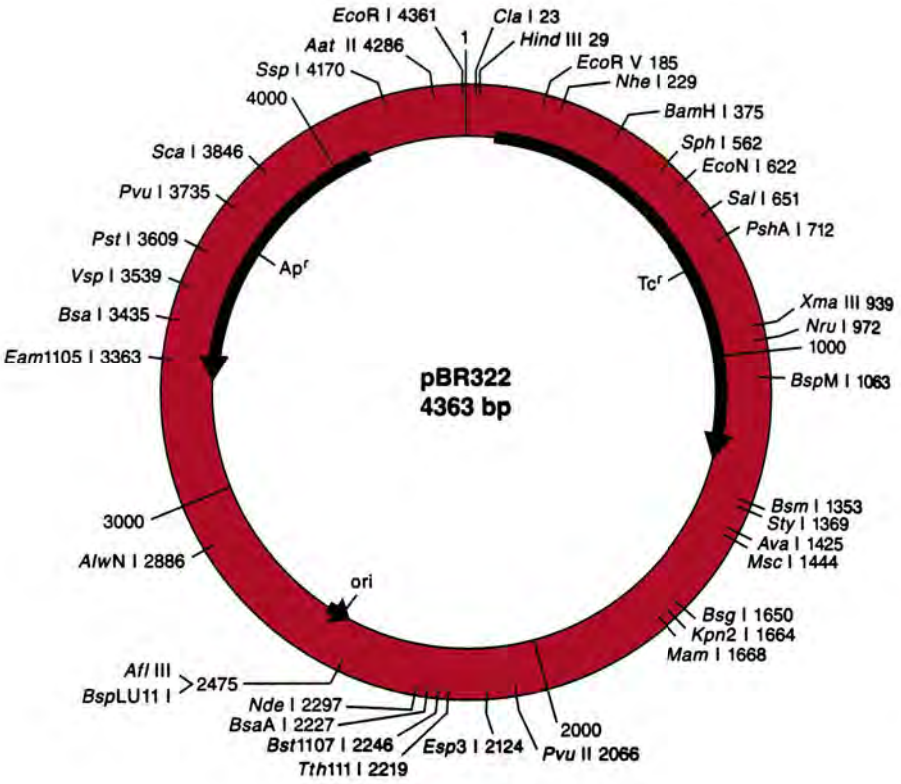

Figure 2.45 Restriction map for plasmid DNA. Bacterial plasmid pBR322 is a 4363-bp circular DNA containing an origin of replication (ori) and genes for resistance to the antibiotics ampicillin (Ap^r) and tetracycline (Tc^r). The locations of unique DNA sequences that are recognized by a number of restriction endonuclease are marked. Other endonucleases may cleave this plasmid many times or not at all. For example, the recognition sequence for Bgl I appears in three locations on this plasmid, whereas Bgl II does not cleave this plasmid at all.

not encode functional molecules at all. *E. coli* DNA is densely packed with sequence information, and there is little repetition of information within it. As much as 1% is composed of multiple copies of short **repetitive sequences** known as repeated extragenic palindromic (REP) elements. These are present at sites of DNA interaction with functional proteins, for example, in the region of initiation of DNA replication (referred to as OriC). At OriC, REP elements have a consensus sequence of 34 nucleotides and bind topoisomerase II. REP elements with the sequence GCTGGTGG (Chi sites) bind the enzyme RecBCD, which initiates DNA recombination. Chi sites are regularly spaced at intervals separated by about 4,000 bp. Genetic information is even more densely organized in smaller organisms, such as bacteriophages, where the primary sequence of DNA reveals that structural genes—nucleotide sequences coding for protein—do not always have exclusive physical locations. Rather, they frequently overlap with one another, as illustrated by the partial sequence of phage φX174 (Figure 2.46). The overlap makes the efficient and economic utilization of the limited DNA present and may control the order of gene expression.

Only a Small Percentage of Eukaryotic DNA Consists of Functional Genes

Eukaryotes have much larger genomes than prokaryotes, from about 1.5×10^7 bp for yeast to about 1.15×10^{11} bp for the haploid genome of the lily *Fritillaria assyrica*. Results from the Human Genome Project, however, indicate that the human genome codes for only 20,000–25,000 genes. As a result, genetic information need not be as densely packed as in bacteria. A typical mammalian DNA, with only 7 times as many genes as that of *E. coli*, contains 500 times more DNA than *E. coli*. In fact, only 2% to 4% of DNA in a mammalian cell may suffice for all its genes. Some of the remaining DNA, such as that in centromeres and telomeres, has a well-defined function. No specific function can be assigned to the majority of noncoding DNA, and it has been referred to as "junk DNA". However, there is increasing evidence that junk DNA may have a vital role in regulation of gene expression during development. Paradoxically, the amount of junk DNA correlates better to the complexity of the organism than the number of genes.

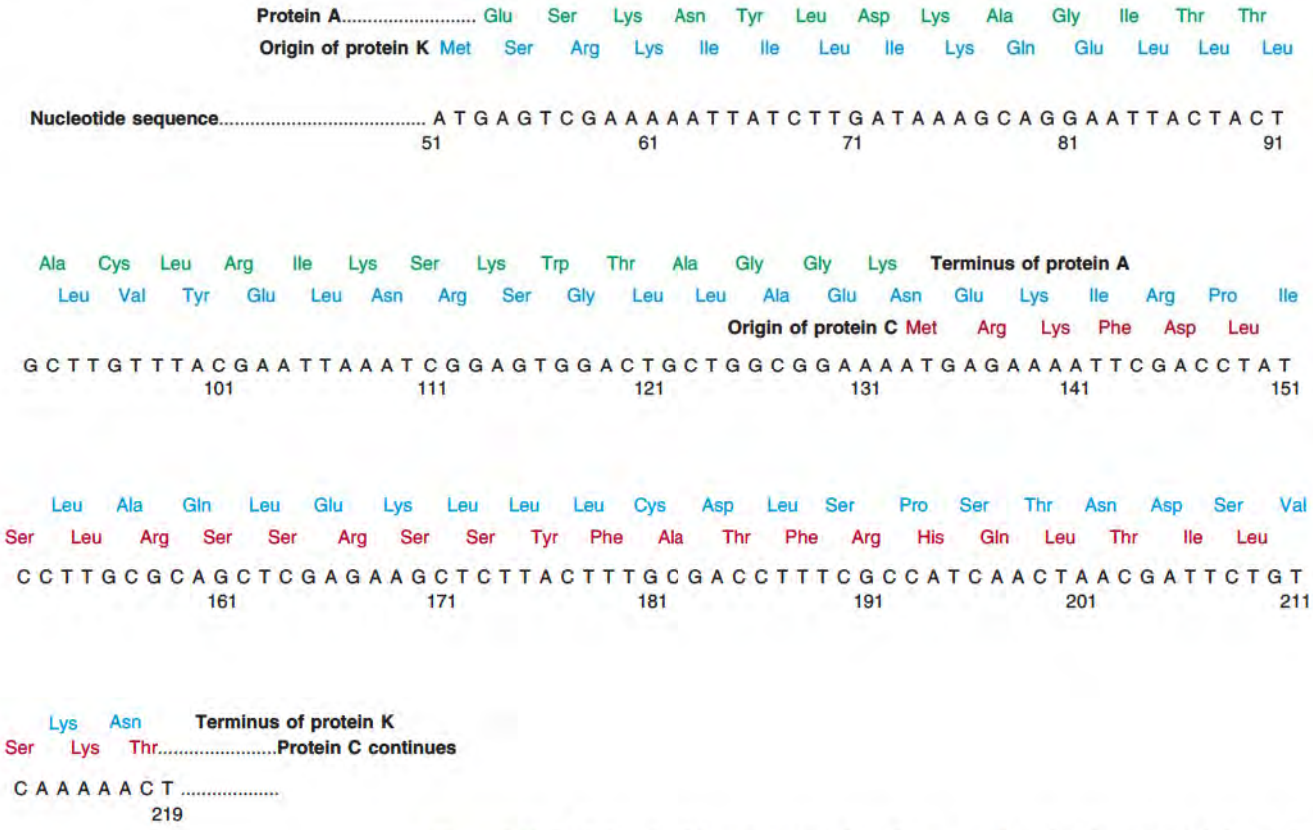

Figure 2.46 Partial nucleotide sequences of contiguous and overlapping genes of phage φX174. The sequence for protein K, nucleotides 51–219, is shown in this figure. This sequence codes. A part of this sequence, nucleotides 51–133, codes for part of protein A. Another part of the sequence, nucleotides 133–219, for part of protein C. Similar overlaps are noted between other genes of φX174. Adapted from Smith, M. *Am. Sci.* 67:61, 1979.

Eukaryotic genes do not overlap and are spaced, on average, about 40,000 bp apart. However, some may be closer together in regions that contain genes expressed in a tightly coordinated manner (gene clusters). Most eukaryotic genes are interrupted by noncoding intervening nucleotide sequences, **introns** (Figure 2.47). The sequences in the gene that are expressed, either in the final RNA product (mature RNA) or as a protein, are termed **exons.** Introns are removed during the processing of the RNA transcript, and the exons are ligated together. This tailoring of the original transcript is called **splicing.** The sequence and size of introns vary greatly among species. Added together they may be 5 to 10 times the length of the exons they separate. Most genes are interrupted by introns at least once, whereas others are interrupted more frequently. Some genes, such as that for human interferon-α, contain no introns.

Introns are common in genes of vertebrates and flowering plants but infrequent in those of other species. The biological role of introns is not clear. They may have arisen relatively recently in evolution because of the migration of mobile DNA elements (transposons) from

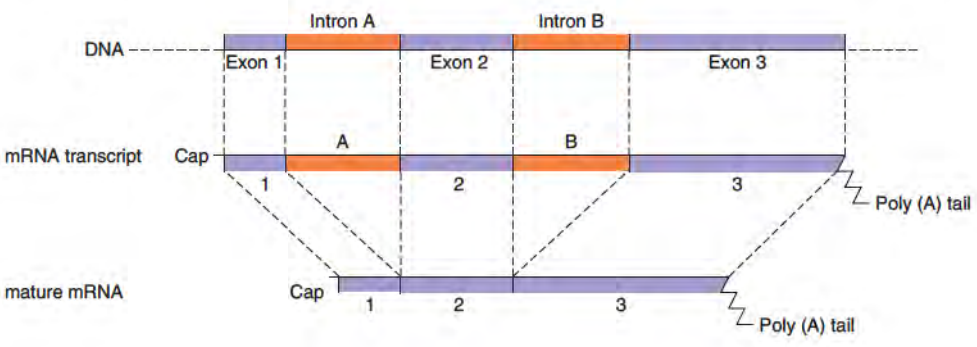

Figure 2.47 Schematic presentation of a eukaryotic gene. The top line represents a part of the DNA genome: the bottom line represents the mRNA produced by it. In this example the DNA consists of two introns and three exons. The intron sequences are transcribed but are removed during splicing; this produces a mature mRNA. Redrawn from Crick, F. *Science* 204:264, 1979.

other parts of the genome and their insertion into protein-coding genes (p. 316). Through mutation, these inserts may have subsequently lost their mobility.

Repeated Sequences

While repetition of particular DNA sequences in prokaryotes is very limited, the DNA of eukaryotes contains sequences that are repeated a few times, for specified coding genes, to millions of times per genome, for certain simple, relatively short, sequences. Depending on the species, **repetitive DNA** may constitute 3% to 80% of total DNA. In mammalian genomes, including the human genome, 25% to 35% of the DNA is repetitive. Sequences can be classified as **single copy, moderately reiterated, highly reiterated,** and **inverted repeat.** The content of single-copy DNA varies among eukaryotes. The exact boundaries between the various types of reiterated DNAs are not strictly defined.

About one-half of the human genome consists of unique sequences, but only a small fraction of these encode proteins. Some DNA contains **pseudogenes,** sequences of DNA that have significant nucleotide homology to a functional gene but contain mutations that prevent gene expression. Pseudogenes significantly increase the size of eukaryotic genomes without contributing to their expressible genetic content. Additional single-copy DNA sequences serve as introns and as control regions that flank genes.

Moderately reiterated DNA consists of copies of identical or closely related sequences that are reiterated from a few to a thousand times. These sequences are relatively long, varying from a hundred to many thousands of nucleotides. About 20% of mouse DNA consists of sequences a few hundred base pairs long that are repeated more than a thousand times. About 15% of the human genome consists of moderately reiterated DNA. Some sequences involve genes for highly abundant proteins and for ribosomal RNAs (rRNAs). For example, the sea urchins carry hundreds of copies of histone genes. Eukaryotes generally possess hundreds of copies of the gene coding for rRNA. The function of other moderately repeated sequences is not clearly known.

Normally, single-copy and moderately reiterated sequences occur on a chromosome in an orderly pattern known as the **interspersion pattern,** which consists of alternating blocks of single-copy DNA and moderately reiterated DNA. **Long interspersed elements** (LINEs) consist of sequences several thousand nucleotides long with up to 1000 copies per genome. They are flanked on either side by sequences that are direct repeats. An example of a **short interspersed element** (SINE) is the Alu family, a sequence of unknown function that constitutes a substantial portion (about 5%) of the human genome. Alu sequences are approximately 300 bp long and are repeated over 500,000 times. The structures of the short interspersed repeats, including the Alu family, are reminiscent of transposons.

Approximately 1% to 15% of eukaryotic genomic DNA consists of sequences typically shorter than 20 nucleotides reiterated thousands or millions of times. Most highly reiterated sequences have a characteristic base composition and can be isolated by shearing the DNA into segments a few hundred nucleotides long and separating the fragments by density gradient centrifugation. These fragments are termed **satellite DNA** because they appear as satellites of the band of bulk DNA after centrifugation. Other highly reiterated sequences, which cannot be isolated by centrifugation, can be identified by their property of rapid reannealing. These highly reiterated DNAs are also called simple-sequence DNA. Simple sequences are typically present in the DNA of most, if not all, eukaryotes. In some species, one major sequence is present, while in others, several simple sequences are repeated up to 1 million times. Simple sequence DNA can often be isolated as satellite DNA. That found in the centromeres of higher eukaryotes consists of thousands of tandem copies of one or a few short sequences. Satellite sequences are only 5–10 bp long and are a constituent of telomeres where they have a well-defined role in DNA replication. Some longer simple-sequence DNA has been identified. For instance, in the genome of the African green monkey a 172-bp segment that contains some sequence repetitions is highly reiterated.

Inverted repeats are a structural motif of DNA. Short inverted repeats, consisting of up to six nucleotides long, for example, the palindromic sequence GAATTC, occur by chance about once for every 3000 nucleotides. Such short repeats cannot form a stable cruciform structure as is formed by longer palindromic sequences. Inverted repeat sequences that are long enough to form stable cruciforms are not likely to occur by chance and should be

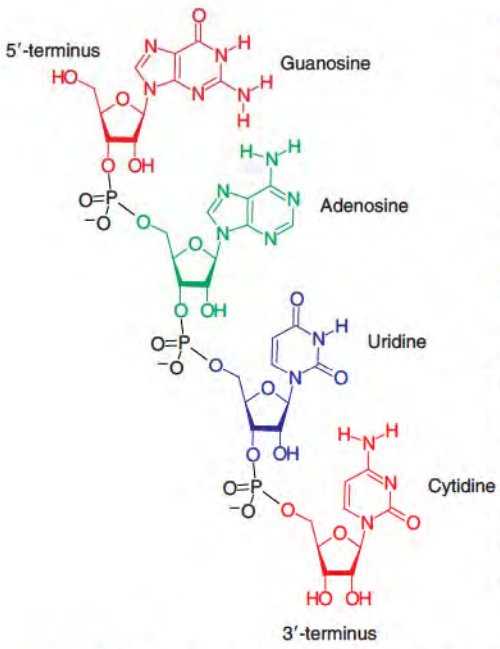

Figure 2.48 Structure of the 3′, 5′-phosphodiester bonds between ribonucleotides forming a single strand of RNA. Phosphate joins the 3′-OH group of one ribose with the 5′-OH group of the next ribose. This linkage produces a polyribonucleotide having a sugar–phosphate backbone. Purine and pyrimidine bases extend away from the axis of the backbone and may pair with complementary bases to form double-helical base-paired regions.

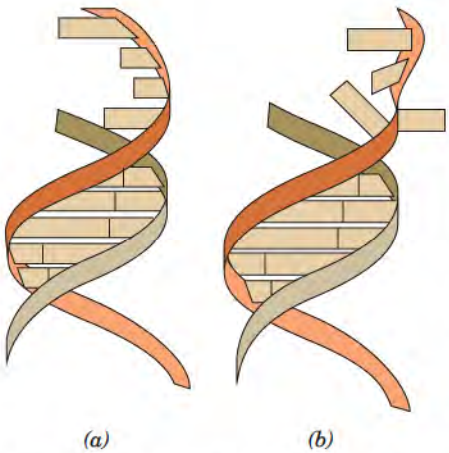

Figure 2.49 Helical structure of RNA Models indicating a helical structure due to (*a*) base stacking in the CCA terminus of tRNA and (*b*) lack of an ordered helix when no stacking occurs in this nonbase-paired region.

classified as a separate class of eukaryotic sequence. In human DNA about 2 million inverted repeats are present, with an average length of about 200 bp; however, inverted sequences longer than 1000 bp have been detected. Most inverted repeat sequences are repeated 1000 or more times per cell.

2.6 • STRUCTURE OF RNA

RNA Is a Polymer of Ribonucleoside 5′-Monophosphates

RNA is a linear polymer of ribonucleoside monophosphates. The purine bases in RNA are adenine and guanine; the pyrimidines are cytosine and uracil (Figure 2.2; p. 27). Except for uracil, which replaces thymine, these are the same bases found in DNA. A, C, G, and U nucleotides (Figure 2.3; p. 27) are incorporated into RNA during transcription. Many RNAs also contain modified nucleotides that are produced by **post-transcriptional processing.** Modified nucleotides are especially characteristic of stable RNA species (e.g., tRNA and rRNA); however, some methylated nucleotides are also present in eukaryotic mRNA. For the most part, modified nucleotides in RNA have fine tuning rather than indispensable roles in the cell.

The 3′,5′-phosphodiester bonds of RNA form a backbone from which the bases extend (Figure 2.48). Eukaryotic RNAs vary from approximately 20 nucleotides long to more than 200,000 nucleotides long. Each RNA is complementary to the base sequences of specific portions of only one strand of DNA. Thus, unlike the base composition of DNA, molar ratios of (A + U) and (G + C) in RNA are not equal. Cellular RNA is linear and single stranded. Stable, double-stranded RNA is not present in the cell. Rather, the presence of double-stranded RNA signals its destruction. This appears to be a part of the cellular response to virus infection, since some virus genomes are composed of double-stranded RNA, and double-stranded RNA is an intermediate in the replication of single-stranded RNA viruses.

Chemically, RNA is similar to DNA. Both contain negatively charged phosphodiester bonds, and the bases are very similar chemically. The differences between DNA and RNA are largely due to two factors. First, RNA contains ribose rather than 2′-deoxyribose as the nucleotide sugar component, and second, RNAs are generally single stranded rather than double stranded.

The 2′-hydroxyl group makes the phosphodiester bonds of an RNA molecule more susceptible to chemical hydrolysis, especially in alkaline solution, than those of DNA (Figure 2.11, p. 31). The chemical instability of RNA is reflected in its metabolic instability. Some RNAs, such as bacterial mRNA, are synthesized, used, and degraded within minutes. Others, such as human rRNA, are more stable metabolically, with a lifetime measured in days. Nevertheless, even the most stable RNAs are much less stable than DNA.

Secondary Structure of RNA Involves Intramolecular Base Pairing

Since RNA molecules are single stranded, they do not usually form extensive double helices. Rather, the secondary structure of an RNA molecule results from relatively short regions of intramolecular base pairing. Even nonpaired sequences of single-stranded RNAs may contain considerable helical structure (Figure 2.49). Helices within RNA are usually the A-type with 11 nucleotides per turn.

Double-helical stem-loop regions in RNA often form "hairpins." There are considerable variations in the fine structural details of hairpin structures, including the length of base-paired regions and the size and number of unpaired loops (Figure 2.50). Transfer RNAs are excellent examples of base stacking and hydrogen bonding in a single-chain RNA molecule (Figure 2.51). About 60% of bases are paired in four double-helical stems, and two loops interact with each other, resulting in an L-shaped molecule. The anticodon region in tRNA is an unpaired, base-stacked loop of seven nucleotides. The partial helix caused by base stacking in this loop binds, by base pairing, to a complementary codon in mRNA so that translation can occur.

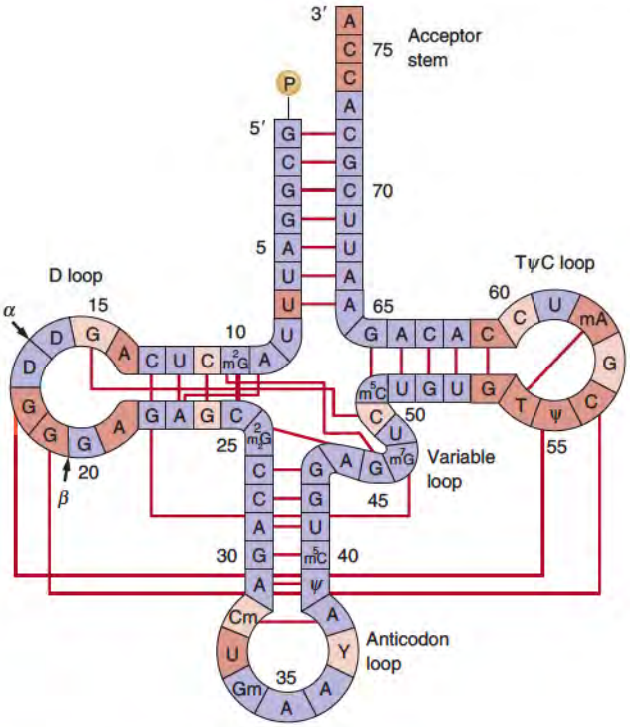

Figure 2.50 Cloverleaf structure of tRNA Cloverleaf diagram of the two-dimensional structure and nucleotide sequence of yeast $tRNA^{Phe}$. Red lines connecting circled nucleotides indicate hydrogen-bonded bases. Solid squares indicate constant nucleotides; dashed squares indicate a constant purine or pyrimidine. Insertion of nucleotides in the D loop occurs at positions α and β for different tRNAs.
Redrawn from Quigley, G. J., and Rich, A. *Science* 194:797, 1976.

RNA Molecules Have Tertiary Structures

Structures of functional RNA molecules are more complex than is suggested by the base-stacked and hydrogen-bonded helices mentioned above. In particular, the bases in unpaired regions can form hydrogen bonds or otherwise interact with each other and with helical portions of the molecule. *In vivo* RNAs are dynamic molecules that can change their conformations during synthesis, processing, and functioning. Proteins associated with RNA molecules often lend stability to the RNA structure. In fact, cellular RNA usually functions as RNA–protein complexes, rather than as free RNA molecules.

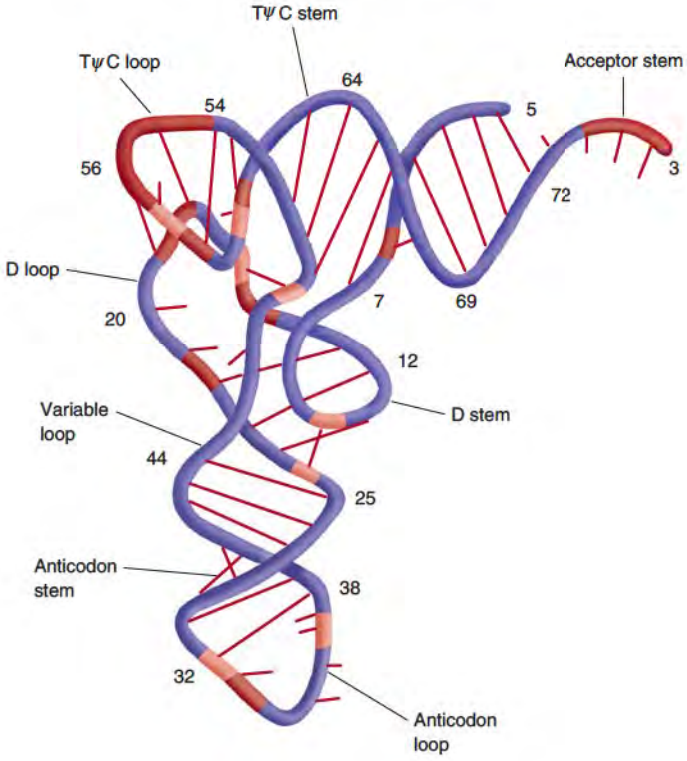

Figure 2.51 Tertiary structure on tRNA Tertiary folding of the cloverleaf structure of $tRNA^{Phe}$. Hydrogen bonds are indicated by cross rungs. Compare the presentation with Figure 2.50.
Redrawn from Quigley, G. J., and Rich, A. *Science* 194:797, 1976.

The tertiary structure of RNA molecules results from base stacking and hydrogen bonding between different parts of the molecule. tRNA provides a number of examples. In solution, tRNA is folded into a compact "L-shaped" conformation (Figure 2.51), stabilized by Watson–Crick base pairing and base interactions involving more than two nucleotides. This is true for other RNAs. Figure 2.52*a* shows a well-defined base triplet from bacterial ribosomal RNA. Bases can donate hydrogen atoms to bond with the phosphodiester backbone. The 2′-OH of the ribose is also an important donor and acceptor for hydrogen-bond formation. All these interactions contribute to the folded shape of an RNA molecule.

Other tertiary features were deduced from the three-dimensional structure of RNAs in solution or in crystal form. The term *tetraloop* refers to specific sequences (for example, UUCG or GAGA) that are often found at the closed end of RNA hairpins (Figure 2.52*b*). These tetraloops impart extra stability to RNA hairpins by forming internal hydrogen bonds between bases and sugars. Tetraloops can hydrogen-bond with regions of the double helix or with internal loops in other parts of RNA, thereby forming a complex tertiary structure.

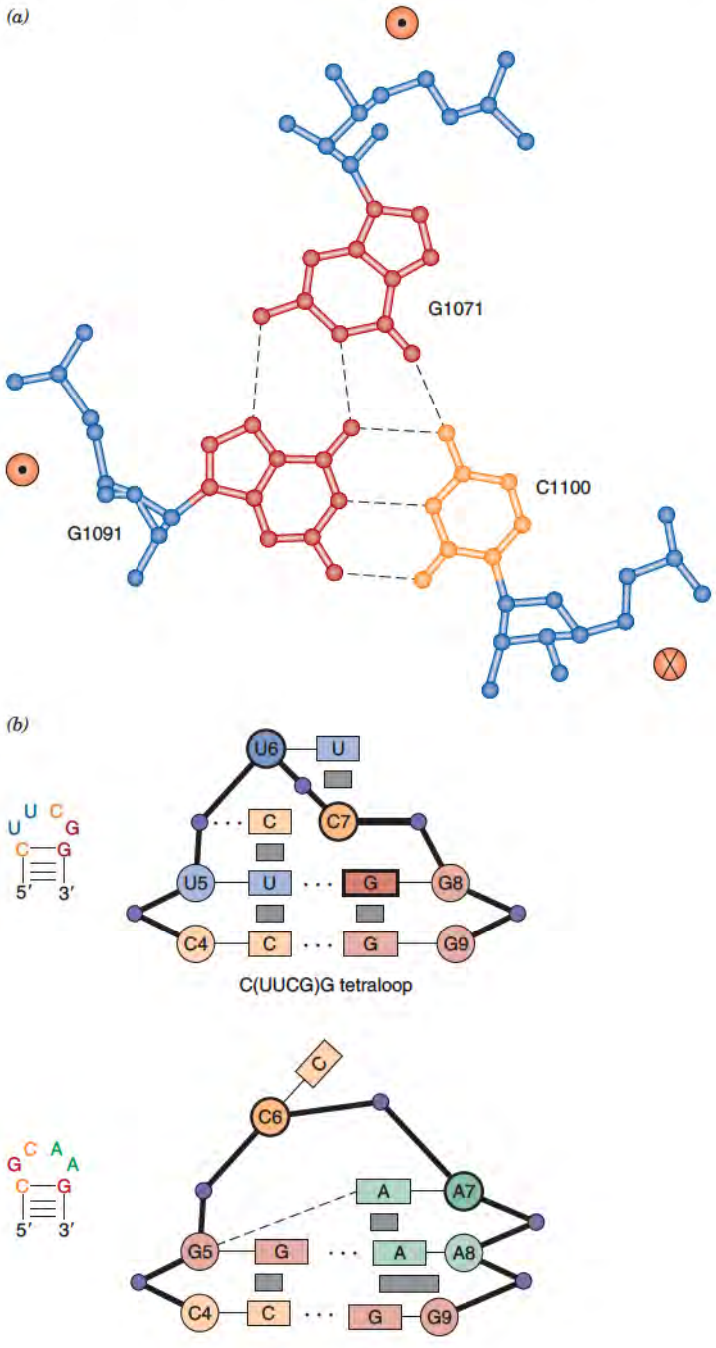

Figure 2.52 Hydrogen bonding in tRNA (*a*) A base triplet from 23S ribosomal RNA. In this case, the third base (G1071) forms hydrogen bonds with the top or Hoogsteen face of both G1091 and C1100. (*b*) Schematic diagram showing that two RNA tetraloops have similar structures. Both structures are stabilized by stacking of the loop bases, by non-Watson–Crick hydrogen bonds between bases, and by hydrogen bonding between sugar, phosphate, and ribose residues. 2.7 • TYPES OF RNA

RNA molecules are traditionally classified as transfer, ribosomal, and messenger RNAs according to their usual function; however, RNA molecules perform a variety of other functions in a cell.

Transfer RNA Has Two Roles: Activating Amino Acids and Recognizing Codons in mRNA

About 15% of total cellular RNA is **tRNA**, an essential intermediary between DNA and protein information in the Central Dogma. The enzyme-catalyzed formation of aminoacyl-tRNA activates amino acids for protein synthesis so that formation of peptide bonds is energetically favored. Aminoacyl-tRNAs bind to ribosomes where the amino acids are transferred to growing peptide chains (hence tRNA's name). tRNA recognizes nucleotide sequence information in mRNA to ensure that the correct amino acid is incorporated into the growing peptide chain. Amino acid activation occurs at the 3′-OH terminal CCA sequence, to which specific amino acids are attached enzymatically. Codon recognition occurs by the binding of the anticodon triplet to a three-nucleotide codon in mRNA. Base pairing of the mRNA codon and tRNA anticodon triplets is the major mechanism to ensure accurate peptide bond formation.

Each tRNA can transfer only one amino acid. Although only 20 amino acids are used in protein synthesis, free-living organisms synthesize a larger set of tRNAs. This is a consequence of the genetic code being redundant (having more than one codon per amino acid). For example, the genomic sequence of the bacterium *Haemophilus influenzae* contains genes for 54 tRNA species. Mitochondria synthesize a much smaller number of tRNAs. tRNAs that accept the same amino acid are called isoacceptors. A tRNA that accepts phenylalanine would be written as $tRNA^{Phe}$, whereas one accepting tyrosine would be written $tRNA^{Tyr}$.

tRNAs are 65 to 110 nucleotides long, corresponding to a molecular weight range of 22,000 to 37,000. The sequences of all tRNA molecules (thousands are known) can be arranged into a common cloverleaf secondary structure by complementary Watson–Crick base pairing to form three stem-loop structures. The anticodon triplet sequence is at one "leaf" of the cloverleaf while the CCA acceptor stem is at the "stem". This arrangement is preserved in the tertiary structure of $tRNA^{Phe}$ (Figure 2.51), where the anticodon and acceptor stems are at each end of the L-shaped molecule. Additional non-Watson–Crick hydrogen bonds form the tertiary structure of the L-shaped molecule.

tRNAs contain modified nucleotides, for example, 7-methylguanine at position 46 in Figure 2.50. Modified nucleotides affect tRNA structure and stability but are not required for their basic functioning. For example, a modified base next to the anticodon makes codon recognition more efficient, but a tRNA without this modification can still be read correctly by the ribosome.

Many structural features are common to all tRNA cloverleafs. Seven base pairs form the amino acid acceptor stem, which terminates with the nucleotide triplet CCA. This CCA triplet is not base paired. The dihydrouracil- or D-stem has three or four base pairs, while the anticodon and T-stems have five base pairs each. Both the anticodon loop and T-loop contain seven nucleotides. Differences in the number of nucleotides in different tRNAs are accounted for by the variable loop. Most tRNAs have small variable loops of 4–5 nucleotides, while others have larger loops of 13–21 nucleotides. The positions of some nucleotides are constant in all tRNAs (see the dark orange boxes in Figure 2.50).

Ribosomal RNA Is Part of the Protein Synthesis Apparatus

Protein synthesis takes place on ribosomes. In eukaryotes, these complex assemblies are composed of four RNA molecules, representing about two-thirds of the particle mass, and 82 proteins. The smaller subunit, the 40S particle, contains one 18S RNA and 33 proteins. The larger subunit, the 60S particle, contains one copy each of three RNAs, 28S, 5.8S, and 5S rRNAs along with 49 proteins. The total assembly forms the 80S ribosome. Prokaryotic ribosomes are smaller; the 30S subunit contains a single 16S rRNA and 21 proteins while

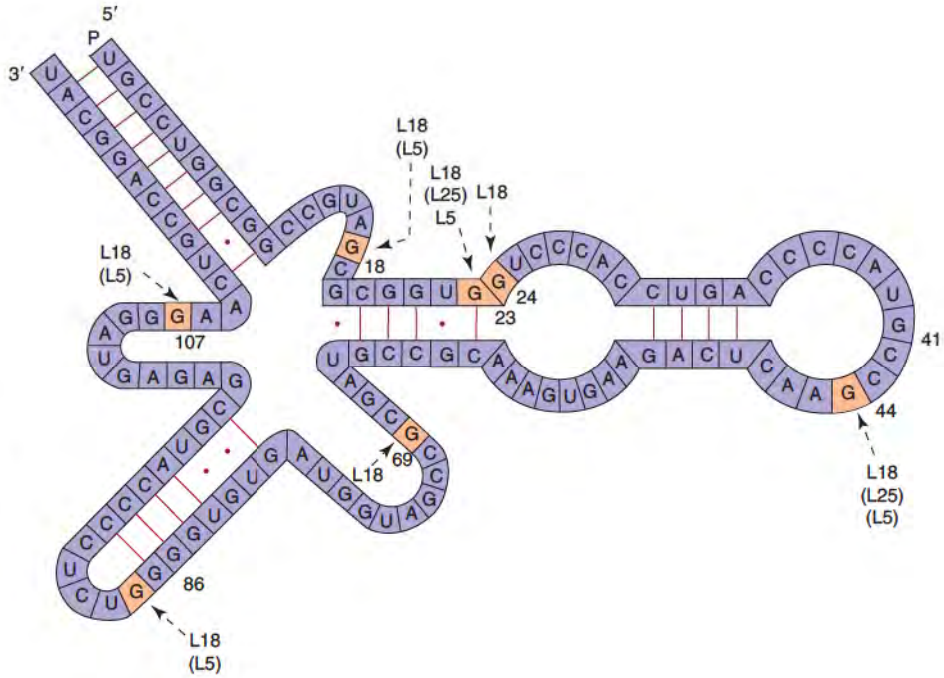

Figure 2.53 Secondary, base-paired, structure proposed for 5S rRNA. Arrows indicate regions protected by proteins in the large ribosomal subunit.
Combined information from Fox, G. E., and Woese, C. R. *Nature* (London) 256:505, 1975, and Gray, P.N., Bellemare, G., Monier, R., Garrett, R. A., and Stoffler, G. *J. Mol. Biol.* 77:133, 1973.

the larger 50S subunit contains one copy each of 5S and 23S rRNAs and 34 proteins (see p. 217 for a discussion of the structure of ribosomes).

rRNA accounts for 80% of cellular RNA and is metabolically stable. This stability is required for repeated functioning of the ribosome and is enhanced by association with ribosomal proteins. Eukaryotic 28S (4718 nucleotides), 18S (1874 nucleotides), and 5.8S (160 nucleotides) rRNAs are synthesized in the nucleolus. The 5S rRNA (120 nucleotides) is not transcribed in the nucleolus but rather from separate genes within the nucleoplasm (Figure 2.53). The three larger rRNAs are synthesized as part of one long polynucleotide chain that is then processed to yield the individual molecules.

Nucleotide modifications in rRNA are primarily methylations to form 2′-*O*-methylribose. Methylation of rRNA has been directly related to bacterial antibiotic resistance in a pathogenic species (Clin. Corr. 2.9). A small number of N^6-dimethyladenines is present in 18S rRNA. The 28S rRNA has about 45 methyl groups and the 18S rRNA has 30 methyl groups.

CLINICAL CORRELATION 2.9

Staphylococcal Resistance to Erythromycin

Bacteria exposed to antibiotics in clinical or agricultural settings often develop resistance to the drugs. This resistance can arise from a mutation in the target cell's DNA, which gives rise to resistant descendants. An alternative and clinically more serious mode of resistance arises when plasmids coding for antibiotic resistance proliferate through the bacterial population. These plasmids may carry multiple resistance determinants and render several antibiotics useless at the same time.

Erythromycin inhibits protein synthesis by binding to the large ribosomal subunit. *Staphylococcus aureus* can become resistant to erythromycin and similar antibiotics as a result of a plasmid-borne RNA methylase that converts a single adenosine in 23S rRNA to N^6-dimethyladenosine. Since the same ribosomal site binds lincomycin and clindamycin, the plasmid causes cross-resistance to these antibiotics as well. Synthesis of the methylase is induced by erythromycin.

A microorganism that produces an antibiotic must also be immune to it, or else it would be killed by its own toxic product. The producer of erythromycin, *Streptomyces erythraeus*, itself possesses an rRNA methylase that acts at the same ribosomal site as the one from *S. aureus*. Which came first? It is likely that many of the resistance genes in target organisms evolved from those of producer organisms. In several cases, DNA sequences from resistance genes of the same specificity have been conserved in producer and target organisms. We may therefore look on plasmid-borne antibiotic resistance as a case of "natural genetic engineering" whereby DNA from one organism (e.g., *Streptomyces* producer) is appropriated and expressed in another (e.g., the *Staphylococcus* target).

Cundliffe, E. How antibiotic-producing microorganisms avoid suicide. *Annu. Rev. Microbiol.* 43:207, 1989.

Ribosomal RNA is the catalytic component of the ribosome. The X-ray crystal structure of the large subunit of a bacterial ribosome species shows that the active site for peptide bond synthesis is composed of 23S RNA only; any potential catalytic amino acid side chains are too far away to participate directly in the reaction. The chemical reactions necessary for peptide bond synthesis are catalyzed by the large subunit rRNA (see p. 68 for a discussion of catalytic RNAs).

Messenger RNAs Carry the Information for the Primary Structure of Proteins

mRNAs are the direct carriers of genetic information from genome to ribosomes. Each eukaryotic mRNA is **monocistronic,** that is, contains information for only one polypeptide chain. In prokaryotes, mRNA species are often **polycistronic,** encoding more than one protein. A cell's phenotype and functional state are related directly to its mRNA content.

In the cytoplasm, mRNAs have relatively short life spans. Some are synthesized and stored in an inactive or dormant state in the cytoplasm, ready for a quick response when protein synthesis is required. In various animals, immediately on fertilization the egg undergoes rapid protein synthesis in the absence of transcription, indicating that preformed mRNA and ribosomes are present in its cytoplasm.

Eukaryotic mRNAs have unique structural features (Figure 2.54). Because the information within mRNA lies in the linear sequence of the nucleotides, the integrity of this sequence is extremely important. Any loss or change of nucleotides could alter the structure of the protein being translated. Translation of mRNA on the ribosomes must also begin and end at specific sequences. In eukaryotes, a "cap" structure at the 5′-end of an mRNA specifies where translation should begin. The caps of eukaryotic mRNAs contain an inverted phosphodiester bond, a methylated base attached to the mRNA via a 5′,5′-triphosphate diester rather than the usual 3′, 5′-phosphodiester linkage. The cap is attached to the first transcribed nucleotide, usually a 2′-*O*-methylated purine (Figure 2.55). The cap is

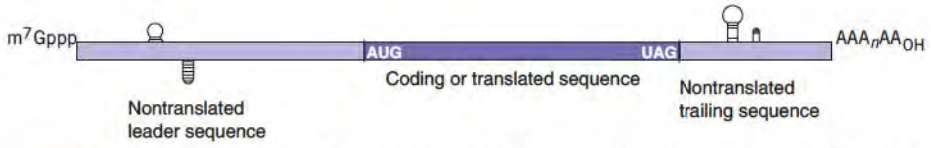

Figure 2.54 General structure for a eukaryotic mRNA. There is a blocked 5′-terminus cap, followed by an untranslated leader containing a promoter sequence. The coding region usually begins with the initiator codon AUG and continues to the translation termination sequence UAG, UAA, or UGA. This is followed by the untranslated trailer and a poly(A) tail on the 3′-end.

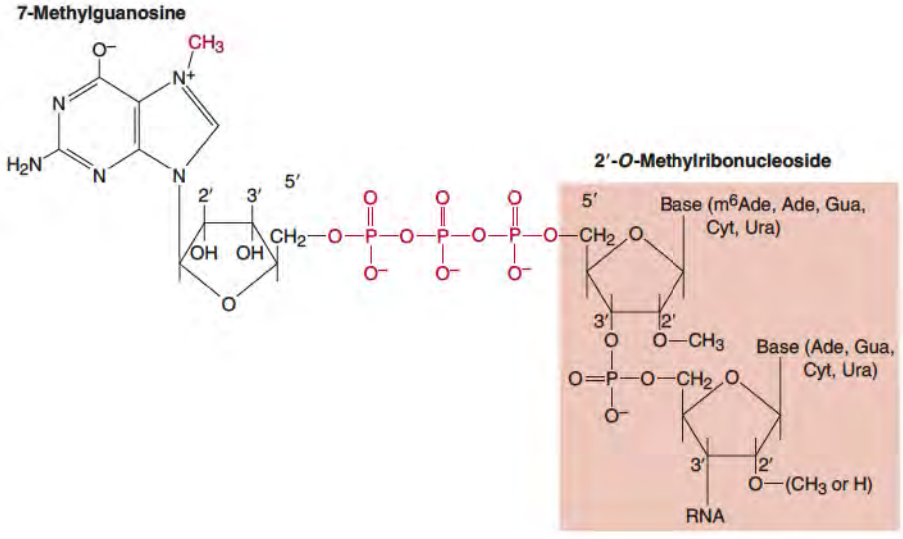

Figure 2.55 Diagram of "cap" structure or blocked 5′-terminus in mRNA. The 7-methylguanosine is inverted to form a 5′-phosphate to 5′-phosphate linkage with the first nucleotide of the mRNA. This nucleotide is often a methylated purine.

followed by an untranslated, or "leader" sequence. Translation starts at the initiation codon, most often AUG, and continues through the coding sequence. At the end of the coding sequence, a termination sequence signals termination of polypeptide formation and release from the ribosome. A second untranslated, or "trailer" sequence follows, terminated by a string of 20–200 adenine nucleotides, called a **poly(A) tail**, which makes up the 3′-terminus of the mRNA.

The 5′-cap has a positive effect on the initiation of message translation. During the initiation of translation of mRNA, the cap structure is recognized by a specific initiation factor (p. 221). The poly(A) sequence affects the stability of the mRNA; degradation of an mRNA generally begins with shortening of its poly(A) tail.

Mitochondria Contain Unique RNA Species

Mitochondria (mt) have their own protein synthesizing apparatus, including ribosomes, tRNAs, and mRNAs. Mitochondrial rRNAs, 12S and 16S, are transcribed from the mitochondrial DNA (**mtDNA**) as are (mtDNA) 22 specific tRNAs and 13 mRNAs, most of which encode proteins of the electron transport chain and ATP synthase. Note that there are fewer mitochondrial tRNAs than prokaryotic or cytosolic tRNA species; there is generally only one mitochondrial tRNA species per amino acid. The mtRNAs account for 4% of the total cellular RNA. They are transcribed by a mitochondrial-specific RNA polymerase and are processed from a pair of RNA precursors that contain tRNA and mRNA sequences. Expression of the nuclear and mitochondrial genomes is tightly coordinated. Most of the amino acylating enzymes for the mitochondrial tRNAs and all of the mitochondrial ribosomal proteins are specified by nuclear genes, translated in the cytosol and transported into mitochondria. The modified bases in mitochondrial tRNA species are synthesized by enzymes encoded in nuclear DNA.

RNA in Ribonucleoprotein Particles

Other small, stable RNA species can be found in the nucleus, cytosol, and mitochondria. These small RNA species function as ribonucleoprotein particles (RNPs), with one or more protein subunits attached. Different RNP species have been implicated in RNA processing, RNA transport, control of translation, and recognition of proteins due to be exported. The actual roles of these species, where known, are described more fully in the discussion of specific metabolic events.

Catalytic RNA: Ribozymes

RNA can be an enzyme. In several cases, the RNA component of a ribonucleoprotein particle is the catalytically active subunit of the enzyme. In other cases, catalytic reactions can be carried out *in vitro* by RNA in the absence of any protein. Enzymes whose RNA subunits carry out catalytic reactions are called ribozymes. There are five classes of ribozymes. Three of these RNA species carry out self-processing reactions while the others, ribonuclease P (RNase P) and rRNA, are true catalysts that act on separate substrates.

In the ciliated protozoan, *Tetrahymena thermophila,* an intron in the rRNA precursor is removed by a multistep reaction (Figure 2.56). A guanine nucleoside or nucleotide reacts with the intron–exon phosphodiester linkage to displace the donor exon from the intron. This reaction, a transesterification, is promoted by the folded intron itself. The free donor exon then similarly attacks the exon–intron phosphodiester bond at the acceptor end of the intron. Introns of this type (Group I introns) have been found in a variety of genes in fungal mitochondria, in bacteria, and the bacteriophage T4. Although these introns are not true enzymes *in vivo* as they only work for one reaction cycle, they can be made to carry out catalytic reactions under specialized conditions.

Group II self-splicing introns are present in the mitochondrial RNA precursors of yeasts and other fungi. Even though these RNAs self-splice, there are many parallels between this reaction and the removal of introns from mRNA precursors during processing.

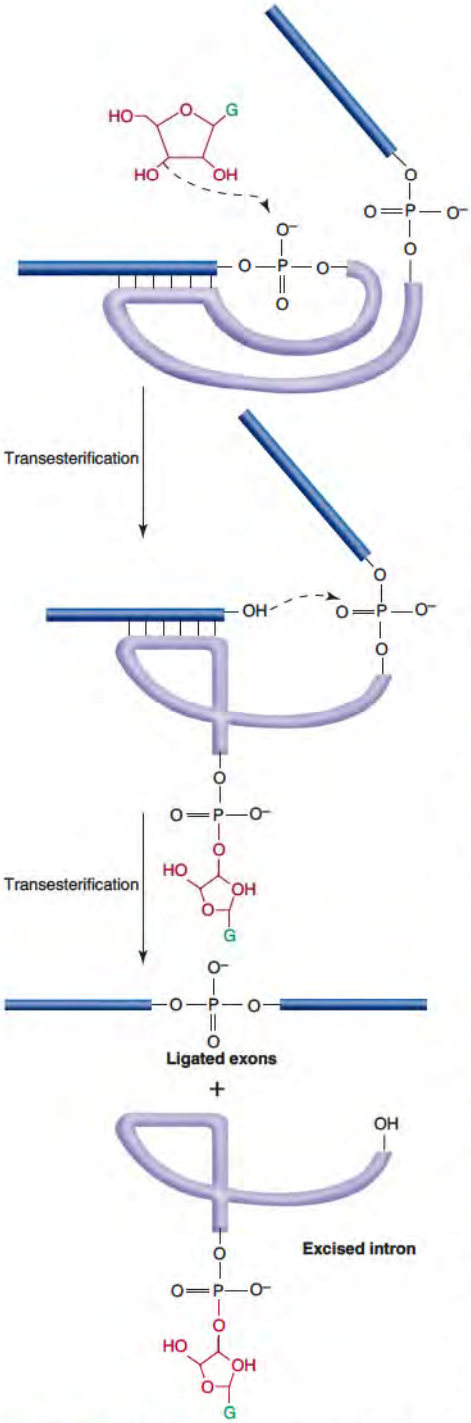

Figure 2.56 Mechanism of self-splicing of the rRNA precursor of Tetrahymena. Two exons of rRNA are denoted by white and shaded boxes, respectively. Catalytic functions reside in the intron, which is black. This splicing function requires an added guanine nucleoside or nucleotide. Reproduced with permission from Cech, T. R. *J. Am. Med. Assoc.* 260:308, 1988.

Group III self-cleaving RNAs are found in the genomic RNAs of several viruses. These RNAs self-cleave during the generation of single genomic RNA molecules from larger precursors. The three-dimensional structure of the hammerhead ribozyme, a member of this third class, has been determined (Figure 2.57). Although the catalytic cycle is not completely determined, the amino group of a cytosine base plays an essential role in the cleavage reaction. The phosphate of the cleaved bond is left at the 3′-hydroxyl position of the RNA product. A self-cleaving RNA found in a small satellite virus, hepatitis delta virus, is implicated in severe human infectious hepatitis. All of the above self-processing RNAs can be made to act as true catalysts (i.e., exhibit multiple turnover) *in vitro* and *in vivo.*

The fourth type of ribozyme, Ribonuclease P, contains both a protein and an RNA component. It acts as a true enzyme in cells, cleaving tRNA precursors to generate the mature 5′-end of tRNA molecules. RNase P recognizes constant structures associated with tRNA precursors (e.g., the acceptor stem and CCA sequence) rather than using extensive base pairing to bind the substrate RNA to the ribozyme. The product of cleavage contains a 5′-phosphate in contrast to the products of hammerhead and similar RNAs. In all of these events, the structure of the catalytic RNA is essential for catalysis.

Finally, the X-ray crystallographic structure of a bacterial ribosome reveals that it, too, is a ribozyme. The active site of the ribosome is on the 50S subunit. There is no protein functional group close enough to catalyze peptide bond formation. Instead, residues within 23S RNA helps transfer a hydrogen ion during peptide bond synthesis.

Discovery of RNA catalysis has greatly altered our concepts of biochemical evolution and the range of allowable cellular chemistry. We now recognize that RNA can serve as both a catalyst and a carrier of genetic information. This has raised the possibility that the earliest living organisms were based entirely on RNA and that DNA and proteins evolved later. This model is sometimes called the "RNA world". Secondly, we know that many viruses, including human pathogens, use RNA genetic information; some of these RNAs have been shown to be catalytic. Thus, catalytic RNA presents opportunities for the discovery of RNA-based pharmaceuticals. Thirdly, many of the information-processing events in mRNA splicing require RNA components. These RNAs may also be acting as catalysts.

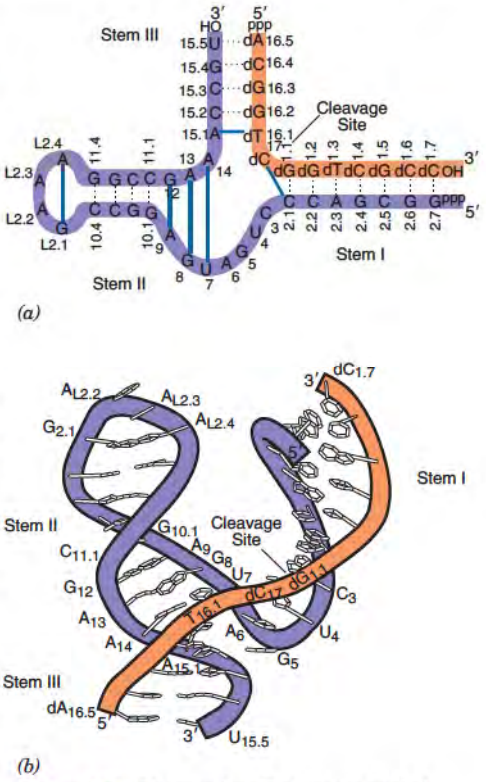

Figure 2.57 "Hammerhead" structure of viral RNA. (*a*) "Hammerhead" structure of a self-cleaving viral RNA. This artificial molecule is formed by the base pairing of two separate RNAs. Cleavage of the RNA sequence at the site indicated by the arrow in the top strand requires its base pairing with the sequence at the bottom of the molecule. The boxed nucleotides are a consensus sequence found in self-cleaving RNA of viral RNAs. (*b*) Three-dimensional folding of the hammerhead catalytic RNA. Star indicates the position of the cleaved bond while M indicates a binding site for a metal ion. Helices II and III stack to form an apparently continuous helix while non-Watson–Crick interactions position the noncomplementary bases in the hammerhead into a "uridine turn" structure identical to that found in tRNA.
(*a*) is redrawn from Sampson, J. R., Sullivan, F. X., Behlen, L. S., DiRenzo, A. B., and Uhlenbeck, O. C. *Cold Spring Harbor Sym. on Quan. Bio.* 52:267, 1987. (*b*) is redrawn from Pley, H. W., Flaherty, K. M., and McKay, D. B. *Nature* 372:68, 1994.

RNAs Can Bind Other Molecules

Consideration of the RNA world has led to a new type of "combinatorial biochemistry" based on the large number of potential sequences (4^N) that could be made if A, C, G, or U were inserted randomly in each of *N* positions in a nucleic acid. A set of chemically synthesized, randomized, nucleic acid molecules 25 nucleotides long would contain $4^{25} = 10^{15}$ potential members. Individual molecules within this large collection of RNAs would be expected to fold into a similarly large collection of shapes. The large number of molecular shapes implies that some member of this collection should be capable of strong, specific binding to ligands, as Group I introns bind guanine nucleotides specifically. These binding RNAs are termed **aptamers.** Though a single molecule would be too rare to study within the original population, the aptamer RNA can be selected and preferentially replicated *in vitro.* For example, an RNA capable of distinguishing theophylline from caffeine was selected from a complex population (Figure 2.58). Theophylline is used in the treatment of chronic asthma, but the level must be carefully controlled to avoid side effects. Monitoring of theophylline concentrations by conventional antibody-based assay is difficult because caffeine and theophylline differ only by a single methyl group. Therefore, anti-theophylline antibodies show considerable cross-reaction with caffeine. RNA aptamers have been found that bind theophylline 10,000-fold more tightly than caffeine. Other extensions of the technology have used selection procedures to identify new, synthetic ribozymes and potential therapeutic RNAs.

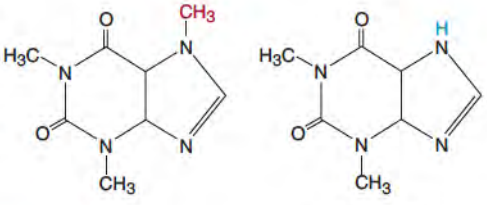

Figure 2.58 Structures of theophylline and caffeine. Although these compounds differ only by a single methyl group, a specific synthetic RNA can bind to theophylline 10,000-fold more tightly than to caffeine.

RNAs Control Translation

Translation of an mRNA requires that it be bound to and move relative to the ribosome. Controlling the efficiency of these processes allows for translational control. One way to do this is through aptamer sites contained in mRNA. Some bacterial mRNAs contain naturally

occurring aptamer sites in the 5′-untranslated region of the mRNA molecule. These sites bind specific ligands such as amino acids, purine bases, glucosamine 6-phosphate, or enzyme cofactors that are products of the pathway whose enzymes are encoded by each mRNA. Binding of the ligand prevents translation of the mRNA, thereby controlling synthesis of the proteins that are responsible for the biosynthetic pathway for the ligand. This is a form of regulation in **cis** because control is exerted on the same molecule that contains the aptamer site.

Double-stranded RNA is a negative regulator of eukaryotic gene expression in **trans**, that is, on another molecule. For example, double-stranded RNA is a necessary intermediate in the replication of some RNA viruses. As a means of defense, the host processes the double-stranded RNA to produce short single-stranded RNAs about 23 nucleotides long. These RNAs, termed **microRNAs (miRNAs)** base-pair to specific mRNAs, and either stop their translation or trigger their degradation (p. 289). Further work on miRNAs and the closely related small inhibitory RNAs (siRNAs) has shown that these species are important regulators of many gene products, including those involved in malignancy (see Clin. Corr. 5.8, p. 203).

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. The best definition of an endonuclease is an enzyme that hydrolyzes a
   A. nucleotide from only the 3′-end of an oligonucleotide.
   B. nucleotide from either terminal of an oligonucleotide.
   C. phosphodiester bond located in the interior of a polynucleotide.
   D. bond only in a specific sequence of nucleotides.
   E. bond that is distal to the base that occupies the 5′ position of the bond.

2. In the structure of a naturally occurring DNA,
   A. circular DNA is formed by linking the 3′-OHs at each end of a linear DNA.
   B. base stacking reduces the hydrophobic surface area that must be solvated by water and stabilizes the double helix.
   C. the two strands may be either parallel or antiparallel.
   D. which tautomeric form the nitrogen and oxygen functions assume is not relevant to their ability to form hydrogen bonds.
   E. interwinding of the two strands produces two helical grooves of nearly identical size.

3. The Z-DNA helix
   A. is the primary form in living organisms.
   B. is favored by an alternating G-C sequence.
   C. tends to be found at the 3′-end of genes.
   D. is inhibited by methylation of the bases.
   E. is a permanent conformation of DNA.

4. A nucleosome
   A. is a regularly repeating structure of DNA and histone proteins.
   B. has a core of DNA with proteins wrapped around the outside.
   C. uses only one type of histone per nucleosome.
   D. is separated from a second nucleosome by nonhistone proteins.
   E. has histones in contact with the major groove of the DNA.

5. RNA
   A. incorporates both modified and unmodified bases during transcription.
   B. does not exhibit any double-helical structure.
   C. structures exhibit base stacking and hydrogen-bonded base pairing.
   D. usually contains about 65–100 nucleotides.
   E. does not exhibit Watson–Crick base pairing.

6. Ribozymes
   A. are any ribonucleoprotein particles.
   B. are enzymes whose catalytic function resides in RNA subunits.
   C. carry out self-processing reactions but cannot be considered true catalysts.
   D. require a protein cofactor to form a peptide bond.
   E. function only in the processing of mRNA.

Questions 7 and 8: Nearly every process in which DNA participates requires that the DNA interact with proteins. Interaction with proteins depends on the local three-dimensional structure of DNA. One antitumor drug, cisplatin, is a tetracoordinate platinum complex. It forms intra-strand cross-links with DNA causing the double helix to strongly bend toward the major groove. Cellular processes such as transcription and programmed cell death are affected.

7. Bent DNA:
   A. occurs only in the presence of external agents like the antitumor drugs.
   B. may be a fundamental element in the interaction between DNA sequences and proteins.
   C. occurs primarily in the presence of triple-stranded DNA.
   D. requires the presence of inverted repeats.
   E. occurs only in DNA that is in the Z form.

8. Another unusual form of DNA is a triple-stranded complex. Triple-stranded DNA
   A. generally occurs in DNA in regions that play no role in transcription.
   B. involves Hoogsteen hydrogen bonding.
   C. is characterized by the presence of a string of alternating purine-pyrimidine bases.
   D. forms only intermolecularly.
   E. assumes a cruciform conformation.

Questions 9 and 10: Since topoisomerases play important roles in many activities of nucleic acid metabolism, they are targets of some antimicrobial and antineoplastic agents. They trap the immediate complex between topoisomerase and DNA, which may result in DNA degradation, introduction of mutations, or inhibition of translation and replication.

9. Topoisomerases
   - **A.** regulate the level of superhelicity of DNA in cells.
   - **B.** always break only one strand of DNA.
   - **C.** can create but not remove supercoils.
   - **D.** must hydrolyze ATP for their action.
   - **E.** of the subclass gyrases, introduce negative superhelices in eukaryotic DNA.

10. In addition to superhelicity, DNA must be still further packaged to fit into the bacteria or cell. Which of the following is correct?
   - **A.** Both prokaryotic and eukaryotic DNA form chromatin.
   - **B.** A bacterial chromosome contains a single DNA molecule, but a human chromosome contains more than one DNA.
   - **C.** Packaging of DNA into nucleosomes does not involve topoisomerases.
   - **D.** Polysomes are the highest level of packaging DNA undergoes.
   - **E.** Thirty-nm fibers (solenoids) can organize into a series of looped, condensed domains.

Questions 11 and 12: Eukaryotic DNA contains many sequences that can be repeated a few times, for certain coding genes, to millions of times, for some relatively short sequences. Abnormal expansion of reiterated three base-pair DNA sequences can lead to a number of diseases. Fragile X syndrome, which causes mental retardation, is characterized by expansion of a GCC triplet near the FMR-1 gene, from a normal 30 copies to thousands of copies. Diseases of this type generally increase in severity with each successive generation. One possible mechanism of expansion involves slippage of DNA during synthesis of the lagging strand.

11. Slipped, mispaired DNA occurs when the DNA region has
   - **A.** direct repeats.
   - **B.** homopurine–homopyrimidine sequences.
   - **C.** inverted repeats.
   - **D.** mirror repeats.
   - **E.** palindromes.

12. Normally, certain kinds of reiterated sequences occur in a chromosome as an interspersion pattern that is
   - **A.** highly repetitive DNA sequences.
   - **B.** the portion of DNA composed of single-copy DNA.
   - **C.** Alu sequences.
   - **D.** alternating blocks of single-copy DNA and moderately repetitive DNA.
   - **E.** alternating blocks of short interspersed repeats and long interspersed repeats.

Problems

13. Which conformation of DNA, totally double helix, minimally unwound or largely unwound, would have the highest relative optical density at 260 nm? Would a molecule of DNA having a higher content of guanine and cytosine than of adenine and thymine have a higher or lower T_m than one with the reverse composition?

14. An approach to reducing telomerase activity in tumor cells involves drugs that bind to G-quadroplex DNA since telomeres have the potential to form such structures. What is a G-quadroplex, and what about telomere structure might lead to it?

Answers

1. **C** Both A and B describe exonucleases. D refers specifically to a restriction endonuclease and is not a definition of the general type. E: Both endo- and exonucleases show specificity toward the bond hydrolyzed.
2. **B** This is a major contributor to the stability of the double helix. A: Joining of nucleotides is always by the 5′-OH of one to the 3′-OH of the other. C: The antiparallel arrangement permits opposing nucleotides to be in the proper position to form hydrogen bonds. D: Each pair in hydrogen bonding must be in the proper tautomeric form so that one is the donor and the other the acceptor. E: The grooves are different with the major groove wider than the minor groove.
3. **B** The alternating purine–pyrimidine sequence is important. A: This is the more flexible B-form. C: It is more likely to be found at the 5′-end, consistent with one of its proposed roles in transcriptional regulation. D: Methylation favors the Z-form in which the methyl is protected from water. E: B-to-Z transition is influenced by such things as methylation.
4. **A** The "beads-on-a-string" structure is called a polynucleosome. B: Histones form the core with DNA on the outside. C: All five types of histones are present, four in the core and one outside. D: The linker regions are DNA. E: Proteins that regulate gene expression and other activities bind to the major groove. Histones bind to the minor groove.
5. **C** Stacking stabilizes the single-strand helix. Folded portions of the structure have hydrogen-bonded base pairing. A: Only the four bases A, G, U, and C are incorporated during transcription. B: Although single stranded, RNA exhibits considerable secondary and tertiary structure. D: Only tRNA would be this small. E: This occurs in the intrachain helical regions.
6. **B** Ribozymes are a very specific type of particle. A: See previous comment. C: One of the four classes, RNase P, catalyzes a cleavage reaction. D: X-ray crystallography has shown there is no amino acid chain sufficiently close to catalyze peptide bond formation. E: Ribozymes have been implicated in the processing of ribosomal and tRNAs.
7. **B** The bent DNA may be a recognition site for specific proteins to bind. A and D: Bent DNA occurs naturally either in runs of 4 to 6 adenosines separated by spacers or is induced by interactions of DNA with certain proteins. C: Bent DNA is double stranded. E: Z-DNA does not have a prominent major groove and the bending is toward the major groove.
8. **B** Hoogsteen bonding in TAT and GGC triplets is responsible for holding the third strand in the major groove. A: They are found frequently in regions involved in gene regulation. C: The required sequence is a homopurine string. D: They can also form intramolecularly by unfolding and refolding of the DNA. E: A cruciform is an alternative conformation of DNA but does not involve a third strand.
9. **A** Topoisomerase I relaxes DNA, and topoisomerase II generates supercoils. B: Topoisomerase I breaks one strand, but topoisomerase II nicks both strands. C: Topoisomerase I removes supercoils. D: Topoisomerase II uses ATP, but Topoisomerase I does not. E: Gyrases are found only in bacteria.
10. **E** These loops are bound to a protein scaffold. A: Chromatin is found in eukaryotes, nucleoids in prokaryotes. B: A human chromosome contains a single DNA. C: There is adding and breaking of supercoils. D: Polysomes organize into 10-nm fibers and then 30-nm fibers, which in turn, further pack.

11. A When DNA unwinds and realigns one copy of a direct repeat on one-strand pairs with an adjacent copy on the other strand. B, C, D, and E: These are other types of structures important in DNA.

12. D A and B: These are two of several kinds of DNA but do not constitute patterns. C and E: Alu is a type of short interspersed repeat. Short and long interspersed repeats are the two classes of moderately repetitive DNA.

13. Unstacked purine and pyrimidine bases have a higher relative optical density than stacked bases so the most unwound form of DNA would have the highest value. T_m is the midpoint of the transition between double-stranded and separated DNA. Higher G-C content means the DNA is more stable so its T_m would be higher.

14. G-quartets contain a planar array of guanines connected by Hoogsteen hydrogen bonds, which can stack on each other to form a multilayered structure. They are stabilized by Na^+ and K^+. Telomeres contain 800–2400 copies of the required G-rich sequence $d(TTAGGG)_n$.

Key Concepts

- Two types of amino acids compose polypeptides: common and derived amino acids. Common amino acids have a central carbon atom to which is attached an amino group, a carboxylic acid group, a hydrogen atom, and a side-chain group.
- Amino acids in polypeptide chains are joined by a peptide bond that connects the α-carboxylic acid group of one amino acid with the α-amino group of a second amino acid.
- Amino acids and proteins have acid-base and related charge properties that determine their biological activity and are used for characterization and purification.
- A protein is defined by its secondary, tertiary, and quaternary structure. α-Helical and β-structures are common stable secondary structures found in folded proteins.
- Globular proteins domains are formed from structural motifs and characteristic folds.
- Proteins in cells are present in complexes that are organized in networks and participate in interactomes.
- Some proteins are intrinsically unstructured, which is required for their biological functions.
- Nonglobular proteins include fibrous proteins such as collagen with characteristic repeating amino acid sequence and unusual helix and rod-shaped geometry.
- A protein folds to its conformation of lowest Gibbs free energy, within kinetic constraints, under the control of noncovalent forces.
- Folded protein structures are dynamic with atoms fluctuating and rotating around an average position.
- Proteins are purified and characterized by techniques that utilize charge and molecular weight. Protein structure is characterized by spectral, optical, and X-ray diffraction techniques.
- Proteomic techniques determine the expression of thousands of proteins within a cell or tissue in a single assay.

3.1 • FUNCTIONAL ROLES OF PROTEINS IN HUMANS

Proteins perform a surprising variety of essential dynamic and structural functions in mammalian organisms. Dynamic functions include catalysis of chemical transformations, transport, metabolic control, and contraction. In their structural roles, proteins provide the matrix for bone and connective tissue, giving structure and form to the human organism. The approximately 25,000 human genes through alternate splicing of RNA and post-translational modifications of translated proteins produce an estimated 1 million unique proteins. The number of proteins simultaneously expressed in a single human cell ranges between 20,000 and 50,000.

Enzymes are proteins that catalyze chemical reactions. Almost all of the thousands of chemical reactions in living organisms require a specific enzyme catalyst to ensure that these reactions occur at a rate compatible with life. The character of any cell is based on its particular chemistry, which is determined by its specific enzyme composition that establishes the cellular phenotype. Many genetic diseases result from altered levels of enzyme production or from specific alterations to their amino acid sequence. Approximately one-third of human genes code for enzyme proteins.

Transport is another major function of proteins. Examples discussed in detail in this text are hemoglobin and myoglobin, which transport oxygen in blood and store it in muscle, respectively. Proteins bind and carry lipids, metabolites, steroid hormones, vitamins, signaling molecules, and minerals in blood from their sites of synthesis or entry to their sites of action or elimination. Many drugs and toxic compounds are transported bound to proteins. Other proteins act intracellularly to transport compounds as well as other proteins to their sites of action. Proteins act to transmit compounds and signals across the plasma membrane of cells and organelle membranes. Proteins also participate in contractile mechanisms. Myosin and actin function in muscle contraction and are responsible for changes in cell shape.

Proteins with a protective role include immunoglobulins, complement proteins, and interferon that protect against bacterial or viral infection. The proteins of coagulation stop the loss of blood on injury to the vascular system.

Many hormones are proteins or peptides. Insulin, thyrotropin, somatotropin (growth hormone), prolactin, luteinizing hormone, and follicle-stimulating hormone are proteins. Many polypeptide hormones have a low molecular weight (<5 kDa) and are referred to as peptides. In general, the term **protein** is used for molecules that contain over 50 amino acids and **peptide** is used for those which contain less than 50 amino acids. Important peptide hormones include adrenocorticotropic hormone, antidiuretic hormone, glucagon, and calcitonin.

Proteins control and regulate gene transcription and translation. These include the histone proteins that are closely associated with DNA, repressor and enhancer transcription factors that control gene transcription, proteins that regulate DNA structure to promote or inhibit gene expressions, proteins that transcribe the DNA into RNA, and components of the heteronuclear RNA particles and ribosomes.

Structural proteins function in "brick-and-mortar" roles. They include collagen and elastin, which form the matrix of bone and ligaments and provide structural strength and elasticity to organs and the vascular system. Tubulin and actin are proteins that polymerize into fibers of microtubules and filaments that form the cytoskeleton of each cell.

An understanding of normal functioning and pathology of the mammalian organism requires a clear understanding of the properties of proteins.

3.2 • AMINO ACID COMPOSITION OF PROTEINS

All the different types of proteins are polymers of only 21 amino acids. The **common amino acids** are defined as the amino acids for which at least one codon exists in the genetic code. Transcription and translation of the DNA code result in the join-

ing together of amino acids into a specific linear sequence characteristic of a protein (Figure 3.1). Many proteins also contain **derived amino acids**, which are usually formed by enzymatic modification of one of the common amino acids after it has been incorporated into a protein. Examples of derived amino acids are cystine (p. 79), desmosine, and isodesmosine found in elastin, hydroxyproline and hydroxylysine in collagen, γ-carboxyglutamate in prothrombin, and phosphoserine, phosphothreonine, and phosphotyrosine.

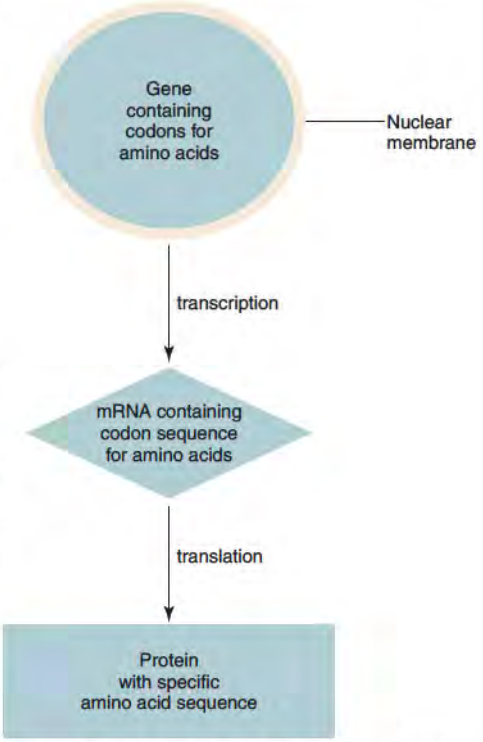

Figure 3.1 Genetic information is transcribed from a DNA sequence into mRNA and then translated to the amino acid sequence of a protein.

Common Amino Acids

Common amino acids have the general structure depicted in Figure 3.2. They contain in common a central alpha (α)-carbon atom to which a carboxylic acid group, an amino group, and a hydrogen atom are covalently bonded. In addition, the fourth valency of the α-carbon atom is linked to a specific chemical group, designated R and called the side chain that uniquely defines each of the common amino acids. Figure 3.2 depicts the ionized form of the common amino acids in solution at pH 7. Under physiological conditions, the α-amino group is protonated and in its ammonium ion form; the carboxylic acid group is in its unprotonated or carboxylate ion form.

Side Chains Define the Chemical Nature and Structures of α-Amino Acids

Structures of the common amino acids are shown in Figure 3.3. Amino acids that contain alkyl group side chains include glycine, alanine, valine, leucine, and isoleucine. **Glycine** has the simplest structure, with R = H. **Alanine** contains a methyl (CH_3—) group. **Valine** has an isopropyl R group (Figure 3.4, p. 79). The leucine and isoleucine R groups are isobutyl groups that are structural isomers of each other. In **leucine** the branching of the isobutyl side chain occurs on the gamma (γ)-carbon and in **isoleucine** it is branched on the beta (β)-carbon (Figure 3.4).

Phenylalanine, tyrosine, and tryptophan are aromatic amino acids. **Phenylalanine** contains a benzene ring, **tyrosine** a phenol group, and **tryptophan** the heterocyclic structure, indole. In each case the aromatic moiety is attached to the α-carbon through a methylene (—CH_2—) carbon (Figure 3.3).

Sulfur-containing amino acids are cysteine and methionine. The **cysteine** side-chain group is a thiolmethyl ($HSCH_2$—), and in **methionine** the side chain is a methyl ethyl thiol ether ($CH_3SCH_2CH_2$—).

The two hydroxy (alcohol)-containing amino acids are serine and threonine. In **serine** the side chain is a hydroxymethyl ($HOCH_2$—). In **threonine** an ethanol structure is connected to the α-carbon to produce a secondary alcohol (CH_3—CHOH—CH_α—).

Proline is unique in that it incorporates the α-amino group in its side chain and is more accurately classified as an α-imino acid, since its α-amine is a secondary amine with its α-nitrogen having two covalent bonds to carbon. Incorporation of the α-amino nitrogen into a five-member ring constrains the rotational freedom around the —N_α—C_α— bond in proline and thereby limits proline participation to particular polypeptide chain conformations.

The amino acids described so far contain side chains that are uncharged at physiological pH. The **dicarboxylic-monoamino acids** contain a carboxylic group in their side chain. In **aspartate**, this group is separated by a methylene carbon (—CH_2—) from the α-carbon (Figure 3.5, p. 79). In **glutamate** (Figure 3.5), the group is separated by two methy-lene (—CH_2—CH_2—) carbon atoms from the α-carbon (Figure 3.5). At physiological pH, these groups are unprotonated and negatively charged. The **dibasic-monocarboxylic** acids are lysine, arginine, and histidine (Figure 3.3). In these, the R group contains one or two nitrogen atoms that act as a base by binding a proton. In **lysine** the side chain is an *N*-butyl amine. In **arginine**, the side chain contains a guanidino group (Figure 3.6, p. 79) separated from the α-carbon by three methylene carbon atoms. Both the guanidino group of arginine and the ε-amino group of lysine are protonated at physiological pH (pH ~7) and positively charged. In **histidine** the side chain contains a five-member heterocyclic structure, the imidazole group

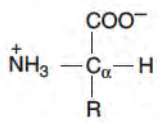

Figure 3.2 General structure of the common amino acids.

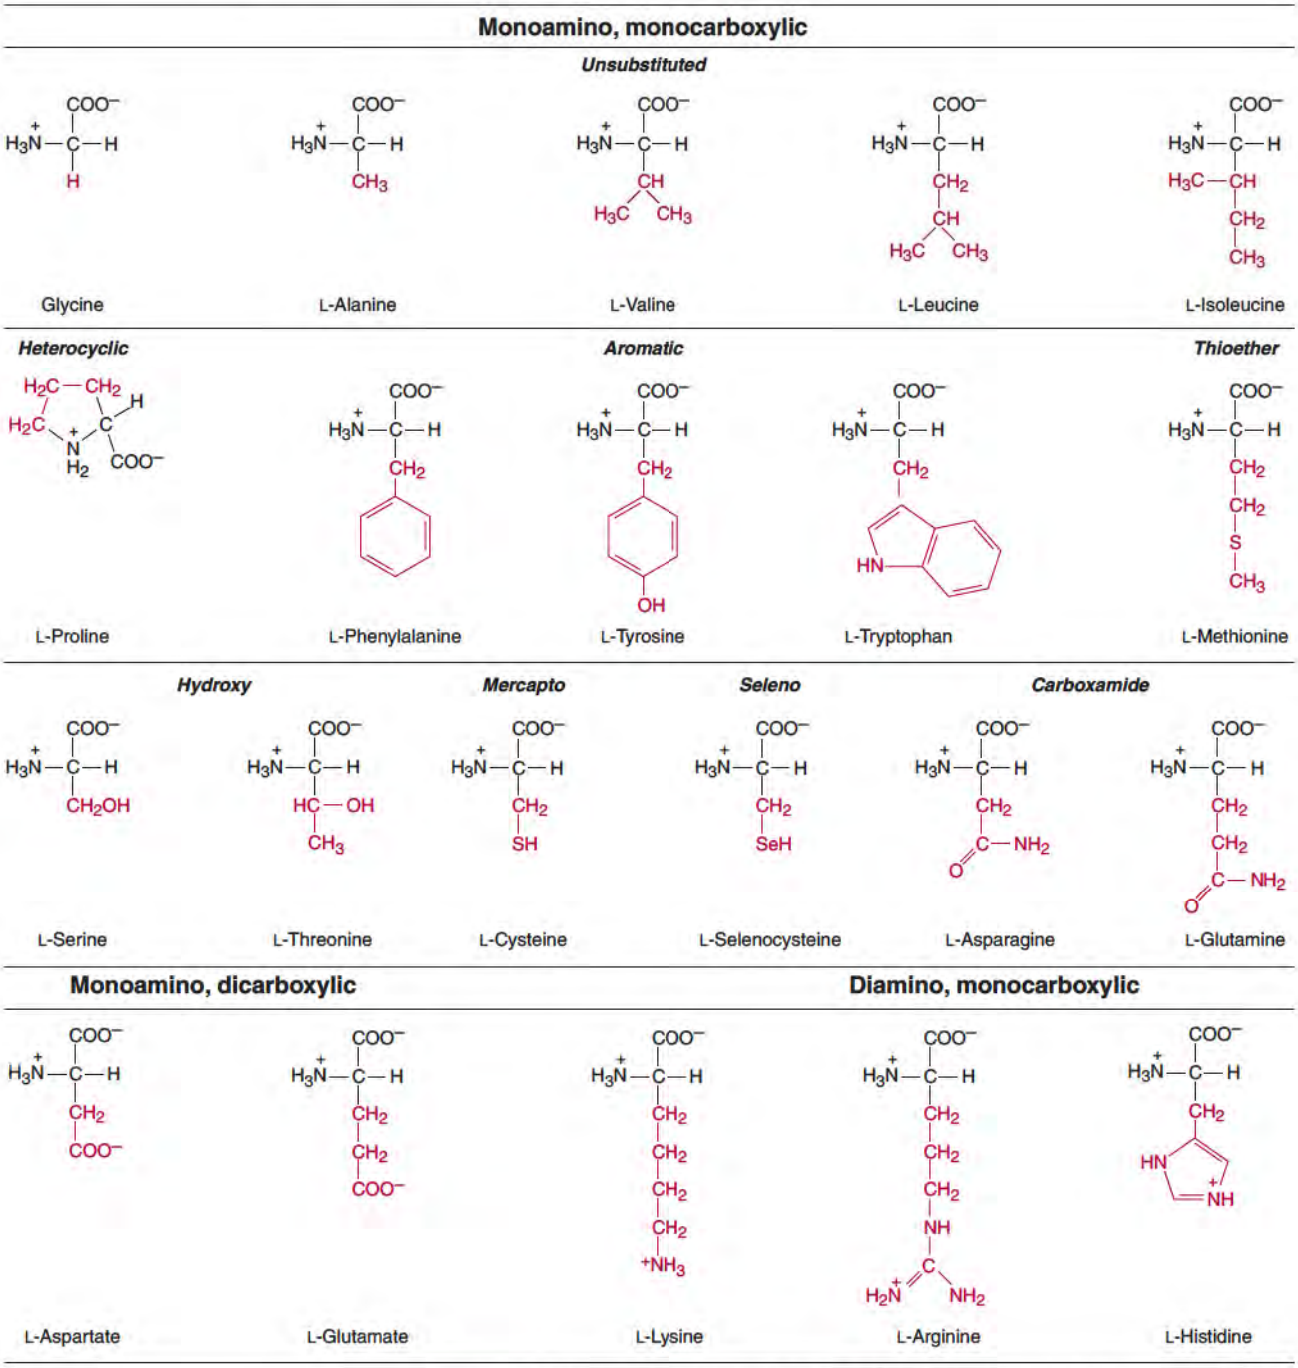

Figure 3.3 Structures of the common amino acids. Charge forms are those present at pH 7.0.

(Figure 3.6). The p$K'a$ of the imidazole group is approximately 6.0 in water; thus physiological solutions contain relatively high concentrations of both basic (imidazole) and acidic (imidazolium) forms of the histidine side chain.

Glutamine and **asparagine** are structural analogs of glutamic acid and aspartic acid with their carboxylic acid side-chain groups amidated. Unique DNA codons exist for glutamine and asparagine separate from those for glutamic acid and aspartic acid. The amide side chains of glutamine and asparagine cannot be protonated and are uncharged at physiological pH.

By the mid-1960s it was believed that the three-nucleotide DNA codons specifying the common amino acids found in proteins had been determined. The total number of common

amino acids was 20 derived from 64 possible triplet codons with 3 codons assigned to terminate the translation of open reading frames (Table 6.1, p. 211). However, in 1988 a 21st common amino acid, **selenocysteine** (Figure 3.3), with a specific mRNA codon and tRNA that places the selenocysteine into polypeptide chains during mRNA translation was shown. The selenocysteine is structurally similar to cysteine, but with a selenium atom replacing the sulfur atom. A difficulty with the codon for selenocysteine is that it was identical to one of the termination codons that translates to a stop translation signal. Thus this codon, UGA, has two meanings. The codon codes a stop translation signal the great majority of the time, but within special RNA contexts it will code for selenocysteine incorporation into a polypeptide sequence. These instances are rare as only 25 genes have been identified within the human genome that code for proteins that incorporate selenocysteine. In addition, while selenocysteine proteins are found in all animals, the codon is not universal as it is not present in higher plants, yeast, or the majority of bacteria. In animal studies, knockout of the gene for the selenocysteine tRNA is lethal, inferring that selenocysteine is essential for life in animal species. Many of the selenoproteins have an antioxidant role in eliminating reactive oxygen species.

To represent sequences of amino acids in proteins, three-letter or one-letter abbreviations for the common amino acids are used (Table 3.1). These abbreviations are universally accepted and will be used throughout this book. The three-letter abbreviations of aspartic acid (Asp) and glutamic acid (Glu) should not be confused with those for asparagine (Asn) and glutamine (Gln). In determination of the amino acid composition of a protein by chemical procedures, one cannot easily differentiate between Asn and Asp, or between Gln and Glu, because the amide side-chain groups in Asn and Gln are often hydrolyzed in the procedure and generate Asp and Glu (Section 3.9). The symbols of Asx for Asp or Asn, and Glx for Glu or Gln indicate this ambiguity in the analysis. A similar scheme is used with the one-letter abbreviations for Asp or Asn, and Glu or Gln.

Cystine Is a Derived Amino Acid Produced by Oxidation of Two Cysteine Residues

A derived amino acid found in many proteins is cystine. It is formed by the oxidation of two cysteine thiol side chains to form a covalent disulfide bond (Figure 3.7). Within proteins, disulfide links of cystine formed from cysteine residues, separated from each other within a polypeptide chain (intrachain) or between two polypeptide chains (interchain), have an important role in stabilizing the folded conformation of proteins (insulin structure; see Figure 3.23, p. 91).

TABLE 3.1 • Abbreviations for the Amino Acids

	Abbreviation	
Amino Acid	*Three Letter*	*One Letter*
Alanine	Ala	A
Arginine	Arg	R
Asparagine	Asn	N
Aspartate	Asp	D
Asparagine or aspartate	Asx	B
Cysteine	Cys	C
Glycine	Gly	G
Glutamine	Gln	Q
Glutamate	Glu	E
Glutamine or glutamate	Glx	Z
Histidine	His	H

α-Amino Acids Have an Asymmetric Center

The common amino acids (see Figure 3.2) have four substituents (R, H, COO^-, and NH_3^+) covalently bonded to an α-carbon atom. A carbon atom with four different substituents in a tetrahedral configuration is asymmetric and exists in two enantiomeric forms. Thus, all amino acids exhibit optical isomerism except glycine, in which R = H and so two of the four substituents on the α-carbon atom are hydrogen. The absolute configuration for an amino acid is depicted in Figure 3.8 using the Fischer projection to show the position in space of the tetrahedrally arranged α-carbon substituents. The α-COO^- group is directed up and behind the plane of the page, and the R group is directed down and behind the plane of the page. The α-H and α-NH_3^+ groups are directed toward the reader. An amino acid held in this way projects its α-NH_3^+ group to either the left or right of the α-carbon atom. By convention, if the α-NH_3^+ is projected to the left, the amino acid has an L absolute configuration. Its enantiomer, with α-NH_3^+ projected toward the right, has a D absolute configuration. Mammalian proteins contain amino acids of only L configuration. The L and D designations refer to the ability to rotate polarized light to the left (L, levo) or right (D, dextro) from its plane of polarization. As the amino acids in proteins are asymmetric, the proteins also exhibit asymmetric properties.

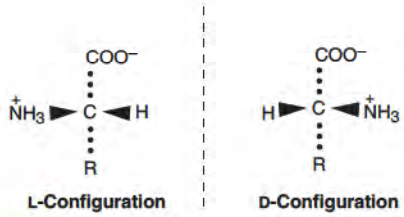

Figure 3.8 **Absolute configuration of an amino acid.**

Amino Acids Are Joined into Peptides and Proteins

Linking of a selection of the common amino acids into polypeptide chains in cells is enzymatically catalyzed (p. 221). Chemically, this is a dehydration reaction (Figure 3.9). The α-carboxyl group of one amino acid forms a covalent **peptide bond** with the α-amino group of another amino acid by elimination of a molecule of water. The **dipeptide** (two amino acid residues joined by a single peptide bond) can then form a second peptide bond through its terminal carboxylic acid group and the α-amino of a third amino acid, to generate a tripeptide (Figure 3.9). Repetition of this process generates a **polypeptide** or protein of specific amino acid sequence. This is the **primary structure** of the protein, and it is predetermined by the nucleotide sequence of its gene. The unique primary structure enables a polypeptide chain to fold into a specific three-dimensional structure that gives the protein its chemical and physiological properties.

A peptide bond can be represented as two **resonance isomers** (Figure 3.10). In structure I, a double bond is located between the carbonyl carbon and carbonyl oxygen

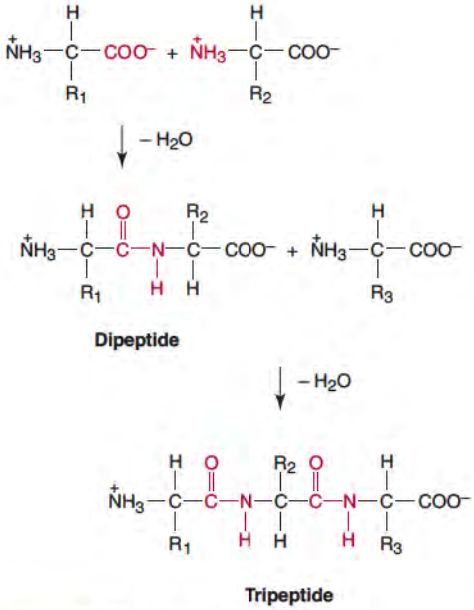

Figure 3.9 **Peptide bond formation.**

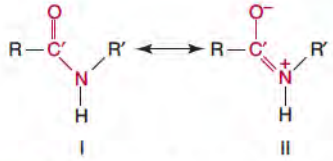

Figure 3.10 **Electronic isomer structures of a peptide bond.**

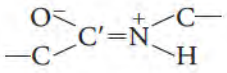
(C′=O), and the carbonyl carbon to nitrogen (C′—N) linkage is a single bond. In structure II, the carbon to oxygen bond (C′—O⁻) is a single bond and the bond located between the carbon and nitrogen is a double bond (C′=N). In structure II there is a negative charge on the oxygen and a positive charge on the nitrogen. Actual peptide bonds are a resonance hybrid of these two electron isomer structures, the carbon to nitrogen bond having a 50% double-bond character. X-ray diffraction studies confirm this and show the carbonyl carbon to nitrogen bond length (1.33 Å) is approximately half way between that of a C′—N single bond (~1.45 Å) and a C′=N double bond (~1.25 Å).

A consequence of the partial double bond character is that rotation does not occur about the carbonyl carbon to nitrogen of a peptide bond at physiological temperatures. A second consequence of the double bond character is that all the atoms attached to C′ and N lie in a common plane.



Thus a polypeptide chain consists of peptide-bond planes interconnected at the α-carbon atoms. The α-carbon interconnects the peptide bonds through single bonds that allow rotation of adjacent peptide planes with respect to each other. Each **amino acid residue** contributes one α-carbon, two single bonds, and a peptide bond to the polypeptide chain (Figure 3.11). The term *residue* refers to the atoms contributed by an amino acid to a polypeptide chain including those of the side chain.

The peptide bond in Figure 3.12*a* shows a ***trans* configuration** of its oxygen (O) and hydrogen (H) atoms. This is the most stable configuration with the two side chains of the adjacent residues (R and R′) also being in *trans*. The ***cis* configuration** (Figure 3.12*b*) brings the two side-chain groups to the same side of the C′=N bond, which is unfavorable because of steric hindrance between the R groups. Accordingly, *trans* peptide bonds occur in proteins except where there are proline residues. In proline the side chain includes the α-amino group, and both the *cis* and *trans* peptide bond configurations with the proline α-imino group have unfavorable interactions with the α-carbon of the adjacent amino acid forming a peptide bond with the α-imino. Accordingly, the peptide bond of proline in an unstructured or denatured polypeptide chain will have significant amounts of its peptide bond in both *trans* and *cis* configurations. The configuration of the proline peptide bond in a folded protein depends on the forces on the proline bond generated by the three-dimensional structure of the particular protein molecule in which the proline is imbedded.

One of the largest polypeptides in humans is the muscle protein titin, which contains about 27,000 amino acid residues in a single polypeptide chain. Chain length alone, however, does not determine the function of a polypeptide. Many small peptides of less than 10 amino acids perform important biochemical and physiological functions in humans (Table 3.2). Primary structures are written in a standard convention and sequentially numbered from their NH_2-terminal end to their COOH-terminal end, consistent with the order of addition of the amino acid to the chain during biosynthesis. Accordingly, for thyrotropin-releasing hormone (Table 3.2) the glutamic acid residue on the left is the NH_2-terminal amino acid of the tripeptide and amino acid residue 1 in the sequence. The proline is the COOH-terminal amino acid and is residue 3. The defined direction of the polypeptide chain is from Glu to Pro (NH_2-terminal amino acid to COOH-terminal amino acid).

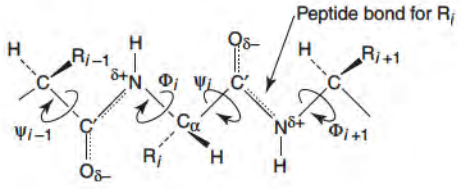

Figure 3.11 Amino acid residue within a polypeptide chain. Each residue of a polypeptide contributes two single bonds and one peptide bond to the chain. The single bonds are those between the C_α and carbonyl C′ atoms, and the C_α and N atoms. (See p. 92 for the definition of φ and ψ.)

TABLE 3.2 • Biologically Active Peptides

Amino Acid Sequence	*Name*	*Function*
1 3 pyroGlu-His-Pro(NH_2)[a]	Thyrotropin-releasing hormone	Secreted by hypothalamus; causes anterior pituitary gland to release thyrotropic hormone
1 9 H-Cys-Tyr-Phe-Gln-Asn-Cys-Pro-Arg-Gly(NH_2)[b,d] S—S	Vasopressin (antidiuretic hormone)	Secreted by posterior pituitary gland; causes kidney to retain water from urine
1 5 H-Tyr-Gly-Gly-Phe-Met-OH	Methionine enkephalin	Opiate-like peptide found in brain that inhibits sense of pain
1 10 pyroGlu-Gly-Pro-Trp-Leu-Glu-Glu-Glu-Glu- 11 17 Ala-Tyr-Gly-Trp-Met-Asp-Phe(NH_2)[c,d] SO_3	Little gastrin (human)	Hormone secreted by mucosal cells in stomach; causes parietal cells of stomach to secrete acid
1 10 H-His-Ser-Gln-Gly-Thr-Phe-Thr-Ser-Asp-Tyr- 11 20 Ser-Lys-Tyr-Leu-Asp-Ser-Arg-Arg-Ala-Gln- 21 29 Asp-Phe-Val-Gln-Trp-Leu-Met-Asn-Thr-OH	Glucagon (bovine)	Pancreatic hormone involved in regulating glucose metabolism
1 8 H-Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-OH	Angiotensin II (horse)	Pressor or hypertensive peptide; also stimulates release of aldosterone from adrenal cortex
1 9 H-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg-OH	Plasma bradykinin (bovine)	Vasodilator peptide
1 10 H-Arg-Pro-Lys-Pro-Gln-Phe-Phe-Gly-Leu-Met(NH_2)[a]	Substance P	Neurotransmitter

[a]The NH_2-terminal Glu is in the pyro form in which its γ-COOH is covalently joined to its α-NH_2 via amide linkage; the COOH-terminal amino acid is amidated and thus also not free.

[b]Cysteine-1 and cysteine-6 are joined to form a disulfide bond structure within the nonapeptide.

[c]The Tyr 12 is sulfonated on its phenolic side-chain OH.

[d]The COOH-terminal amino acid is amidated.

3.3 • CHARGE AND CHEMICAL PROPERTIES OF AMINO ACIDS AND PROTEINS

Ionizable Groups of Amino Acids and Proteins Are Critical for Biological Function

Ionizable groups common to proteins and amino acids are shown in Table 3.3. The acid forms are on the left of the equilibrium sign and the base forms on the right. In forming its conjugate base, the acid form releases a proton. In reverse, the base form associates with a proton to form the respective acid. The dissociation of an acid is characterized by an acid dissociation constant (K'_a) and its pK'_a value: $pK'_a = \log(1/K'_a)$. Table 3.3 shows a range of pK'_a values for each acid group, as the actual pK'_a depends on the environment in which an acid group is placed. For example, when a positively charged ammonium group (—NH_3^+) is placed near a negatively charged group in a protein, the negative charge stabilizes the positively charged acid form, making it more difficult to dissociate its proton. The pK'_a of the —NH_3^+ will have a higher value than normal for an ammonium group in the absence of a nearby negative-charge stabilization. Other factors that affect the pK'_a include polarity of the environment, absence or presence of water, and the potential for hydrogen bond formation. In addition, acid groups (α-COOH or α-NH_3^+) at the ends of polypeptides

TABLE 3.3 • pK'_a Values for the Common Acid Groups in Proteins

Where Acid Group Is Found	*Acid Form*		*Base Form*	*Approximate pK'_a Range for Group*
NH_2-terminal or lysine side chain	$R—NH_3^+$ Ammonium	⇌	$R—NH_2+H^+$ Amine	7.6–10.6
COOH-terminal or glutamate and aspartate side chains	R—COOH Carboxylic acid	⇌	$R—COO^-+H^+$ Carboxylate	3.0–5.5
Arginine side chain	 Guanidinium	⇌	 Guanidino	11.5–12.5
Cysteine side chain	R—SH Thiol	⇌	$R—S^-+H^+$ Thiolate	8.0–9.0
Histidine side chain	 Imidazolium	⇌	 Imidazole	6.0–7.0
Tyrosine side chain	Phenol	⇌	 Phenolate	9.5–10.5

TABLE 3.4 • pK'_a of Side Chain and Terminal Acid Groups in Ribonuclease

	$—NH_3^+$	—COOH
Side chain	Lysines = 10.2	Glu and Asp = 4.6

$$pH = pK_a + \log \frac{[\text{conjugate base}]}{[\text{conjugate acid}]}$$

or

$$pH - pK_a = \log \frac{[\text{conjugate base}]}{[\text{conjugate acid}]}$$

Figure 3.13 Henderson–Hasselbalch equation. (For a more detailed discussion of this equation, see p. 9).

typically have a lower pK'_a value than the same types of acid groups in the side chains (Table 3.4). The amino acids whose R groups contain nitrogen atoms (Lys and Arg) are the **basic amino acids**, since their side chains have relatively high pK'_a values and function as bases at physiological pH. They are usually in their acid form and are positively charged at physiological pH. Amino acids whose side chains contain a carboxylic acid group have relatively low pK'_a values that easily lose their protons and are **acidic amino acids**. They are predominantly in their unprotonated forms and negatively charged at physiological pH. Proteins in which the ratio $(\Sigma Lys + \Sigma Arg)/(\Sigma Glu + \Sigma Asp)$ is greater than 1 are **basic proteins**. Proteins in which the ratio is less than 1 are **acidic proteins**.

Ionic Form of an Amino Acid or Protein Can Be Determined at a Given pH

From the pK'_a value for each acid group in an amino acid or protein and the Henderson–Hasselbalch equation (Figure 3.13), the ionic form of the molecule can be calculated at a given pH. This is an important equation as it shows the change in ionization state and charge of a molecule with pH. Physiological activities of a molecule differ with changes in pH and ionization state. For example, some enzymes require a histidine imidazole in its base form for catalytic activity. If the pK'_a of this histidine is 6.0, at pH 6.0 one-half of the enzyme molecules are in the active base (imidazole) form and one-half of the enzyme molecules are in the inactive acid (imidazolium) form. Accordingly, the enzyme exhibits 50% of its potential activity. At pH 7.0, the ratio of [imidazole]/[imidazolium] is 10:1 (Table 3.5) and the enzyme exhibits $10/(10 + 1) \times 100 = 91\%$ of its maximum potential activity. Thus a change in pH has a dramatic effect on the enzyme's activity.

TABLE 3.5 • Relationship between the Difference of pH and Acid pK'_a and the Ratio of the Concentrations of Base to Its Conjugate Acid

$pH - pK'_a$ (Difference Between pH and pK'_a)	*Ratio of Concentration of Base to Conjugate Acid*
0	1
1	10
2	100
3	1000

−2	0.01
−3	0.001

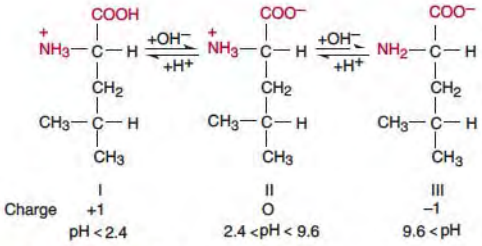

Figure 3.14 **Ionic forms of leucine.**

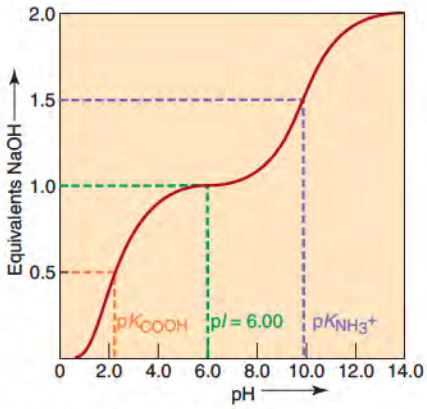

Figure 3.15 **Titration curve of leucine.**

Titration of a Monoamino Monocarboxylic Acid: Determination of the Isoelectric pH

An understanding of a protein's acid and base forms and their relation to charge is made clearer by following the titration of the ionizable groups for a simple amino acid. In Figure 3.14, leucine has an α-COOH with $pK'_a = 2.4$ and an α-NH_3^+ group with $pK'_a = 9.6$. At pH 1.0 the predominant ionic form (form I) has a charge of +1 and migrates toward the cathode in an electrical field. Addition of 0.5 equivalent of base titrates half the α-COOH groups; that is, the ratio of $[COO^-]/[COOH]$ will equal 1. The Henderson–Hasselbalch equation, with the second term on the right side of the equation $\log_{10}[(\text{base})/(\text{acid})] = \log(1) = 0$ at a ratio of conjugate base to acid of 1:1, shows that the pH (when the α-COOH is half titrated) is directly equal to the pK_a (αCOOH) (Figure 3.15).

Addition of 1 equiv of base at pH 6.0 completely titrates the α-COOH, but has no effect on the α-NH_3^+ group. In the resulting form (II), the negative and positive charges cancel each other and the net charge is zero. Form II is the **zwitterion** form, the ionic form in which the total of positive charges equals the total of negative charges. As the net charge on a zwitterion molecule is zero, it will not migrate in an electric field. Further addition of 0.5 equiv of base to the zwitterion form (total base added is 1.5 equiv) will half-titrate the α-NH_3^+ group. At this point, the ratio of $[NH_2]/[NH_3^+] = 1$, and the pH is equal to the value of the pK'_a for the α-NH_3^+ group (Figure 3.15). Addition of a further 0.5 equiv of base (total of two full equivalents of base added; Figure 3.15) completely titrates the α-NH_3^+ group to its base form (α-NH_2). The pH becomes greater than 11, and the predominant molecular species has a negative charge (form III).

It is useful to calculate the pH at which an amino acid is in its zwitterion form. This pH is the **isoelectric pH** for the molecule, represented as **pI**. The pI value is a constant for a compound at a particular ionic strength and temperature. For simple amino acid molecules, such as leucine, pI is calculated as the average of the two pK'_a values that regulate the boundaries of the zwitterion form. For leucine,

$$pI = \frac{pK'_a\text{COOH} + pK'_a\text{NH}_3^+}{2} = \frac{2.4 + 9.6}{2} = 6.0$$

At pH > 6.0, leucine has a partial negative charge that increases at high pH to a full negative charge of –1 (form III) (Figure 3.14). At pH < 6, it has a partial positive charge, until at a very low pH, it has a charge of +1 (form I). The charge at any pH can be calculated from the Henderson–Hasselbalch equation or from extrapolation from the titration curve of Figure 3.15.

Titration of a Monoamino-Dicarboxylic Acid

A more complicated example is provided by glutamic acid. As shown in Figures 3.16 and 3.17, in glutamic acid the α-COOH $pK'_a = 2.2$, the γ-COOH $pK'_a = 4.3$, and the α-NH_3^+ $pK'_a = 9.7$. The zwitterion form is generated after 1.0 equiv of base is added to

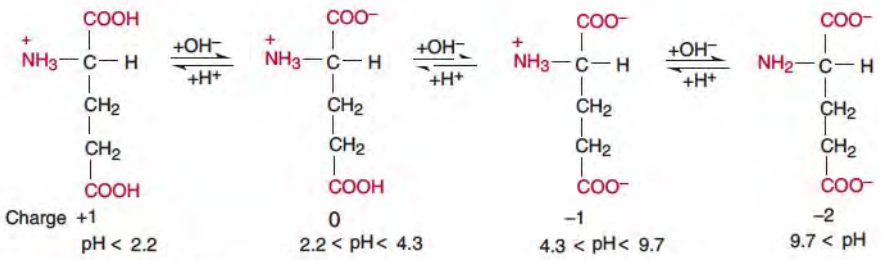

Figure 3.16 **Ionic forms of glutamic acid.**

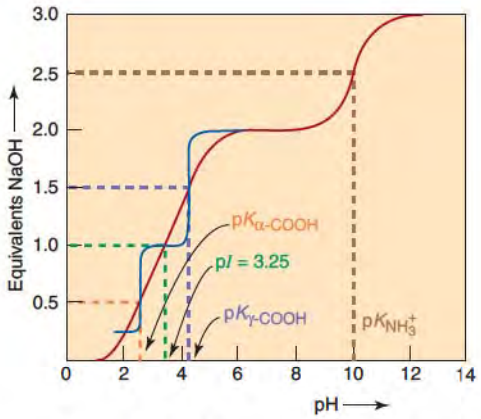

Figure 3.17 Titration curve of glutamic acid. Observed line (red) hides titrations of pK'_γ and pK'_α, which are too close to observe individually. Titrations of these groups are shown in overlapping blue line.

the low pH form, and the isoelectric pH (pI) is calculated from the average of the two pK'_a values that control the boundaries of the zwitterion form.

$$pI = \frac{2.2 + 4.3}{2} = 3.25$$

Accordingly, at values above pH 3.25 the molecule assumes a net negative charge, until at high pH it has a net charge of –2. At pH < 3.25 glutamic acid is positively charged, and at extremely low pH it has a net positive charge of +1.

General Relationship between Charge Properties of Amino Acids and Proteins, and pH

The relationship between pH and charge for leucine and glutamate is generally true for the other amino acids. At a pH less than pI, the molecule is positively charged. At a pH greater than pI, it is negatively charged. The degree of positive or negative charge is a function of the magnitude of the difference between pH and pI. As proteins are complex polyelectrolytes that contain many ionizable groups that regulate the zwitterion form, calculation of a protein's isoelectric pH from its multiple acid pK'_a values utilizing the Henderson–Hasselbalch relationship is difficult. Accordingly, pI values of proteins are experimentally measured by determining the pH value at which the protein does not move in an electric field. pI values for some proteins are given in Table 3.6.

As with amino acids, at a pH greater than its pI, a protein has a net negative charge. At a pH less than its pI, it has a net positive charge (Figure 3.18). The magnitude of the net charge increases as the difference between pH and pI increases. An example is human plasma albumin with 585 amino acid residues including 61 glutamates, 36 aspartates, 57 lysines, 24 arginines, and 16 histidines. The titration curve is shown in Figure 3.19. Albumin's pI = 5.9, at which pH its net charge is zero. At pH 7.5 the imidazolium groups of histidines are partially titrated and there is a negative charge of −10. At pH 8.6 the net charge is approximately −20, and at pH 11 it is approximately −60. At pH 3, the approximate net charge is +60.

TABLE 3.6 • pI Values for Some Proteins

Protein	*pI*
Pepsin	~1
Human serum albumin	5.9
α_1-Lipoprotein	5.5
Fibrinogen	5.8
Hemoglobin A	7.1
Ribonuclease	7.8
Cytochrome c	10.0
Thymohistone	10.6

pH > p*I*, then protein charge negative
pH < p*I*, then protein charge positive

Figure 3.18 Relationship between solution pH, protein pI, and protein charge.

Amino Acids and Proteins Can Be Separated on the Basis of Their Differences in pI

The techniques of electrophoresis, isoelectric focusing, and ion-exchange chromatography separate and characterize biological molecules based on their pI (p. 84). In clinical medicine, electrophoretic separation of **plasma proteins** has led to their

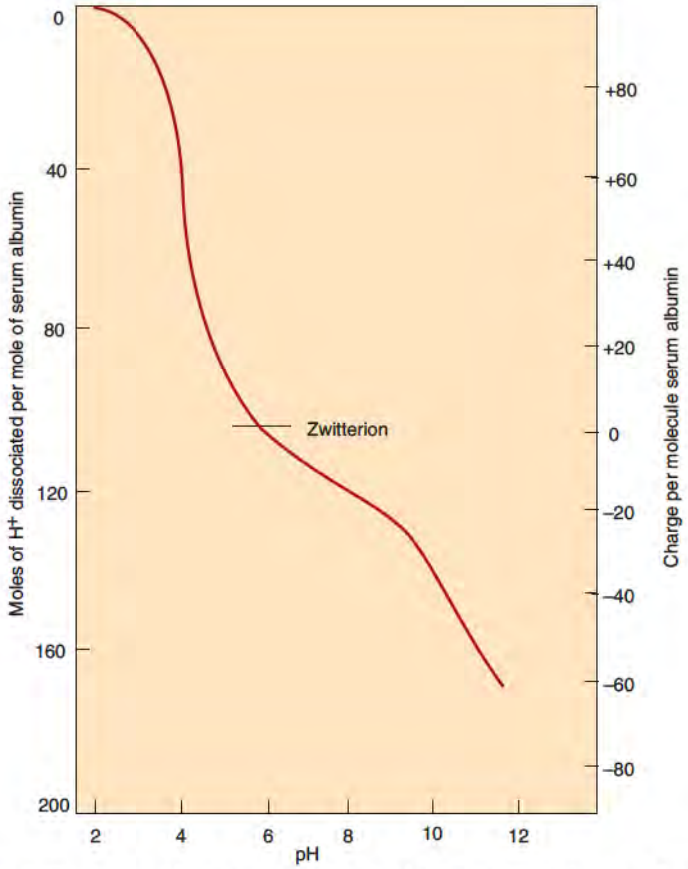

Figure 3.19 Titration curve of human serum albumin at 25 °C and an ionic strength of 0.150. Redrawn from Tanford, C., J. *Am. Chem. Soc.* 72:441, 1950.

classification being based on their relative electrophoretic mobility. The separation of the plasma proteins is commonly carried out at pH 8.6, which is higher than the pI values of the major proteins. Accordingly, the proteins are negatively charged and move toward the anode at a rate dependent on their net charge. Figure 3.20 shows an electrophoresis of plasma proteins in an agarose gel at pH 8.6 that separates the proteins into the five classical bands used to classify the plasma proteins. In order of their migration the major fractions are albumin, α1-, α2-, β-, and γ-globulins (Figure 3.20). Some of these bands actually represent tens to hundreds of different proteins that migrate similarly at pH 8.6. However, certain proteins predominate in each band, and variation in their relative amounts is characteristic of certain diseases (Figures 3.20 and 3.21, and Clin. Corr. 3.1).

Amino Acid Side Chains Have Polar and Apolar Properties

The **hydrophobicity** of amino acid side chains is critical for the folding of a protein to its native structure and for stability of the folded protein. Figure 3.22 (p. 88) plots the relative hydrophobicity of the amino acids on the basis of their tendency to partition in a mixture of water and a nonpolar solvent. The scale is based on a value of zero for glycine. Side chains that preferentially dissolve in the nonpolar solvent relative to glycine show a positive (+) hydrophobicity value, the more positive the greater the preference for the nonpolar solvent. In folded protein structures, the majority of hydrophobic amino acids are buried away from the water solvent that interacts with the surface of a soluble protein. However, the general correlation is not perfect due to the amphoteric nature of many of the hydrophobic amino acids that place the more polar portions of their side-chain structure near the surface to interact with water. In addition, some nonpolar side chains may be on the surface. However, when on the surface, the hydrophobic groups are generally dispersed among the polar side

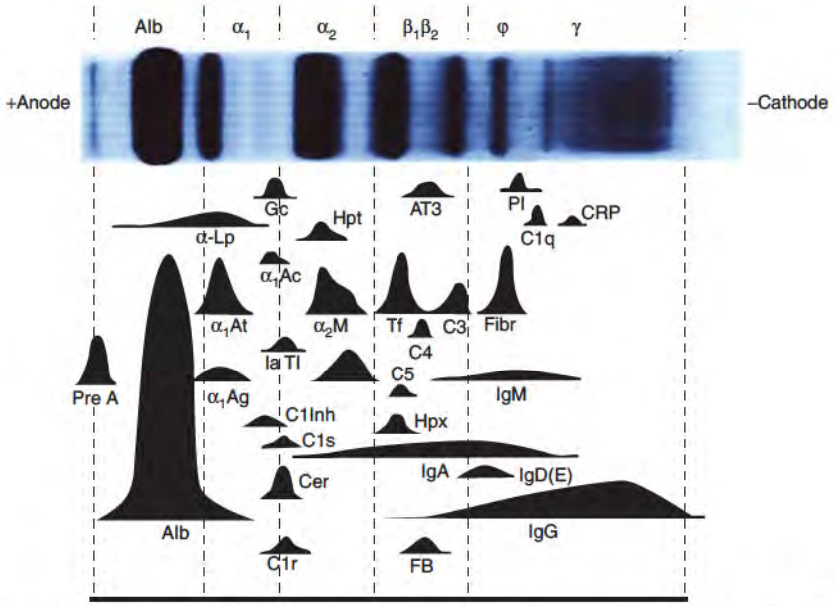

Figure 3.20 Electrophoresis pattern in agarose gel for plasma proteins at pH 8.6. Migration along horizontal axis from right to left (cathode toward anode) with proteins of highest mobility closest to anode. The intensity of the band along the vertical axis shows the protein concentration. Different major proteins are designated underneath their electrophoretic mobility peaks. ϕ Designates the fibrinogen peak, which is present in plasma but absent in serum. In some gels the γ-globin band is separated in γ_1 and γ_2 bands (not shown here).
Major protein peaks contained in the bands on the agarose gel are drawn in this figure. Area of drawn peaks show their relative concentration and position in the gel. Abbreviations: α_1Ac = α_1-antichymotrypsin; α_1Ag = α_1-acid glycoprotein; α_1At = α_1-antitrypsin; α_2-M = α_2-macroglobulin; α-Lp = α-lipoprotein; Alb = albumin; AT3 = antithrombin III; β-Lp = β-lipoprotein; complement components C1q, C1r, C1s, C3, C4, and C5 = as designated; C1Inh = C1 esterase inhibitor; Cer = ceruloplasmin; CRP = C-reactive protein; Gc = Gc-globulin (vitamin D–binding protein); FB = factor B; Fibr = fibrinogen; Hpt = haptoglobin; Hpx = hemopexin; immunoglobulins IgA, IgD, IgE, IgG, and IgM = as designated; IaTI = inter-α-trypsin inhibitor; PI = plasminogen; PreA = prealbumin; and Tf = transferrin.

chains. When clustering of nonpolar side chains occurs on the surface, it is usually associated with a function, such as to provide a site for binding of substrate molecules through hydrophobic interactions.

Most charged side chains are on the surface of soluble globular proteins where they are stabilized by favorable energetic interactions with water. The rare positioning of a charged side chain in the interior usually implies an important functional role for that "buried"

CLINICAL CORRELATION 3.1

Plasma Proteins in Diagnosis of Disease

Electrophoretic analysis of the plasma proteins is commonly used in diagnosis of disease. Electrophoresis of plasma buffered at pH 8.6 separates the major proteins as they migrate to the anode in the electric field into bands or peaks, on the basis of their charge differences (see text). Examples of abnormal electrophoresis patterns are shown in Figure 3.21. An immediate response that occurs with stress or inflammation caused by infection, injury, or surgical trauma is shown in pattern (*b*) in which haptoglobins in the α_2 mobility band are selectively increased. A delayed response shown in pattern (*c*) is associated with infection and shows an increase in the γ-globulin peaks due to an increase in immunoglobulins. An example of a hypo-γ-globulinemia due to an immunosuppressive disease is shown in pattern (*d*). In hepatic cirrhosis there is a broad elevation of the τ-globulins with reduction of albumin, as in pattern (*e*). Monoclonal gammopathies are due to the clonal synthesis of a unique immunoglobulin and give rise to a sharp γ-globulin band, as in pattern (*f*). Nephrotic syndrome shows a selective loss of lower molecular weight proteins from plasma, as in pattern (*g*). The pattern shows a decrease in albumin (65 kDa), but a retention of the bands composed of the large proteins α_2-macroglobulin (725 kDa) and β-lipoproteins (2000 kDa) in the α_2 band. Pattern (*h*) is from a patient with a protein-losing enteropathy, who is losing plasma by exudation in the intestinal tract. The slight increase in the α_2-band in pattern (*h*) is due to an immediate or late response from a stressful stimulus, as previously observed in patterns (*b*) and (*c*).

charge within the nonpolar interior in stabilizing protein conformation or participation in catalysis.

Transmembrane proteins reverse the positioning of their side-chain polarity from that of water-soluble globular proteins. Within the membrane, these proteins often position hydrophobic side chains on the outside and ionic groups on the inside to provide binding interactions and to form ion channels (p. 477).

Amino Acids Undergo a Variety of Chemical Reactions

Amino acids in proteins react with a variety of reagents that may be used to investigate the function of specific side chains. Some common chemical reactions are presented in Table 3.7. Reagents that modify acid side chains have been synthesized to bind to specific sites in a protein's structure, such as the substrate-binding site. The strategy is to model the structural features of the enzyme's natural substrate into the modifying reagent. The reagent binds to the active site like the natural substrate and reacts with a specific side chain. This identifies the modified amino acid as being located in the substrate-binding site and helps identify its role in catalysis.

A CLOSER LOOK 3.1

Proteolytic Cleavage of Proinsulin

Proinsulin is produced in pancreatic islet cells as a single polypeptide chain containing 86 amino acids and 3 intrachain cystine disulfide bonds (Figure 3.23). It is transformed into biologically active insulin by proteolytic cleavage prior to its secretion from islet cells. Proinsulin is cleaved, by proteases present in the islet cells, between residues 30 and 31, and 65 and 66. This releases two molecules, a 35-residue fragment (**C-peptide**) and insulin, which consists of two polypeptide chains (A and B) of 21 amino acids and 30 amino acids, respectively, covalently joined by the same disulfide bonds present in proinsulin. The C-peptide is further processed by proteases that hydrolyze a basic dipeptide from the N- and the C-terminal ends. The modified C-peptide is secreted with insulin.

3.4 • PRIMARY STRUCTURE OF PROTEINS

The **primary structure** of a protein refers to the covalent structure, which includes amino acid sequence and location of disulfide (cystine) bonds. The primary structure of a protein is required to understand its structure and mechanism of action, its biosynthesis including the posttranslational modifications of its structure, and its relationship to other proteins with similar physiological roles. The primary structure of several biologically active peptides was shown in Table 3.2 (p. 82). **Insulin** illustrates how knowledge of the primary structure leads to an understanding of the biosynthesis and the physiological forms of this bioactive hormone (Figure 3.23; A Closer Look 3.1 and Clin. Corr. 21.8). Insulin is initially synthesized as proinsulin, which is a single polypeptide chain of 86 amino acids and three intrachain cystine bonds (Figure 3.23). The hormone form consists of two polypeptide chains (A and B) covalently interconnected by two cystine bonds and chain A containing an intrachain cystine. This is the active insulin primary or covalent structure.

Besides providing information on its biosynthesis, the comparison of the primary structures of insulins from different animal species shows the residues essential and nonessential to its hormonal function. The aligned primary structures have identical residues in most amino acid positions, except for residues 8, 9, and 10 of the A chain and residue 30 of the B chain. Amino acids in these positions vary widely (Table 3.8) and apparently do not affect the biological properties (Clin. Corr. 3.2). Other residues are rarely substituted, suggesting that they have an essential role in function.

Sequence comparisons are commonly used to predict the similarity in structure and function between proteins. These comparisons typically require aligning of sequences to maximize the number of identical residues and minimize the number of insertions or deletions required to achieve this alignment. Two sequences are **homologous** when their sequences are highly alignable. Note that in its correct usage homology refers only to proteins that have evolved from the same gene. **Analogy** describes sequences from proteins that are structurally similar but for which no evolutionary relationship has been demonstrated. Substitution of an amino acid by one of similar polarity (i.e., Val for Ile in position 10 of insulin) is a **conservative** substitution and is commonly observed in sequences of the same protein from different animal species. If a particular amino acid is regularly found at the same position, it is an **invariant residue**. It can be assumed that such residues have an essential role in the structure or function of the protein. A **nonconservative** substitution involves replacement of an amino acid by one of different polarity. This may drastically change the properties of the protein or occur in regions that are apparently unimportant functionally (Clin. Corr. 6.2; p. 214). Polarity is only one physical property of amino acids that determines whether a substitution will significantly alter the protein's function. Other important properties are the molecular volume and surface area of the residue.

TABLE 3.8 • Variation in Positions A8, A9, A10, and B30 of Insulin

Species	*A8*	*A9*	*A10*	*B30*
Human	Thr	Ser	Ile	Thr
Cow	Ala	Ser	Val	Ala
Pig	Thr	Ser	Ile	Ala
Sheep	Ala	Gly	Val	Ala
Horse	Thr	Gly	Ile	Ala
Dog	Thr	Ser	Ile	Ala
Chicken[a]	His	Asn	Thr	Ala
Duck[a]	Glu	Asn	Pro	Thr

[a]Positions 1 and 2 of B chain are both Ala in chicken and duck; whereas in the other species in the table, position 1 is Phe and position 2 is Val in B chain.

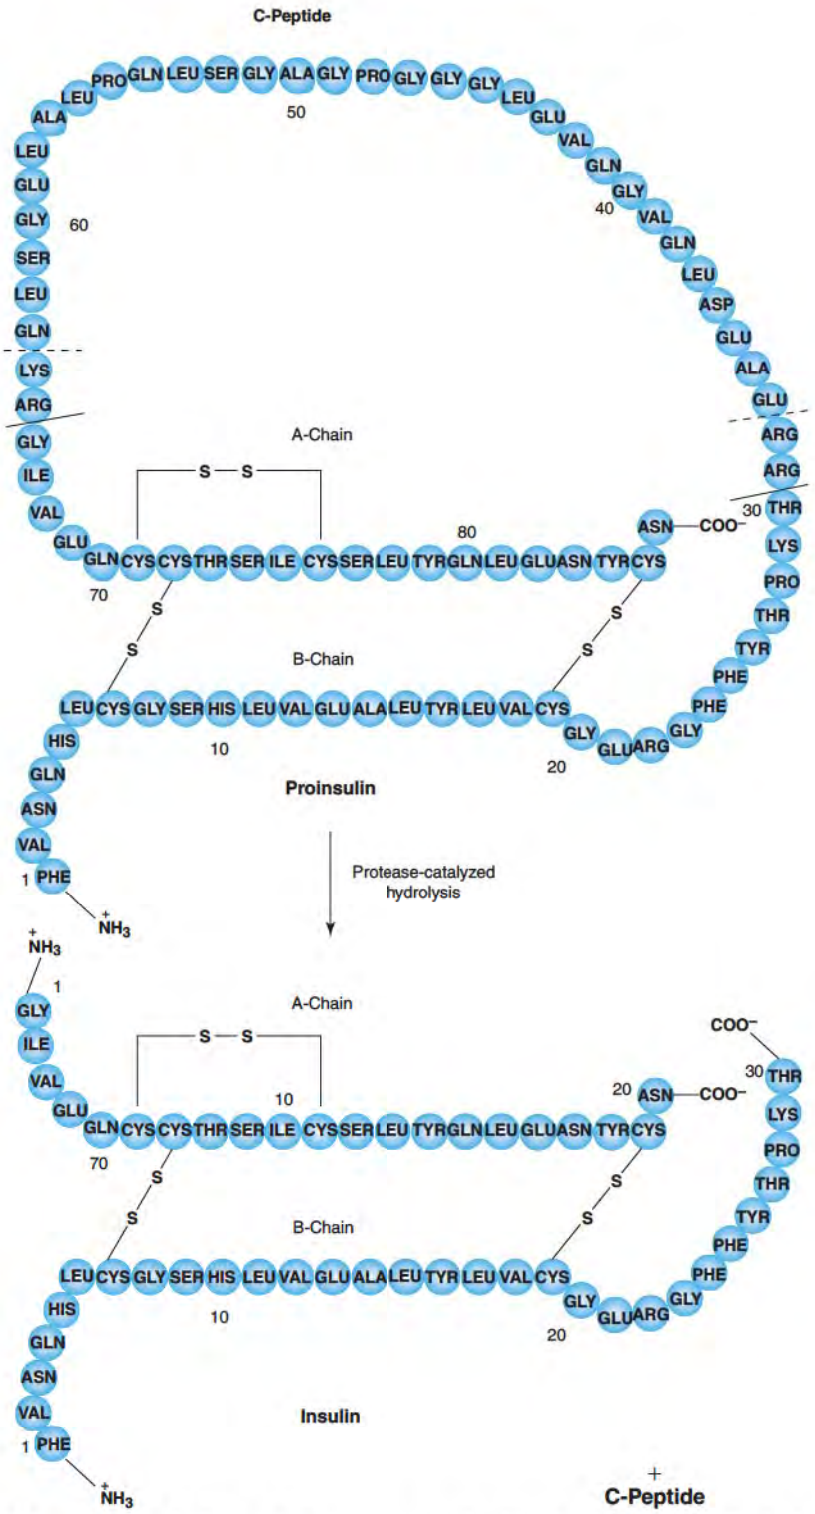

Figure 3.23 Primary structures of human proinsulin, insulin, and C-peptide. In the polypeptide sequence of proinsulin, the incipient B-chain peptide extends from Phe at position 1 to Thr at position 30, the C-peptide from Arg at position 31 to Arg at position 65, and the A-peptide from Gly at position 66 to Asn at position 86. Cystine bonds from positions 7 to 72, 19 to 85, and 71 to 76 are found in proinsulin.

CLINICAL CORRELATION 3.2

Differences in Insulins Used in Treatment of Diabetes Mellitus

Prior to the development of recombinant human insulin, both pig (porcine) and cow (bovine) insulins were used in the treatment of human diabetics. Insulin from animal sources is still used in treatment of diabetes in developing countries. Because of differences in sequence from human insulin, some diabetic individuals will have an initial allergic response to the injected insulin as their immunological system recognizes the insulin as foreign or develop an insulin resistance due to a high anti-insulin antibody titer at a later stage in treatment. However, the frequency of a deleterious immunological response to pig and cow insulins is small; the great majority of the population is able to utilize these insulins without complication. This is due to the small number and the conservative nature of the changes between the amino acid sequences and the fact that they do not significantly change the three-dimensional structure of the insulin relative to that of human insulin. Pig insulin is usually more acceptable than cow insulin in insulin-reactive individuals because it is more similar in sequence to human insulin (see Table 3.8). Human insulin is now the primary insulin used in developed countries, being made from genetically engineered bacteria or by modifying pig insulin.

Human insulin versus animal insulin in people with diabetes mellitus. *Cochrane Database of Systematic Reviews* 3, CD003816, 2002.

3.5 • HIGHER LEVELS OF PROTEIN ORGANIZATION

Higher levels of protein organization refer to noncovalently generated conformations of the polypeptide chain. These higher levels of protein organization are called secondary, tertiary, and quaternary structure. **Secondary structure** refers to the local folding of the polypeptide backbone into helical, pleated sheet, or random conformations. The polypeptide backbone is the covalently interconnected atoms of the peptide bonds and α-carbons that link the amino acid residues of the protein. Side chains are not considered at the level of secondary structure. **Tertiary structure** refers to the three-dimensional structure of the polypeptide. It includes the conformational relationships in space of the side chains and the geometric relationship between distant regions of the polypeptide. **Quaternary structure** refers to the noncovalent association of discrete polypeptide subunits into a multisubunit protein. Not all proteins have a quaternary structure.

Proteins generally assume unique secondary, tertiary, and quaternary conformations to produce the protein's **native conformation**. Folding of the primary structure into the native conformation occurs, in most cases, spontaneously through noncovalent interactions. This conformation is the one of lowest total Gibbs free energy kinetically accessible to the polypeptide(s) for the particular conditions of ionic strength, pH, and temperature in which the folding occurs. In the cell, chaperone proteins (p. 231) can facilitate protein folding.

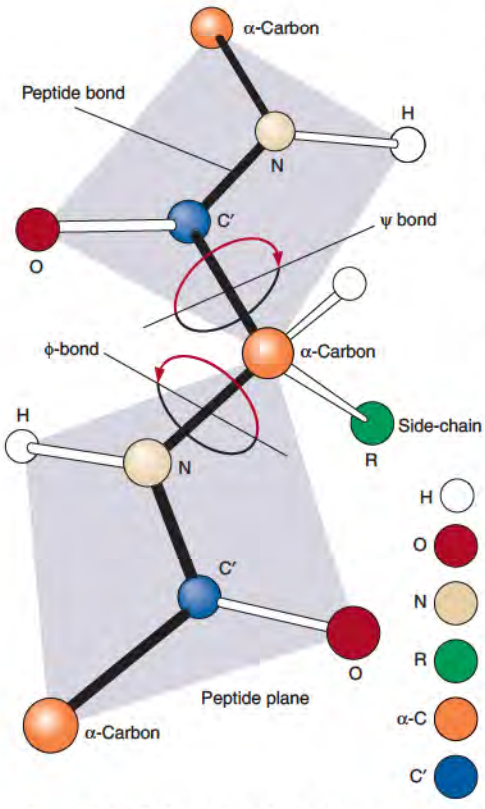

Figure 3.24 Polypeptide chain showing φ, ψ, and peptide bonds for residue R_i within a polypeptide chain. Redrawn with permission from Dickerson, R. E., and Geis, I. *The Structure and Action of Proteins.* Menlo Park, CA: Benjamin, 1969, 25.

Secondary Structure

The conformation of a polypeptide backbone may be described by the rotational angles of covalent bonds that contribute to the chain. These are contributed by each of the amino acids and are between the nitrogen and α-carbon, and the α-carbon and carbonyl carbon. The first is designated the **phi (φ) bond** and the second the **psi (ψ) bond** (Figure 3.24). The third bond contributed by each amino acid to the polypeptide chain is the peptide bond. As previously discussed, due to the partial double-bond character of the C′—N bonds, there is a barrier to free rotation about this peptide bond.

Regular secondary structure occurs in segments of a polypeptide chain in which all φ bond angles are equal, and all ψ bond angles are equal. The rotational angles for φ and ψ bonds for common regular secondary structures are given in Table 3.9.

The α-helix and β-strand conformations of polypeptides are the most thermodynamically stable of the regular secondary structures. However, a particular sequence may have an

TABLE 3.9 • Helix Parameters of Regular Secondary Structures

Structure	Approximate Bond Angles (°) ϕ	ψ	Residues per turn, n	Helix Pitch,[a] p(Å)
Right-handed α-helix [3.6_{13} -helix)	−57	−47	3.6	5.4
3_{10} -helix	+49	−26	3.0	6.0
Parallel β-strand	−119	+113	2.0	6.4
Antiparallel β-strand	−139	+135	2.0	6.8
Polyproline type II[b]	−78	+149	3.0	9.4

[a]Distance between repeating turns on a line drawn parallel to helix axis.
[b]Helix type found for polypeptide chains of collagen.

unordered, or random, secondary structure, in which neither the φ bond angles nor the ψ bond angles are equal. Proline interrupts α-helical conformation since its pyrrolidine side chain sterically interacts with the residue preceding it and prevents formation of an α-helical structure.

Helical structures are characterized by the number n of residues per turn of helix and the distance d between α-carbon atoms of adjacent amino acids measured parallel to the axis of the helix. The helix pitch p, the product of $n \times d$, then, measures the distance between repeating turns of the helix on a line drawn parallel to the helix axis (Figure 3.25).

α-Helical Structure

An amino acid sequence in a right-handed α-helical conformation is shown in Figure 3.26. Characteristic are 3.6 amino acid residues per 360° turn ($n = 3.6$). The peptide bond planes are parallel to the axis of the helix. In this geometry each peptide forms two hydrogen bonds, one to the peptide bond of the fourth residue above and the other to the peptide bond of the fourth amino acid below. Other parameters, such as the pitch p, are given in Table 3.9. In the hydrogen bonds between the peptide groups, the distance between the hydrogen-donor atom and the hydrogen-acceptor atom is 2.9 Å. In addition, the donor, acceptor, and hydrogen atoms are approximately in a straight line. This is an optimum geometry and distance for maximum hydrogen bond strength (Section 3.7, p. 112).

The side chains are on the outside of the spiral structure. Due to the characteristic 3.6 residues per turn, the first and every third and fourth R group of the amino acid sequence in the helix come close to each other. Helices often present polar and nonpolar faces if their amino acid sequences place polar or nonpolar R groups three or four residues apart. This gives rise to unique functional characteristics of the helix. However, if every third or fourth side chain that comes close to another has the same charge sign or is branched at its β-carbon (valine and isoleucine), its unfavorable ionic or steric interactions destabilize the helix structure. The α-helix may theoretically be left handed or right handed, giving it asymmetric properties and appropriate optical activity. A right-handed α-helix is more stable than a left-handed one.

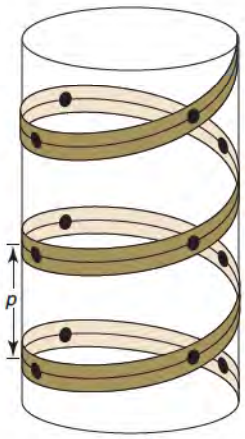

Figure 3.25 Helix pitch (p) for a helix with $n = 4$. Each circle on a line represents an α-carbon from an amino acid residue. The rise per residue would be p/n (see equation in text). Reprinted with permission from Dickerson, R. E., and Geis, I. *The Structure and Action of Proteins.* Menlo Park, CA: Benjamin, 1969, 26.

β-Structure

A polypeptide chain in a β-structure (Figure 3.27) is hydrogen bonded to another similar polypeptide region aligned in a parallel or an antiparallel direction (Figure 3.28). Hydrogen-bonded β strands appear like a pleated sheet (Figure 3.29). The side chains project above and below the pleated sheet-like structure.

Structural Motifs and Protein Folds

Simple arrangements of secondary structure that occur in more than one protein are called **structural motifs**. They include the helix-turn-helix motif found in many DNA-binding proteins, the strand-turn-strand motif found in proteins with antiparallel β-structure, and the alternating strand-turn-helix-turn-strand motif found in many α/β-proteins. In these

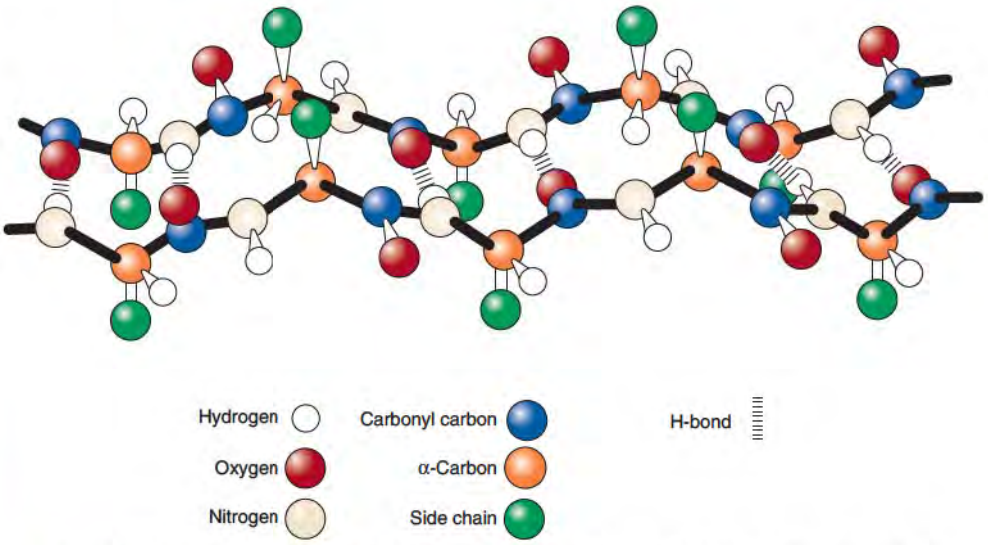

Figure 3.27 Two polypeptide chains in a β-sheet conformation. Polypeptide chains may be added to either edge of the two strands shown to generate a more extended structure.

motifs a turn is a small segment of the polypeptide (approximately three or four residues) of nonregular secondary structure that connects regions of regular secondary structure, whereas a loop is a larger segment of connecting nonregular conformation. Combinations of motifs or more complex organizations of secondary structure may form a **fold**. A fold is the arrangement of secondary structure elements of a **domain**. A structural domain is a compact globular structural unit formed within the polypeptide with a hydrophobic core and hydrophilic surface and usually folds independently of other structural units within the polypeptide chain.

The calmodulin domain can serve as an example for defining the terms *structural motif, fold,* and *domain* (Figure 3.30). Calmodulin binds to target proteins where it acts to sense

the levels of calcium in the cell. At increased cellular calcium levels, calcium activates the calmodulin to transmit a signal to its bound target protein. Target proteins of calmodulin participate in cell signaling, muscle contraction, fertilization, metabolism, programmed cell death, long- and short-term memory, nerve growth, immune response, and cell division. The calcium atom binds in calmodulin within the loop of a helix-turn-helix motif called an EF-hand (Figure 3.30*a* and see Figure 12.57, p. 493). The motif obtained its name from the E and F helices (helices 5 and 6 from the N-terminal end) in the muscle protein parvalbumin, in which this calcium-binding motif was first observed. The EF-hand motif is widely distributed in calcium-binding proteins and is found in over 70 different proteins with determined structures in the Protein Data Bank. The fold of the calmodulin domain contains two EF-hand motifs interconnected by an α-helical segment (Figure 3.30*b*). Addition of the side chain groups to the secondary structure traced by the polypeptide chain generates the complete tertiary structure of the domain (Figure 3.30*c*).

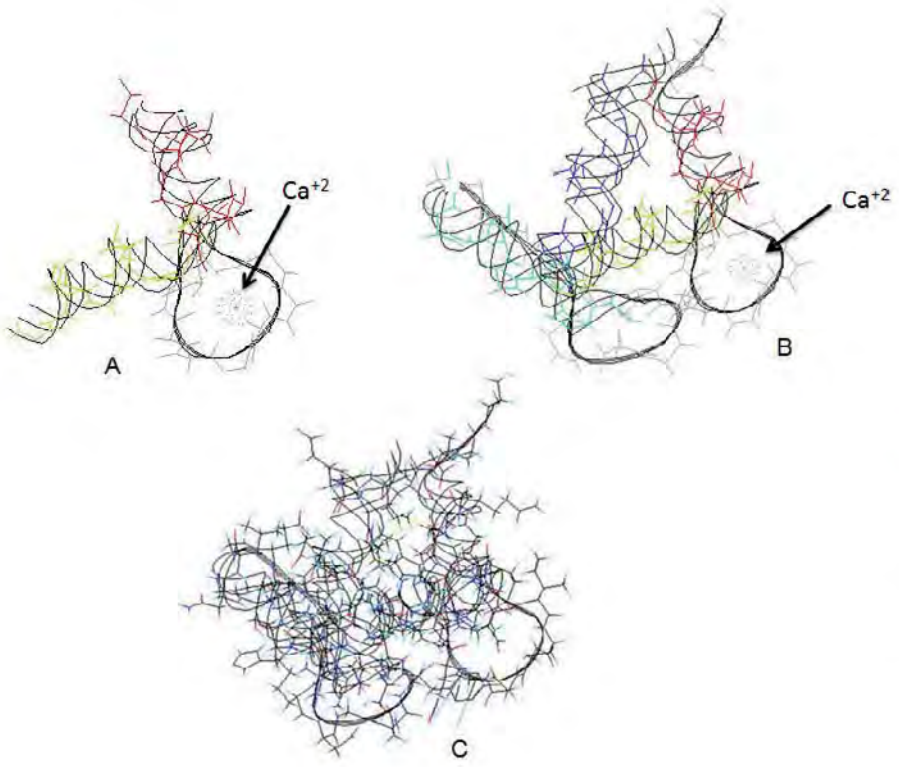

Figure 3.30 Motif and Fold Structures within Calmodulin Domain. (*a*) EF-Hand helix-turn-helix motif with Ca^{+2} bound. (*b*) Two EF-hand motifs combine in the fold of the calmodulin C-terminal domain. (*c*) The side-chain groups are added to generate the tertiary structure of the domain. Each α-helix is differently colored, with the polypeptide chain traced with a black ribbon to more clearly show the secondary structure of the polypeptide chain.

(a) (b)

(c)

Figure 3.31 Tertiary structure of trypsin. (*a*) Ribbon structure outlines conformation of the polypeptide chain. (*b*) Structure shows side chains including active site residues (in yellow) with outline of polypeptide chain (ribbon) superimposed. (*c*) Space-filling structure in which each atom is depicted as the size of its van der Waals radius. In (*c*) the hydrogen atoms are not shown. Different domains are shown in dark blue and white. Active site residues are in yellow, and intrachain disulfide bonds of cystine in red. Light-blue spheres represent water molecules associated with the protein. This structure shows the density of packing within interior of the protein.

Tertiary Structure

The **tertiary structure** of a polypeptide depicts the location of each of its atoms in space. It includes the geometric relationship between distant segments of primary and secondary structures and the positional relationship of the side chains with one another. The tertiary structure of trypsin is shown in Figure 3.31. The ribbon structure (*a*) shows the conformation of the single polypeptide chain and the overall pattern of chain folding (fold structure). Figure 3.31*b* shows the position of side chains. Active site catalytic side chains are shown in yellow, which include the hydroxymethyl group of serine (residue 177), the imidazole of histidine (residue 40), and the side-chain carboxylate of aspartate (residue 85). Although these are widely separated in the primary structure, the tertiary structure brings them together to form the catalytic site. In Figure 3.31*c*, a space-filling model shows C, N, and O atoms represented by balls of radius proportional to their van der Waals radius. The structure conforms to the general rules for soluble proteins (Section 3.3).

Hydrophobic side chains are generally in the interior, away from the water interface. Ionized side chains are on the outside, where they are stabilized by the water of solvation. Within the protein structure (not shown) are buried water molecules often exhibiting specific stabilizing interactions. A large number of water molecules form a solvation shell around the outside of the protein.

A long polypeptide often folds into multiple compact semi-independent regions, or domains, each having a characteristic compact geometry with a hydrophobic core and polar surface. They typically contain 100–150 amino acids. Domains in a **multidomain protein** may be connected by a segment that lacks a regular secondary structure. Alternatively, the dense spherical folded regions may be separated by a cleft or region less dense in tertiary structure (Figure 3.32). Trypsin contains two domains with a cleft in between that contains the substrate-binding catalytic site. An active site within an interdomain interface is characteristic of many enzymes. Different domains within a protein can move with respect to each other. Hexokinase (Figure 3.33), which catalyzes phosphorylation of glucose by adenosine triphosphate (ATP) (p. 596), has a glucose-binding site in a region between two domains. When glucose binds in the active site, the surrounding domains move (Section 3.8) to enclose the substrate to trap it for phosphorylation (Figure 3.33). In enzymes with more than one substrate or allosteric effector sites (p. 413), the different sites may be located within different domains. In multifunctional proteins, each domain may perform a different task.

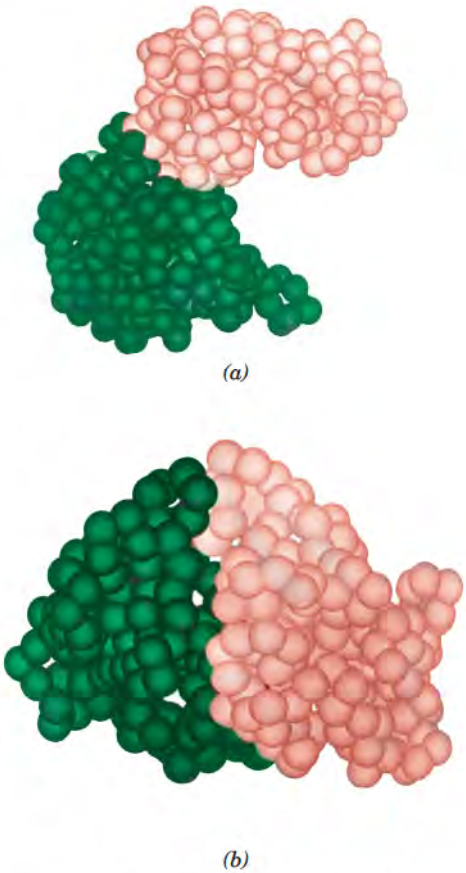

Figure 3.32 Globular domains within proteins. (*a*) Phosphoglycerate kinase has two domains with a relatively narrow neck in between. (*b*) Elastase has two tightly associated domains separated by a narrow cleft. Each sphere in the space-filling drawing represents the α-carbon position for an amino acid within the protein structure.
Reprinted with permission from Richardson, J. S. *Adv. Protein Chem.* 34: 168, 1981.

Quaternary Structure

Quaternary structure refers to the arrangement of polypeptide chains in a multichain protein. The subunits in a quaternary structure are associated noncovalently. α-Chymotrypsin contains three polypeptides covalently joined together by interchain disulfide bonds into a single covalent unit and therefore does not have a quaternary structure. Myoglobin consists of one polypeptide and has no quaternary structure. However, hemoglobin A contains four polypeptide subunits ($\alpha_2\beta_2$) held together noncovalently in a specific conformation as required for its function (p. 361). Thus, hemoglobin has a quaternary structure.

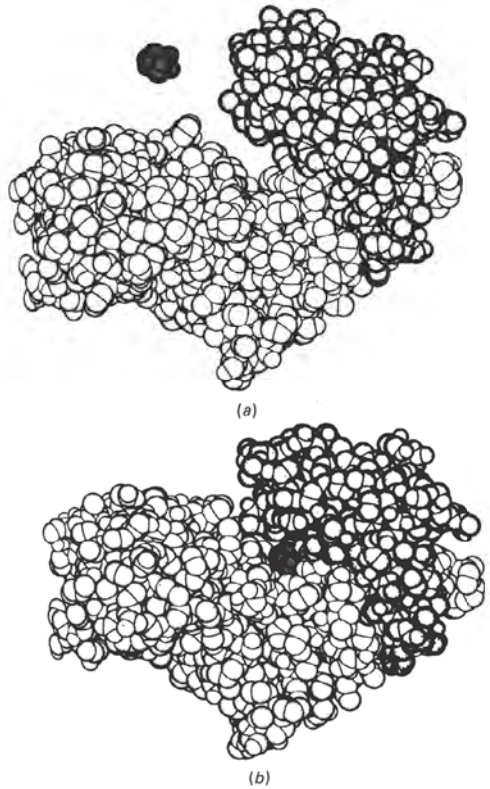

Figure 3.33 Drawings of (*a*) unliganded form of hexokinase and free glucose and (*b*) conformation of hexokinase with glucose bound. In this space-filling drawing, each circle represents the van der Waals radius of an atom in the structure. Glucose is black, and each domain is differently shaded.
Reprinted with permission from Bennett, W. S., and Huber, R. *CRC Rev. Biochem.* 15: 291, 1984.

Bacterial aspartate carbamoyl transferase (p. 822) has a quaternary structure comprised of 12 polypeptide subunits. The poliovirus coat protein contains 60 polypeptide subunits, and the tobacco mosaic virus protein contains 2120 noncovalently associated subunits.

Unstructured Proteins

Proteins described previously have defined folds and tertiary structures in which the average location in space of the atoms of the folded structures are known. In contrast, there are proteins that lack a stable folded structure. This may not be surprising, as folded proteins are typically only 21–42 kJ/mol (5–10 kcal/mol) more stable than their denatured conformation (Section 3.7, p. 112). It should not therefore be unexpected that there are proteins that do not have a stable folded conformation at physiological temperatures. Proteins with a nonfolded conformation are called **intrinsically unstructured proteins (IUPs)**. Other proteins may contain unstructured regions or domains that contain **partially unfolded conformations (PUFs)**. The IUPs and proteins with PUFs include scaffold proteins, hormones, activation domains of transcription factor, cyclin-dependent kinases and their inhibitors, proteins in cellular signal transduction, and the NH_2-terminal segments of histone proteins in nucleosomes.

The unfolded conformations are highly dynamic with the atoms showing mobility in displacement and rotation (see Section 3.8 for a discussion of the mobility of folded proteins). However, the unstructured conformations may contain regions of ordered secondary structure not completely randomized. These unstructured protein domains would resemble the molten globule intermediates present on protein-folding pathways (Section 3.5).

IUPs and PUFs often function by binding to other proteins or to DNA and RNA. The binding interaction induces a structure in the unfolded polypeptide (Figure 3.34). The induction of defined structure in the IUP or PUF is a negative entropic process that requires an unfavorable free energy. Thus, the binding strength of unstructured proteins to their binding partners is generally weaker than for the binding of a molecule to a preformed structure, which does not need to utilize a part of its favorable binding energy to drive an entropically unfavorable conformation change. This property of weak binding is often

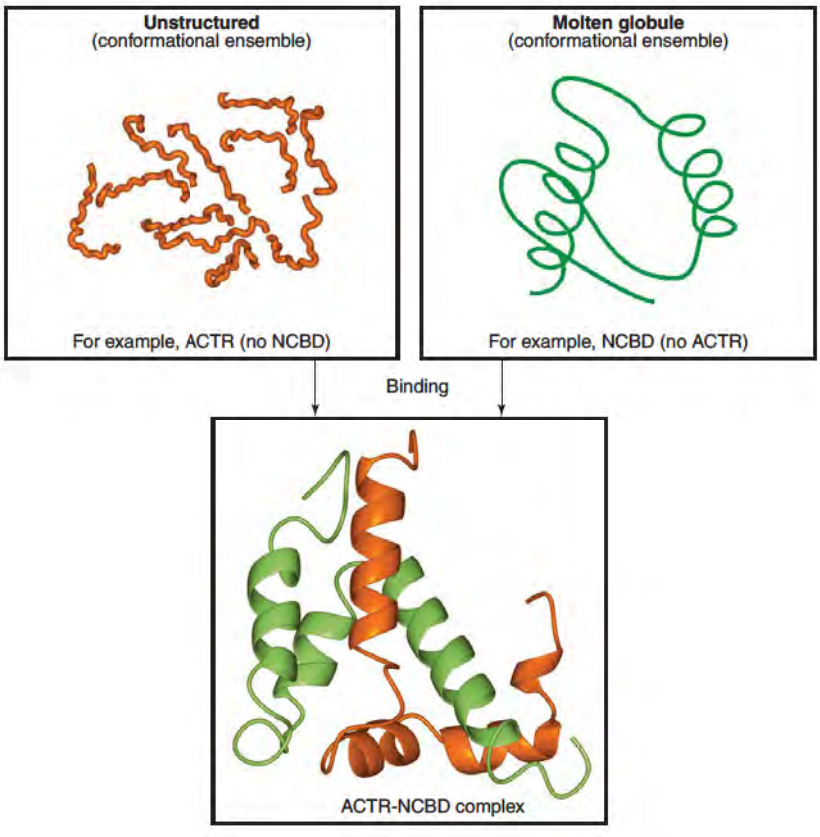

Figure 3.34 Structure Induced in Unstructured Domains on Binding. The interaction domain of activator for thyroid hormone and retinoid receptors (ACTR) is an ensemble of unstructured conformations (reddish brown, upper left panel) and the nuclear-receptor coactivator domain (NCBD) has a molten globule conformation with elements of regular secondary structure and an unstable tertiary structure (green, upper right panel). Association induces a stable secondary and tertiary structure in both proteins (lower panel). Reprinted by permission from Macmillan Publishers Ltd: from Dyson, H. J., and Wright, P. E. *Nature Rev. Mol. Cell Biol.* 6: 197, 2005.

advantageous, as weak and transient interactions are required for many biological processes. In addition, the unstructured domains show promiscuity in their binding partners, as their lack of a preformed structure gives them a plasticity to form complementary binding surfaces to many different binding partners. Thus the cyclin-dependent kinase inhibitor p21 has the ability to bind to different cyclin-dependent kinases and regulate cyclin-dependent kinases present in the different phases of the cell cycle. Scaffold proteins group many proteins into a functional complex. Their plasticity allows the binding of multiple partners into the complex and permits changes in the protein members according to physiological requirements.

Unstructured regions of proteins can be recognized from the amino acid sequence of their polypeptide. Disordered regions are enriched in polar and charged amino acids (glutamate, lysine, and glutamine) and in the amino acid proline and depleted in the aromatic and alkyl amino acids. Algorithms have been developed to search sequences and identify potential unstructured regions of polypeptide chains. The retention of the unstructured proteins and PUFs within specific proteins through evolution shows the importance of such regions to critical biological processes.

Protein Complexes, Networks, and Interactomes

Protein molecules in the cellular milieu are primarily present in protein complexes containing multiple protein subunits. The complexes are functionally essential to most cellular processes including cell signaling, gene transcription, RNA splicing and translation, apoptosis, and cellular metabolism. These complexes typically have 5–10 proteins, but may contain as many as 20–30 different proteins. The complexes communicate with each other through proteins present in two or more different complexes, which can move between the complexes to connect the complexes into **networks**. A complex that interconnects with more than three other complexes is a **hub** in the network, and an important target for drug therapies in disease. A functional network comprising interconnected protein complexes is an **interactome.**

Cellular protein complexes are characterized utilizing **tandem affinity purification (TAP)**, which involves insertion of a reporter gene in tandem with a gene for a protein of interest to produce a chimeric protein in which the target protein product is joined to a tagged protein. The tagged protein is isolated by elution of the cell lysate over an antitag protein antibody affinity column (Figure 3.35). The affinity resin binds the tagged protein and its associated proteins, which are eluted from the column, separated by electrophoresis, and identified by mass spectrometry (p. 127 for a discussion of techniques). Other methods for identification of the complex partners of a target protein include **co-immunoprecipitation** with an antibody directed against the target protein, and the **yeast two-hybrid assay** in which mammalian protein–protein binary interactions are assessed in a yeast cell reporter

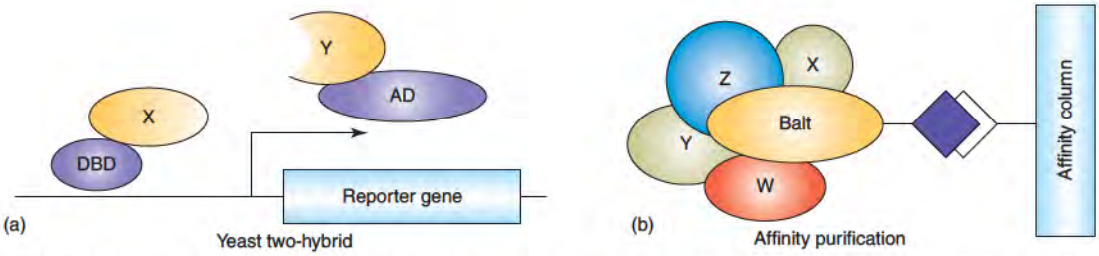

Figure 3.35 Two methods to determine protein–protein interactions. (*a*) The yeast two-hybrid technique determines binary protein–protein interactions in a yeast expression system. A transcription factor protein that binds to an upstream regulatory sequence of a yeast reporter gene such as *Gal4* consists of a DNA binding domain (DBD) and an activation domain (AD) required to activate reporter gene expression. The coding regions of the DBD and AD domains are separated and joined to two mammalian genes of interest (X and Y) and expressed in yeast cells to produce chimeric proteins DBD-X and Y-AD. If protein Y binds to protein X, the DBD and AD domains are brought together and upregulate reporter gene expression. The popular *Gal4* gene produces the enzyme β-galactosidase, which gives a blue color to cells on culture plates imbedded with the appropriate substrate.
(*b*) The tandem affinity purification (TAP) technique joins a tag protein (purple square) to a protein of interest (bait protein, orange) and the chimeric protein is expressed in a cell of interest. The cell lysate is passed over an affinity resin containing antibody to tag protein with the bait protein complex (proteins W–Z). Bound proteins are eluted from affinity column and indentified by mass spectrometry.
Redrawn based on figure from Aloy, P., and Russell, R. B. *Nature Reviews Mol. Cell Biol.* 7:188, 2006.

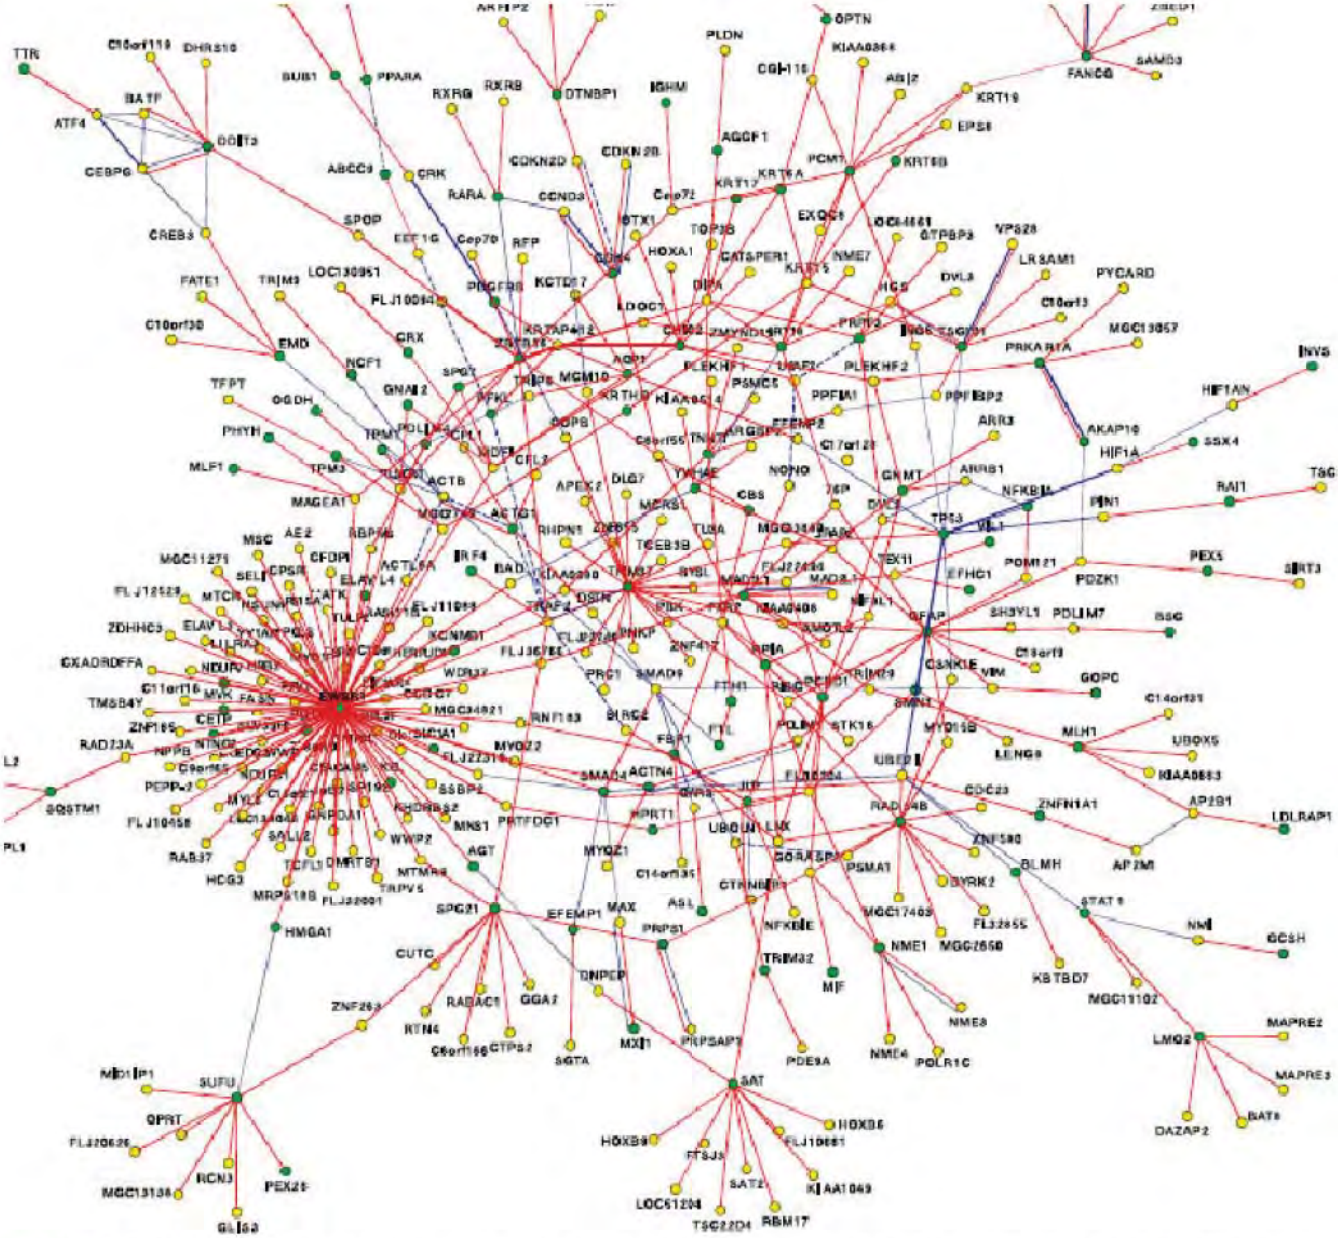

Figure 3.36 Preliminary disease-related interactome map for subset of 7200 human proteins. The yeast two-hybrid binary interactions were determined among a subset of 7200 gene products. The interactome shown is for the binding interactions of known disease-related proteins that are designated in the OMIM database. Green nodes are gene products in the OMIM database, and yellow nodes represent gene products without a current OMIM designation. Red edges show binary interactions identified by Rual et al., and solid blue edges interactions curated by the authors from the literature. Dashed edges show interactions through a third protein.

system (Figure 3.35). Any one of these assay techniques alone is not sufficient to prove an *in vivo* protein–protein interaction, as artifacts are common. A positive result from more than one of these techniques demonstrates an interaction with high confidence. These techniques do not isolate transient complexes, membrane complexes, or complexes from physiological states or phenotypes not present in the cells analyzed.

Theoretical estimates indicate that a human cell has approximately 3000 core protein complexes, each with multiple isoforms (noncore exchangeable protein members generate different isoforms), and approximately 650,000 protein–protein binary interactions generating these protein complexes. Determining the characteristics of complexes and networks for which disease-associated proteins are present show the interdependencies of the multiple gene products affecting a disorder and their interrelationships in the disease-related pathways (Figure 3.36).

Bioinformatics Relates Structure and Function of Protein Gene Products

Over the last decade the nucleotide sequences of the genomes of multiple animal species have been obtained and the sequences of the RNA transcripts and polypeptide sequences produced from the genomic DNA. The amount of data is enormous and is stored in computer databases, which are freely accessible over the Internet. The number of polypeptide sequences in the UniProt Knowledge Base as of 2008 is over 6.4 million of which 75,000 are human. The Protein Data Bank contains 47,000 three-dimensional structures of folded proteins obtained by X-ray diffraction, nuclear magnetic resonance, and electron microscopy. **Bioinformatics** is a computationally based research area that focuses on the integration and analysis of the complex biological data with computer algorithms. A major emphasis of bioinformatics has been to identify patterns within nucleic acid or amino acid sequences that are **signatures** of structural features or motifs and of the protein family or class to which the gene product belongs. These homology-searching algorithms are used to identify and classify gene products on the basis of sequence similarity when the structure is known, homology searching may be based on structural similarity. The scoring for sequence similarity uses criteria from that of the absolute identity of residues at equivalent positions to similarity based on polarity, hydrophobicity, and size. The algorithms allow for insertion or deletion of segments of polypeptide chain or structure to give the maximum possible overlap between two proteins.

Protein domains are classified by class, fold, and family. The **class** is determined by the predominant type of secondary structure present in the protein. Some examples are mainly α-helix (all α), mainly β-strand (all β), and approximately equal amounts of α-helix and β-strand (alternating [α *or* β] and nonalternating [$\alpha + \beta$]). The **fold** is determined by the particular arrangement of secondary structure elements within the domain. The **family** is determined by the degree of sequence identity between the proteins. Proteins that are members of the same family have a common evolutionary relationship and are derived from the same primordial gene. Proteins of the same family have the same fold and often have similar functions.

Of interest in clinical medicine is the finding of mutations in the amino acid sequence, which can give rise to significant alterations in function. At the molecular level, changes in even one amino acid can be significant. An amino acid mutation may perturb the native conformation, the conformational flexibility; the energetics, or motion, of the molecule; and the selectivity of enzymes toward substrates and inhibitors. Examples of this are the hemoglobins for which there are extensive catalogs of mutations. Some hemoglobin mutations produce significant clinical symptoms, such as sickle-cell anemia (Clin. Corr. 6.2; p. 214). Certain positions in the amino acid sequence are variant among populations. These sequence positions, when they involve single changes in the base codon for that amino acid, are termed **single nucleotide polymorphisms** (SNPs) and can lead to an understanding of the differences in response to a disease or therapeutic treatment among human populations.

Homologous Fold Structures Are Often Formed from Nonhomologous Amino Acid Sequences

Although each native conformation is unique, comparison of tertiary structures of different proteins shows that similar arrangements of secondary structure motifs are often observed in the fold structures of domains. Folds of similar structure from proteins unrelated by function, sequence, or evolution are designated **superfolds**. They form because of the thermodynamic stability of their secondary structure arrangements or their kinetic accessibility.

A common all-α fold or domain is found in lysozyme and is designated the globin fold (Figure 3.37), as it was first reported in myoglobin and the subunits of hemoglobin (p. 355). These all-α structures have seven or eight sections of α-helix joined by smaller segments that allow the helices to fold back on themselves to form a characteristic globular shape. As this fold is generated by proteins from different sequence homology families, the globin fold is a superfold. Another common superfold is the ***α/β*-domain structure** of triose phosphate isomerase (Figure 3.38) in which the strands (designated by arrows) form a central ***β*-barrel** with each β-strand in the interior interconnected by α-helical

Figure 3.37 An example of an all α-domain globin fold in lysozyme. In this drawing and Figures 3.38, 3.39, and 3.40, only the outline of the polypeptide chain is shown. β-Strands are shown by arrows with direction of the arrow showing N—>C terminal direction; lightning bolts represent disulfide bonds, and circles represent metal ion cofactors (when present). All α domain is the globin fold.

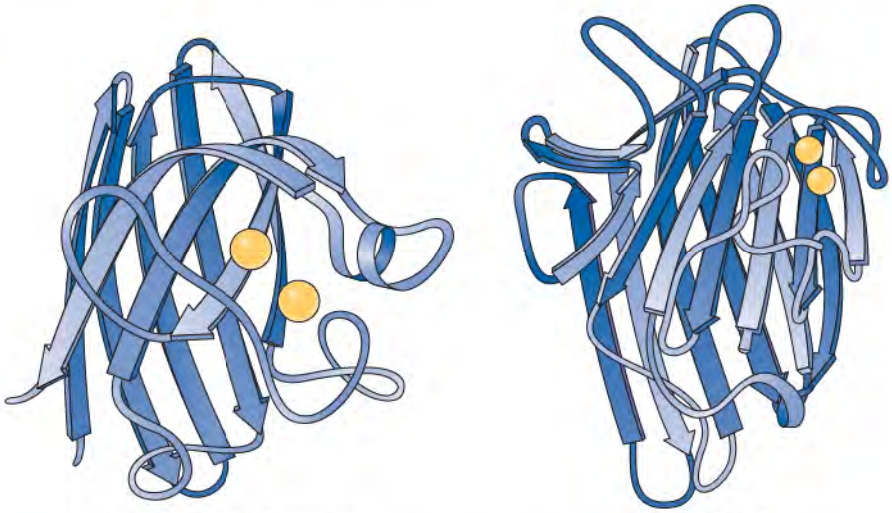
regions located on the outside of the fold. A similar fold forms a domain of pyruvate kinase (Figure 3.38), which has no sequence or functional homology. A different type of α,β-superfold is present in the nonhomologous domain 1 of lactate dehydrogenase and domain 2 of phosphoglycerate kinase (Figure 3.39). In these, central sections participate in a **twisted β-sheet**. Again, the β-strand segments are joined by α-helical regions positioned on the outside to give the characteristic fold pattern. An **all-β-domain** superfold is present in Cu, Zn superoxide dismutase, in which the antiparallel β-sheet forms a Greek key β-barrel (Figure 3.40). A similar fold pattern occurs in each of the domains of the immunoglobulins. Concanavalin A (Figure 3.40) shows an all-β-domain superfold in which the antiparallel β-strands form a β-barrel fold called a "jelly roll". Proteins that are not water soluble may contain nonglobular fold patterns (Section 3.6).



Cu, Zn Superoxide Dismutase Concanavalin A

Figure 3.40 Examples of all β-domain superfolds: The Greek key barrel and jelly roll folds shown in superoxide dismutase and concanavalin A. See the legend to Figure 3.37. β-Strands are mostly antiparallel in all β-domain folds.

3.6 • NONGLOBULAR STRUCTURED PROTEINS

The characteristics of protein structure already discussed are based on observations on globular and water-soluble proteins. **Globular proteins** have a spheroidal shape, vary in size, have relatively high water solubility, and function as catalysts, transporters, and regulators of metabolic pathways and gene expression. Proteins that do not conform to the globular soluble protein model are the fibrous proteins and membrane proteins. These are nonglobular and have low water solubility. In addition, lipoproteins and glycoproteins contain lipid and carbohydrate nonprotein components and may or may not have globular structures.

Fibrous proteins characteristically contain larger amounts of regular secondary structure, a long cylindrical (rodlike) shape, low solubility in water, and a structural rather than a dynamic role. Collagen, keratin, and tropomyosin are important fibrous proteins. Their multistrand structures have polypeptide chains with a high amount of regular secondary structure (polyproline type II helix or α-helix), which associate to form rod-shaped multichain supercoiled conformations. In each case, the amino acid sequences of the chains generate edges on the cylindrical surfaces that stabilize hydrophobic interactions between the chains in the supercoiled conformations. In turn, these molecular structures are aligned into multimolecular fibrils that are stabilized, in some cases, by covalent cross-links.

TABLE 3.10 • Percentage of Collagen in Representative Human Tissues and Organs

Tissue or Organ	*Percent Collagen by weight*

Collagen

Collagen is a family of extracellular proteins present in all tissues and organs, which provide the framework that gives the tissues their form and strength. It is the most prominent protein in humans (Table 3.10 and Clin. Corr. 6.13; p. 246).

Amino Acid Composition of Collagen

The amino acid composition of type I skin collagen and of the globular proteins ribonuclease and hemoglobin are given in Table 3.11. Skin collagen is rich in glycine (33% of its amino acids), proline (13%), and the derived amino acids 4-hydroxyproline (9%) and 5-hydroxylysine (0.6%) (Figure 3.41). Hydroxyproline is unique to collagens being formed enzymatically from proline. Most of the hydroxyproline has the hydroxyl group in the 4 position (γ carbon), although a small amount of 3-hydroxyproline is also formed (Table 3.11). Collagens are glycoproteins with carbohydrate joined to 5-hydroxylysine, by an *O*-glycosidic bond through the δ-carbon hydroxyl group.

Amino Acid Sequence of Collagen

The collagen family is made up of polypeptides derived from 40 known collagen chain genes which produce about 20 types of collagen. Each mature collagen or tropocollagen molecule contains three polypeptide chains. Some types of collagen contain three identical polypeptide chains. In type I (Table 3.12), there are two α1(I) chains and one α2(I). Type V collagen contains three different chains designated α1(V), α2(V), and α3(V). Collagens differ in amino acid sequence, but there are large regions of homologous sequence among all the different collagen types. In all the collagen types there are regions with the tripeptides **Gly-Pro-Y** and **Gly-X-Hyp** (where X and Y are any amino acid) repeated in tandem several hundred times. In type I collagen polypeptides, the triplet sequences encompass over 600 of approximately 1000 amino acids per polypeptide. The collagens differ in their carbohydrate component. Some characteristics of collagen types I–VI are summarized in Table 3.12.

Structure of Collagen

Synthetic polypeptide chains containing only proline (poly-Pro) can be prepared in the laboratory and assume in aqueous solutions a regular secondary helical structure different from an α-helix. The poly-Pro forms a tightly twisted extended helix with three residues per turn ($n = 3$). This helix with all *trans* peptide bonds is the **polyproline type II** helix (Figure 3.12, p. 81, for differences between *cis*- and *trans* peptide bonds). The poly-Pro helix closely resembles that found in collagen chains in regions that contain a proline or hydroxyproline at approximately every third position in the repeated tripeptide sequences, indicating that the thermodynamic forces leading to formation of the collagen helix are due to the properties of proline.

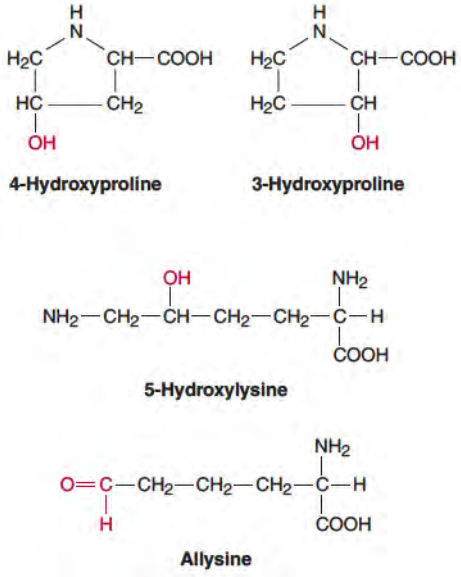

Figure 3.41 Derived amino acids in collagen. Carbohydrate is attached to 5-OH in 5-hydroxylysine by a type III glycosidic linkage (see Figure 3.49).

4-Hydroxyproline	9	1	0	0
5-Hydroxylysine	0.6	0	0	0
Desmosine and isodesmosine	0	1	0	0

[a]Boxed numbers emphasize important differences in amino acid composition between the fibrous proteins (collagen and elastin) and typical globular proteins.

In the polyproline type II helix, the plane of each peptide bond is perpendicular to the axis of the helix. Thus the peptide bond oxygen and nitrogen atoms in a polyproline type II helix point toward neighboring polypeptide chains and form strong interchain hydrogen bonds. This contrasts with the α-helix, in which the plane of the peptide bond is parallel to the axis where the NH and carbonyl oxygen of the peptides form only intrachain hydrogen bonds.

The three chains of a collagen molecule, with each of the chains in a polyproline type II helix conformation, wind around each other to form a superhelical structure known as a superhelix (Figure 3.42, p. 106). The three-chain **superhelix** has a characteristic rise (d) and pitch (p) different from that found in each of the polypeptide chain polyproline helices. The superhelix is stabilized by the interchain hydrogen bonds between the three chains, because glycine occurs at every third position. With the polyproline type II helical conformation of each polypeptide chain with three residues per turn ($n = 3$), the glycines form an **apolar edge** along the length of each of the helices. The glycine edges then form nonpolar interactions between the chains that are critical to stabilize the three-chain superhelix. Any side

TABLE 3.12 • Classification of Collagen Types

Type	*Chain Designations*	*Tissue Found*	*Characteristics*
I	$[\alpha1(I)]_2\ \alpha2(I)$	Bone, skin, tendon, scar tissue, heart valve, intestinal and uterine wall	Low carbohydrate; <10 hydroxylysines per chain
II	$[\alpha1(II)]_3$	Cartilage, vitreous	10% carbohydrate; >20 hydroxylysines per chain
III	$[\alpha1(III)]_3$	Blood vessels, newborn skin, scar tissue, intestinal and uterine wall	Low carbohydrate; high hydroxyproline and Gly; contains Cys
IV	$[\alpha1(IV)]_3$ $[\alpha2(IV)]_3$	Basement membrane, lens capsule	High 3-hydroxyproline; >40 hydroxylysines per chain; low Ala and Arg; contains Cys; high carbohydrate (15%)
V	$[\alpha1(V)]_3\alpha2(V)$ $[\alpha1(V)]_3$ $\alpha1(V)\alpha2(V)\alpha3(V)$	Cell surfaces or extracellular matrix associated with cell; widely distributed in low amounts	High carbohydrate, relatively high glycine, and hydroxylysine
VI	$\alpha1(VI)\alpha2(VI)$ $\alpha3(VI)$	Aortic intima, placenta, kidney, and skin in low amounts	Relatively large globular domains in telopeptide region; high Cys and Tyr; molecular weight relatively low (~160 kDa); equimolar amounts of hydroxylysine and hydroxyproline

chain other than that of glycine along the apolar edge would impede the adjacent chains from coming together into the superhelix structure (Figure 3.42, Osteogenesis Imperfecta, and Clin. Corr. 6.13; p. 246).

In type I collagen the triple helix extends for most of the sequence and only the carboxyl-terminus and amino-terminal segments (known as the **telopeptides**) are not in a triple-helical conformation. The type I collagen molecule is 3000 Å long and only 15 Å wide, a very long cylindrical structure. In other collagen types, superhelical regions may be periodically broken by globular regions.

Formation of Covalent Cross-Links in Collagen

An extracellular enzyme acts on procollagen molecules (p. 107) to convert the ε-amino group of some lysine side chains to a δ-aldehyde (Figure 3.43). The derived amino acid is **allysine**. The newly formed aldehyde side chain spontaneously undergoes nucleophilic addition reactions with nonmodified lysine ε-amino groups and with the δ-carbon atoms of other allysine aldehydic groups. These covalent linkages can be between chains within the superhelical structure or between adjacent superhelical collagen molecules in a collagen fibril (p. 243 for a discussion of collagen biosynthesis).

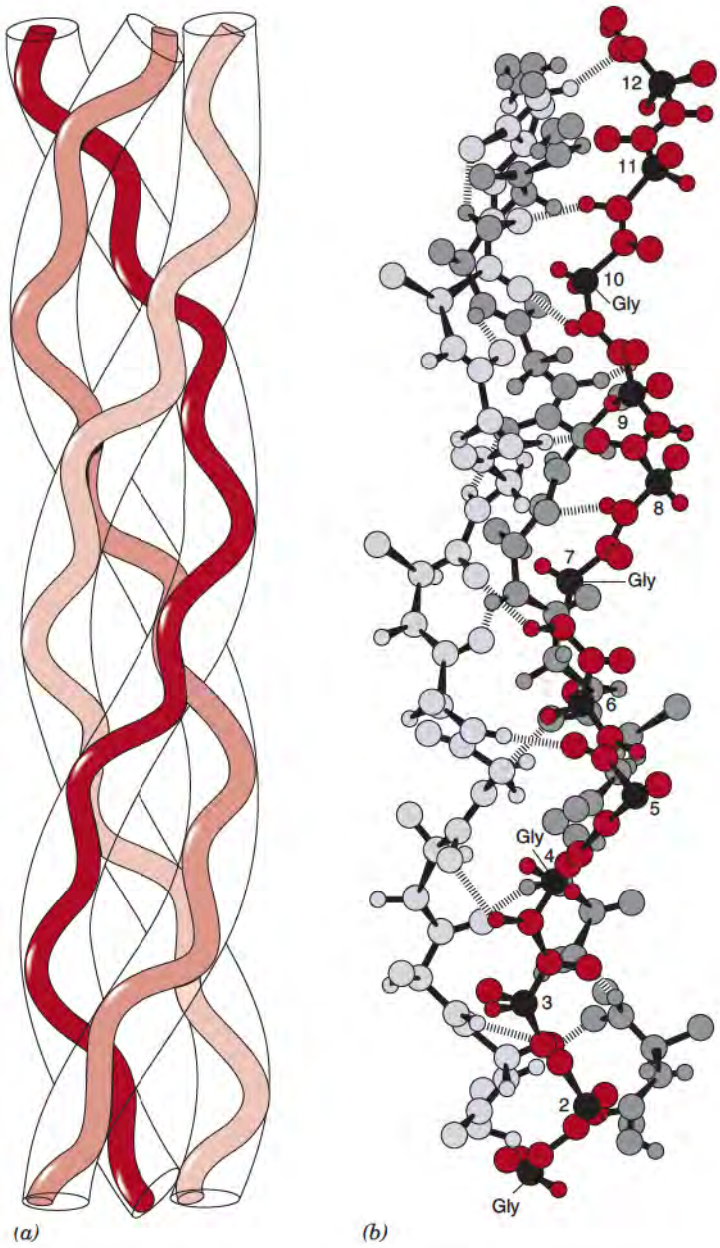

Figure 3.42 **Diagram of collagen demonstrating the necessity for glycine in every third residue to allow different chains to be in close proximity in the structure.** (*a*) Ribbon model for supercoiled structure of collagen with each individual chain in a polyproline type II helix. (*b*) More detailed model of supercoiled conformation. All α-carbon atoms are numbered, and proposed hydrogen bonds are shown by dashed lines.

Elastin Is a Fibrous Protein with Allysine-Generated Cross-Links

Elastin gives tissues and organs the capacity to stretch without tearing. It is classed as a fibrous protein because of its structural function and relative insolubility in water; it is abundant in ligaments, lungs, walls of arteries, and skin. Elastin lacks a regular secondary structure. As in collagen, allysines form cross-links in **elastin**. An extracellular **lysine amino oxidase** converts lysine side chains in the sequence -Lys-Ala-Ala-Lys- and -Lys-Ala-Ala-Ala-Lys- to allysines. Three allysines and an unmodified lysine from different regions in the polypeptide chains react to form the heterocyclic structure of **desmosine** or **isodesmosine**, which cross-link the polypeptide chains in elastin networks (Figure 3.44).

Keratin and Tropomyosin

Keratin and tropomyosin are fibrous proteins in which each polypeptide is α-helical. Keratin is found in the epidermal layer of skin, in nails, and in hair. Tropomyosin is a component of the thin filament in muscle tissue. The sequences in both proteins show tandem

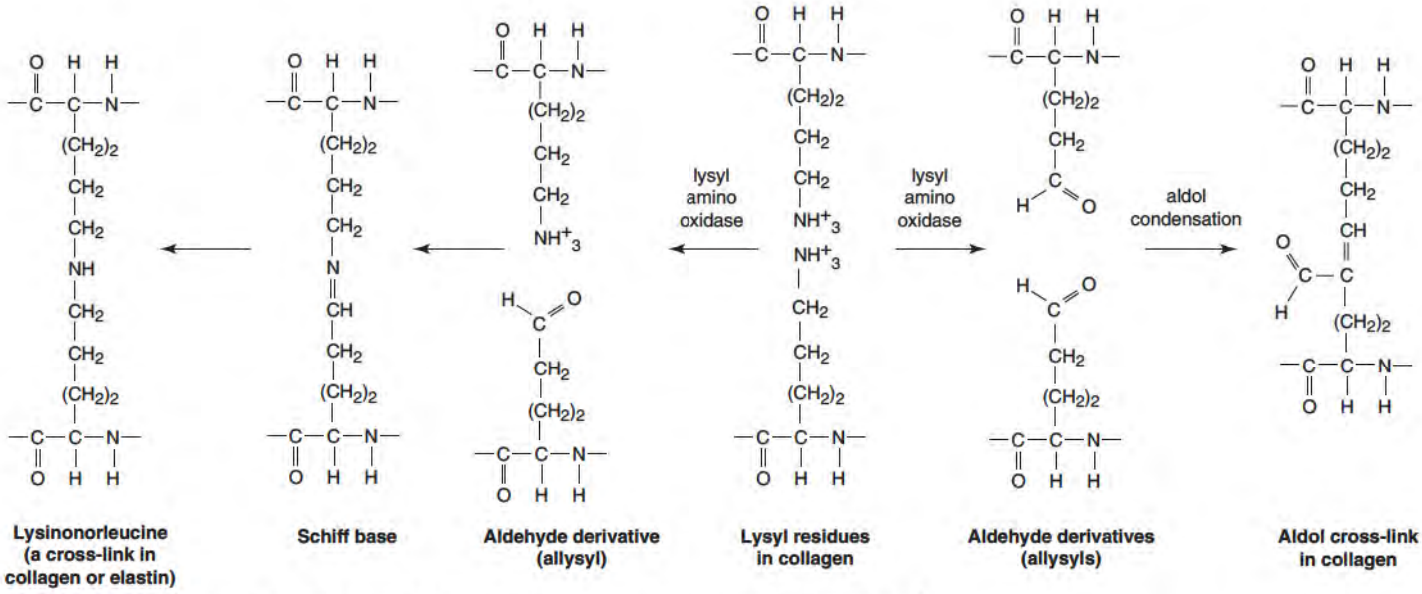

Figure 3.43 Covalent cross-links formed in collagen through allysine intermediates. Formation of allysines is catalyzed by lysyl amino oxidase.

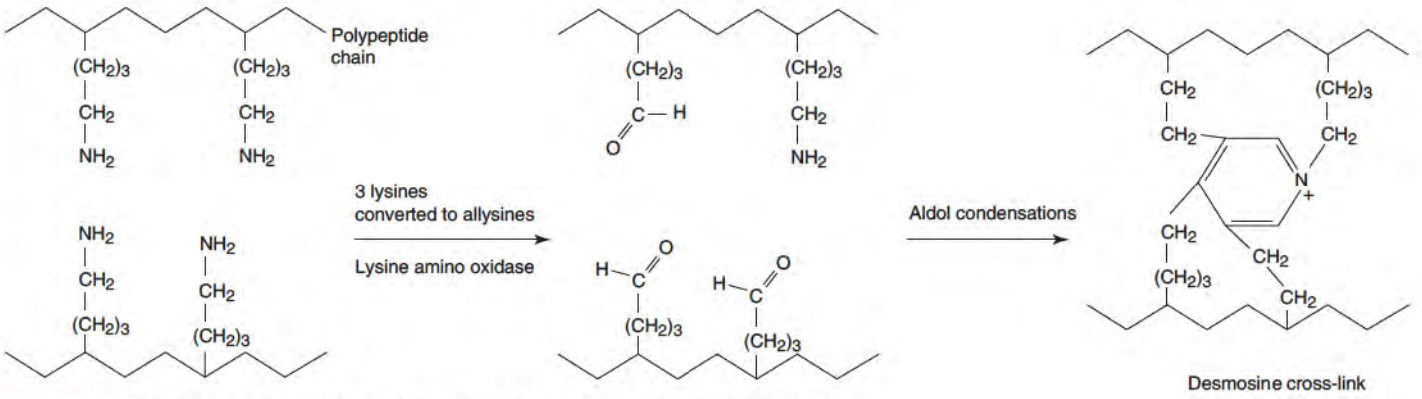

Figure 3.44 Formation of desmosine covalent cross-link in elastin from lysine and allysines. Polypeptide chain drawn schematically with intersections of lines representing placement of α-carbons.

repetition of seven residue segments (heptad), in which the first and fourth amino acids have hydrophobic side chains and the fifth and seventh polar side chains. The reiteration of hydrophobic and polar side chains in heptad segments is symbolically represented by the formulation $(\text{a-b-c-d-e-f-g})_i$, where a and d are hydrophobic amino acids, and e and g are polar or ionized side chain groups. Since a seven amino acid segment represents two complete turns of an α-helix ($n = 3.6$), the apolar residues at a and d align to form an apolar edge along one side of the α-helix (Figure 3.45). This apolar edge interacts with polypeptide apolar edges of other α-keratin chains to form a **coiled-coil** superhelical structure containing two or four polypeptide chains. Each polypeptide also contains a polar edge, due to residues e and g, that interacts with water on the outside of the superhelix and stabilizes the superhelix.

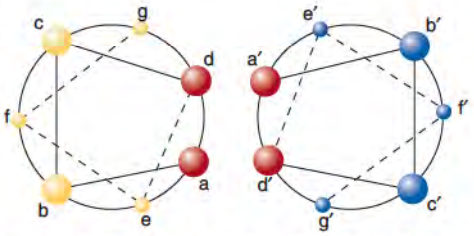

Figure 3.45 Interaction of apolar edges of two chains in α-helical conformation as in keratin and tropomyosin. Interaction of apolar d-a and a′-d residues of two α-helices aligned parallel in an NH_2-terminal (top) to COOH-terminal direction is presented.

Plasma Lipoproteins Are Complexes of Lipids with Proteins

Plasma lipoproteins are complexes of proteins and lipids that form distinct aggregates with an approximate stoichiometry between protein and lipid components. Covalent bonds do not exist between lipid and protein molecules, rather the molecules of the complex are held in the particle structure through noncovalent interactions (p. 722). The lipoprotein particles function to transport lipids from tissue to tissue and participate in lipid metabolism (p. 724).

TABLE 3.13 • Hydrated Density Classes of Plasma Lipoproteins

Lipoprotein Fraction	*Density ($g\,mL^{-1}$)*	*Flotation Rate, S_f (Svedberg units)*	*Molecular Weight (daltons)*	*Particle Diameter (Å)*
HDL	1.063–1.210		HDL_2, 4×10^5	70–130
			HDL_3, 2×10^5	50–100
LDL (or LDL_2)	1.019–1.063	0–12	2×10^6	200–280
IDL (or LDL_1)	1.006–1.019	12–20	4.5×10^6	250
VLDL	0.95–1.006	20–400	$5 \times 10^6 - 10^7$	250–750
Chylomicrons	<0.95	>400	$10^9 - 10^{10}$	$10^3 - 10^4$

Source: Data from Soutar, A. K. and Myant, N. B. In: R. E. Offord (Ed.), *Chemistry of Macromolecules,* IIB. Baltimore, MD: University Park Press, 1979.

Four classes exist in plasma of normal fasting humans (Table 3.13) and in the postabsorptive period a fifth class, chylomicrons, is also present. These are distinguished by their density, as determined by ultracentrifugation and by electrophoresis (Figure 3.46). Changes in their relative concentrations are predictive of atherosclerosis, a major human disease (Clin. Corr. 3.3). Their protein components are termed **apolipoproteins**, and each class of lipoprotein having a characteristic apolipoprotein composition. The most prominent apolipoproteins (Table 3.14) are apolipoprotein **ApoA-I** in high-density lipoproteins (**HDLs**); **ApoB** in low-density lipoproteins (**LDLs**), intermediate-density lipoproteins (**IDLs**); and very-low-density

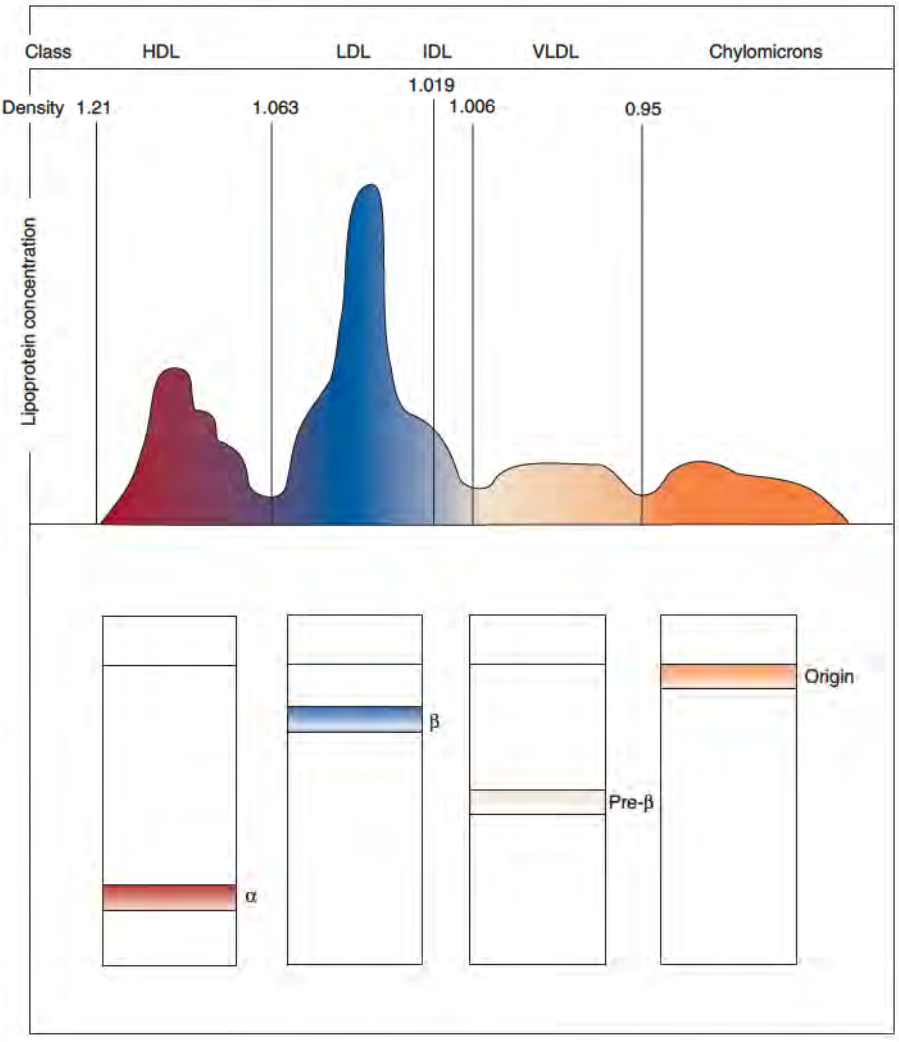

Figure 3.46 Correspondence of plasma lipoprotein density classes with electrophoretic mobility in a plasma electrophoresis. In the upper diagram, an ultracentrifugation Schlieren pattern is shown. At bottom, an electrophoresis on a paper support shows the mobilities of major plasma lipoprotein classes with respect to α- and β-globulin bands.

CLINICAL CORRELATION 3.3

Hyperlipoproteinemias

Hyperlipoproteinemias (OMIM 608083) are disorders of the rates of synthesis or clearance of lipoproteins from the bloodstream. Usually they are detected by measuring plasma triacylglycerol and cholesterol and are classified on the basis of which class of lipoproteins is elevated.

Type I hyperlipoproteinemia is due to accumulation of chylomicrons. Two genetic forms are known: lipoprotein lipase deficiency and ApoCII deficiency. ApoCII is required by lipoprotein lipase for full activity. Patients with type I hyperlipidemia have exceedingly high plasma triacylglycerol concentrations (over 1000 mg/dL) and suffer from eruptive xanthomas (yellowish triacylglycerol deposits in the skin) and pancreatitis.

Type II hyperlipoproteinemia is characterized by elevated LDL levels. Most cases are due to genetic defects in the synthesis, processing, or function of the LDL receptor. Heterozygotes have elevated LDL levels; hence the trait is dominantly expressed. Homozygous patients have very high LDL levels and may suffer myocardial infarctions before age 20.

Type III hyperlipoproteinemia is due to abnormalities of ApoE, which interfere with the uptake of chylomicron and VLDL remnants. Hypothyroidism can produce a very similar hyperlipoproteinemia. These patients have an increased risk of atherosclerosis.

Type IV hyperlipoproteinemia is the commonest abnormality. The VLDL levels are increased, often due to obesity, alcohol abuse, or diabetes. Familial forms are also known.

Type V hyperlipoproteinemia is, like type I, associated with high chylomicron triacylglycerol levels, pancreatitis, and eruptive xanthomas.

Hypercholesterolemia also occurs in certain types of liver disease in which biliary excretion of cholesterol is reduced. An abnormal lipoprotein called lipoprotein X accumulates. This disorder is not associated with increased cardiovascular disease from atherosclerosis.

Havel, R. J., and Kane, J. P. Introduction: Structure and metabolism of plasma lipoproteins. In Scriver, C. R., Beaudet, A. L.. Sly, W. S., and Valle, D. (Eds.), *The Metabolic and Molecular Basis of Inherited Disease*, 8th ed. New York: McGraw Hill, 2001, Chap. 114; and Goldstein, J. L., Hobbs, H. H., and Brown, M. S. Familial hypercholesterolemia. In Scriver, C. R., Beaudet, A. L., Sly, W. S., and Valle, D. (Eds.), *The Metabolic and Molecular Bases of Inherited Disease*, 8th ed. New York: McGraw-Hill, 2001, Chap. 120.

lipoproteins (**VLDLs**), and **ApoC** in IDLs and VLDLs. Each apolipoprotein class is genetically and structurally distinct (Clin. Corr. 3.4). Apolipoproteins vary from 6 kDa (ApoC-I) to 550 kDa for ApoB-100. The latter is a long polypeptide (4536 amino acids) and occurs in truncated form (the N-terminal 2512 residues only) as ApoB -48 in chylomicrons.

A model for the structure of a VLDL particle is shown in Figure 3.47. On the inside are neutral lipids such as cholesteryl esters and triacylglycerols. Surrounding this inner core of neutral lipids, is a shell ~20 Å thick, in which reside the proteins and the charged amphoteric lipids such as unesterified cholesterol and phosphatidylcholines (p. 460). Amphoteric lipids and proteins in the outer shell place their hydrophobic apolar regions toward the inside of the particle and their charged groups toward the outside where they interact with each other and with water.

CLINICAL CORRELATION 3.4

Hypolipoproteinemias

Abetalipoproteinemia is a genetic disease that is characterized by absence of chylomicrons, VLDLs, and LDLs due to an inability to synthesize apolipoproteins apoB-100 and apoB-48. There is accumulation of lipid droplets in small intestinal cells, malabsorption of fat, acanthocytosis (spiny-shaped red cells), and neurological disease (retinitis pigmentosa, ataxia, and retardation).

Tangier disease, a α-lipoprotein deficiency, is a rare autosomal recessive disease in which the HDL level is 1–5% of its normal value. Clinical features are due to the accumulation of cholesterol in the lymphoreticular system, which may lead to hepatomegaly and splenomegaly. The plasma cholesterol and phospholipids are greatly reduced.

Deficiency of the enzyme lecithin:cholesterol acyltransferase is a rare disease that results in the production of lipoprotein X (see Clin. Corr. 3.5). Also characteristic is the decrease in the α-lipoprotein and pre-β-lipoprotein bands and increase in β-lipoprotein because of the presence of lipoprotein X on electrophoresis.

[a]Subclasses of HDL.

This lipoprotein particle model applies to all classes of plasma lipoproteins. As the diameter of a particle decreases, the outer shell makes up a greater percentage of the total particle. Thus, the smaller particles have a higher percentage of the surface protein and amphoteric lipid molecules than the larger particles. The HDL particles, which are much smaller than VLDL particles, thus consist of 45% protein and 55% lipid, while the VLDL particles consist of 10% protein with 90% lipid (Table 3.15).

The apolipoproteins have high α-helical content when in association with lipid. Their helical regions are amphipathic since every third or fourth amino acid is charged. These residues form a polar edge that associates with the polar heads of phospholipids and the aqueous environment. The opposite sides of the helices have hydrophobic side chains that are oriented toward the nonpolar core of the lipoprotein particle. The α-helical structure of part of ApoC-I is shown in Figure 3.48. ApoB contains α-helical and β-strand segments. A single long polypeptide of ApoB-100 circles the circumference of the LDL particle like a belt weaving in and out of the phospholipid outer shell (Figure 3.47).

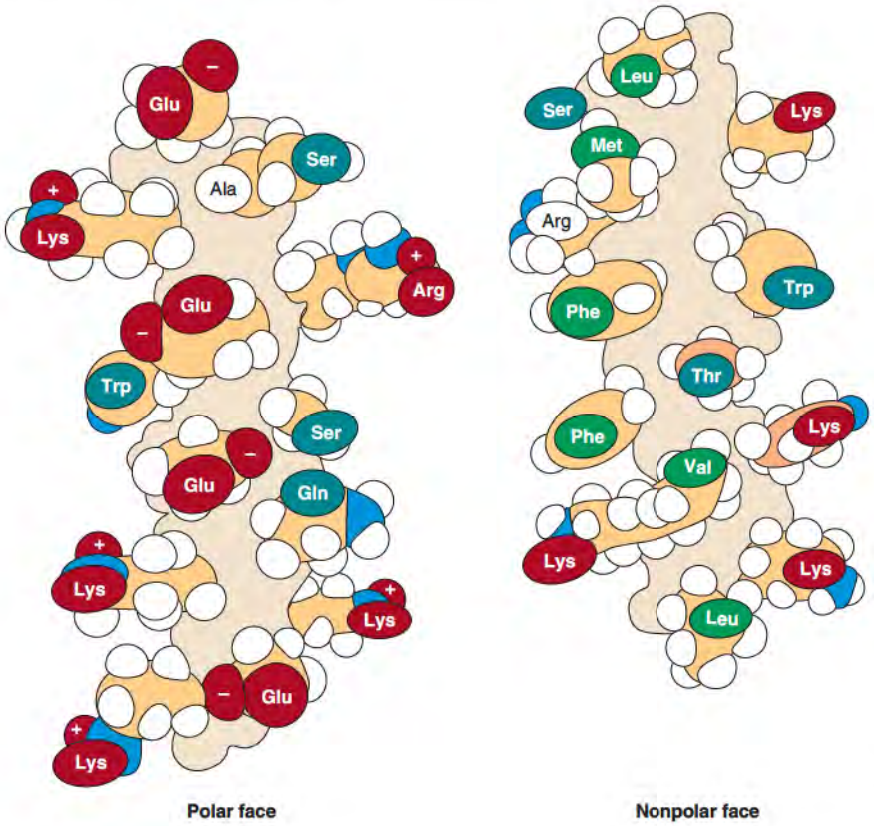

Figure 3.48 Side chains of a helical amphipathic segment of apolipoprotein C-1 between residues 32 and 53. The polar face shows acid residues in the center and basic residues at the edge. On the other side of the helix, hydrophobic residues form a nonpolar longitudinal face.

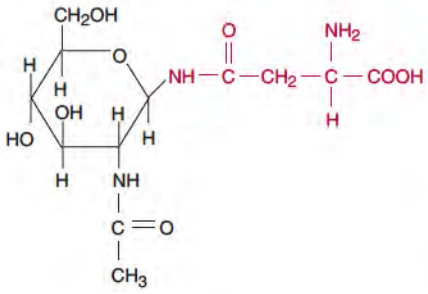
Glycoproteins Contain Covalently Bound Carbohydrate

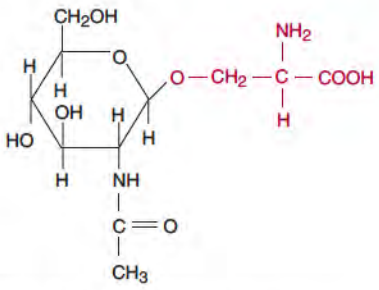
Glycoproteins contain a single or multiple amino acids covalently bonded to carbohydrate (sugar) molecules. Glycoproteins participate in many normal and disease-related functions of clinical relevance. The best-characterized glycoproteins are those of the outer surface of plasma membranes, the extracellular matrix, and blood plasma. Those on plasma membranes provide information for identification of cells by other cells and for regulation of cell growth by contact inhibition. They also provide the antigenic determinants of the various blood group systems (e.g., ABO and Rh) on erythrocytes, the histocompatibility of tissue transplants, and the cellular receptors for hormones, neurotransmitters, and viruses. Tumorigenesis and malignant transformation are associated with changes in the glycoprotein composition of plasma membranes. In the extracellular matrix, many proteins (e.g., collagen and laminin) contain attached carbohydrate as do proteins of mucous secretions that lubricate and protect surfaces. The major plasma proteins (but not albumin) are glycoproteins, including blood-clotting proteins, immunoglobulins, complement proteins, and follicle-stimulating hormone, luteinizing hormone and thyroid-stimulating hormone.

The amount of carbohydrate in glycoproteins is variable. IgG contains 4% by weight, glycophorin of human erythrocyte membranes 60%, and human gastric glycoprotein 82%. The carbohydrate can be distributed evenly along the polypeptide chain or concentrated in defined regions. In proteins of plasma membrane, carbohydrate is attached only on the extracellular portion. The attached carbohydrate usually contains less than 15 sugar residues and in some cases only one. Glycoproteins with the same function from different animal species often have homologous amino acid sequences but vary in their carbohydrate. Heterogeneity in carbohydrate content is common in the same protein even within a single organism. For example, pancreatic ribonuclease A and B forms have an identical amino acid sequence but differ in their carbohydrate composition.

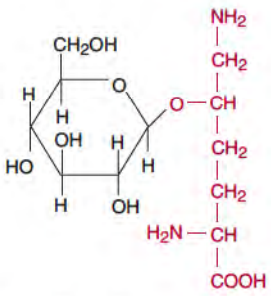
The incorporation of carbohydrate occurs in a series of enzyme-catalyzed reactions as the polypeptide chain is transported through the endoplasmic reticulum and Golgi network (p. 17).



Type I *N*-Glycosyl linkage to asparagine



Type II *O*-Glycosyl linkage to serine



Type III *O*-Glycosyl linkage to 5-hydroxylysine

Figure 3.49 Examples of glycosidic linkages to amino acids in proteins. Type I is an *N*-glycosidic linkage through an amide nitrogen of Asn, type II is an *O*-glycosidic linkage through OH of Ser or Thr, and type III is an *O*-glycosidic linkage to 5-OH of 5-hydroxylysine.

Carbohydrate–Protein Covalent Linkages

The two most common carbohydrate linkages are the ***N*-glycosidic linkage** (type I linkage) between the amide group of asparagine and a sugar, and the ***O*-glycosidic linkage** (type II linkage) between a hydroxyl group of serine or threonine and a sugar (Figure 3.49). In type I the bond is to asparagine within the sequence Asn-X-Thr(Ser). Mammalian glycoproteins also contain *O*-glycosidic bonds to 5-hydroxylysine (type III linkage). This occurs in collagens and in the serum complement protein C1q. Less common are attachments to the hydroxyl group of 4-hydroxyproline (type IV linkage), to a cysteine thiol (type V linkage), and to an α-amino group of a polypeptide chain (type VI linkage). High concentrations of type VI linkages are formed nonenzymatically with hemoglobin and blood glucose in uncontrolled diabetes. Assay of glycosylated hemoglobin is used to follow changes in blood glucose concentration (Clin. Corr. 3.5).

3.7 • FOLDING OF PROTEINS FROM RANDOMIZED TO UNIQUE STRUCTURES: PROTEIN STABILITY

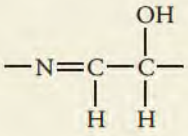
The Protein Folding Problem

The ability of a primary protein structure to fold spontaneously to its native secondary or tertiary conformation, without any information other than the amino acid sequence and the noncovalent forces that act on the sequence, has been demonstrated with many proteins. Thus pancreatic ribonuclease spontaneously refolds to its native conformation after being denatured and its disulfide bonds being reduced without the hydrolysis of peptide

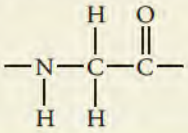
CLINICAL CORRELATION 3.5

Glycosylated Hemoglobin, HbA_{1c}

A glycosylated hemoglobin, designated HbA_{1c}, is formed nonenzymatically in red blood cells by combination of the NH_2 terminal amino groups of the hemoglobin β chains and glucose. The aldehyde form of glucose first forms a Schiff base with the NH_2 terminal amino group,



which then rearranges to a more stable amino ketone linkage,



by a spontaneous reaction known as the Amadori rearrangement. The concentration of HbA_{1c} depends on the concentration of glucose in the blood and the duration of hyperglycemia. In prolonged hyperglycemia, the concentration may rise to 12% or more of the total hemoglobin. Patients with diabetes mellitus have high concentrations of blood glucose and therefore high amounts of HbA_{1c}. The changes in the concentration of HbA_{1c} in diabetic patients can be used to follow the effectiveness of treatment for the diabetes.

Bunn, H. F. Evaluation of glycosylated hemoglobin in diabetic patients. *Diabetes* 30:613, 1980; and Brown, S. B., and Bowes, M. A. Glycosylated hemoglobins and their role in management of diabetes mellitus. *Biochem. Educ.* 13:2, 1985.

bonds. Such observations led to the hypothesis that a polypeptide sequence contains the information for spontaneous folding to its unique active conformation under correct solvent conditions and in the presence of prosthetic groups that may be a part of its structure. As described in the following, chaperone proteins may facilitate protein folding. Quaternary structures also assemble spontaneously, after the tertiary structure of the subunits has formed.

It may appear surprising that a polypeptide chain folds into a single unique conformation given all the possible rotational conformations available around single bonds in its primary structure. For example, the α-chain of hemoglobin contains 141 amino acids and there are at least four single bonds per amino acid residue around which free rotation can occur. If each bond about which free rotation occurs has two or more stable rotamer conformations accessible to it, then there are a minimum of 4^{141} or 5×10^{86} possible conformations for the α-chain polypeptide.

The conformation of a protein is the one of lowest Gibbs free energy accessible to its sequence within a physiological time frame. Thus folding is under both thermodynamic and kinetic control. While a detailed knowledge of *de novo* folding of a polypeptide has at present been proposed for only a few examples, the involvement of certain processes appears reasonable in the majority of folding reactions. There is evidence that folding is initiated by short-range noncovalent interactions between a side chain and its nearest neighbors that form secondary structures in small regions of the polypeptide. Particular side chains have a propensity to promote the formation of α-helices, β-strands, and sharp turns or bends (β-turns) in the polypeptide. Such regions of polypeptide, called **initiation sites**, spontaneously assume a secondary structure. The partially folded structures then interact with each other to form a **molten-globule** state. This is a condensed intermediate on the folding pathway that contains much of the secondary structure elements of the native conformation, but many incorrect tertiary structure interactions. Regions of secondary structure in the molten-globule state are highly mobile relative to one another, and the molten globule is in rapid equilibrium with the fully unfolded state. The correct medium- and long-range interactions between different initiation sites are found by rearrangements within the molten globule, and the low free energy, native conformation of the polypeptide chain is formed. This is followed by formation of disulfide bonds (cystines). The rate-determining step for folding and unfolding of the native conformation lies between the molten globule and the native structure. For some proteins there may exist two or more thermodynamically stable folded conformations of low Gibbs free energy. Clin. Corr. 3.6 contains a discussion of proteins folding and prion infectious agents.

CLINICAL CORRELATION 3.6

Prion Diseases and Proteins as Infectious Agents: Human Transmissible Spongiform Encephalopathies (TSEs)

Prion proteins are able to act as infectious agents in the absence of DNA or RNA. Prion disease in humans can also appear spontaneously (sporadic disease) or due to the inheritance of a mutated prion protein gene. The disease is characterized by ataxia, dementia, and paralysis and is almost always fatal. Pathological examination of the brain shows amyloid plaques and spongiform (vacuolar) degeneration.

In prion disease, **PrP^c** refers to the highly soluble cellular conformation of the prion protein, and **PrP^{Sc}** to the insoluble toxic conformation originally isolated from sheep with scrapie (Sc) disease. The soluble PrP^c protein contains three α-helical and two small β-strand segments (Clin. Corr. Figure 1).

The conversion to the toxic PrP^{Sc} form is characterized by the conversion of an α-helical segment into a β-strand with the probable inducement of the addition of β-strands in the previously undefined N-terminal end of the polypeptide chain (Clin. Corr. Figure 1). The PrP^{Sc} conformation initiates other prion PcP^c molecules to convert to the PcP^{Sc} conformation and, through β-strand interactions between PrP^{Sc} molecules, polymerizes into amyloid fibers. Formation of the amyloid polymer is irreversible and in the brain causes neuronal cell death. In several other neurodegenerative diseases similar conformational equilibriums occur between a soluble predominantly α-helical protein conformation and a less soluble β-strand containing conformation of the protein, with the β-strand conformation proteins polymerizing into insoluble amyloid fibrils (Clin. Corr. Figure 2). The protein unit differs with the disease type, but the plaque formed all have a similar amyloid fibril structure (Clin. Corr. Figure 2). Prominent amyloid induced neuronal diseases include Alzheimer, Parkinson, Huntington, and amyotrophic lateral sclerosis (ALS, Lou Gehrig).

Clin. Corr. Figure 1. Structure of Prion Forms (*a*) Prp (PrP^c) fold structure. Approximately 120 amino acid residues at N-terminal end not observed. (*b*) Model of the toxic PrP (PrP^{Sc}) fold structure, in which an α-helical segment from the PrPc conformation forms a β-strand as well as β-strands now formed from loop region of PrPSc structure and the N-terminal of the segment of the polypeptide chain.

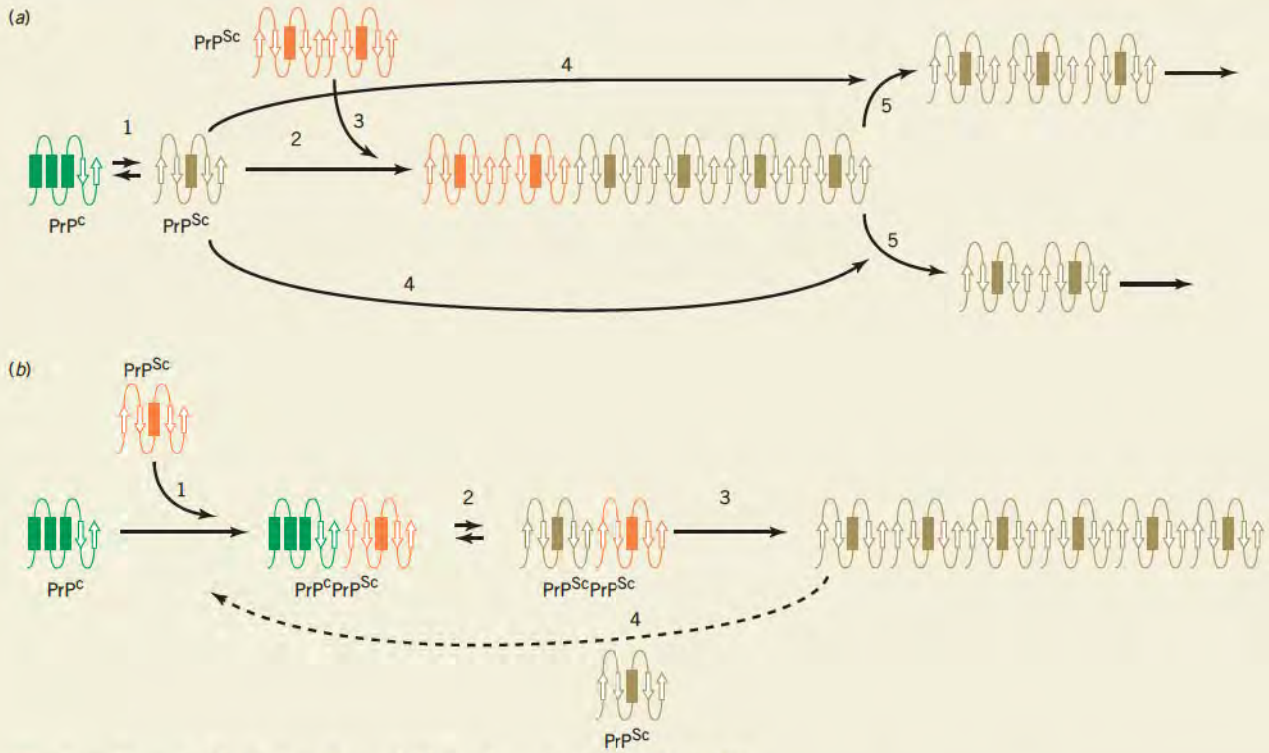
The prion protein is a glycoprotein containing covalently joined carbohydrate molecules and a phosphatidylinositol lipid. The lipid anchors the prion protein on the extracellular side of the plasma membrane. The PrP^c protein at the plasma membrane functions in conjugation with membrane receptor proteins in the transmission of extracellular signals to the cell.

Prion disease in humans is pleiotropic with the phenotype dependent on the cause of the disease (sporadic, inheritable, or infectious)



Clin. Corr. Figure 3. Mechanisms for amyloid fiber formation initiated by PrP^{Sc}.

and the type of polymorphisms presented in an individual's prion genes. There are multiple polymorphisms of the prion gene in the human population with over 50 reported mutations. Initiation of amyloid formation by a "seed" (initiator) PrP^{Sc} molecule can be through three different routes: (a) sporadic disease initiated by the spontaneous chance conformational transformation of a normal PrP^{c} molecule to the PrP^{Sc} conformation, (b) infective PrP^{Sc} proteins introduced through ingestion of PrP^{Sc} contaminated meat or the introduction of foreign PrP^{Sc} through other routes, and (c) inheritance of a mutated prion gene with ability of the gene product to more easily spontaneously fold into a PrP^{Sc} conformation. Inherited phenotypes include Gerstmann–Sträussler–Scheinker syndrome and fatal familial insomnia. Sporadic disease results in Creutzfeldt–Jakob Disease (CJD) and is typically fatal within 1 year of the onset of illness. The incidence of CJD is 1 case per 1 million per year worldwide, which translates into approximately 300 cases per year in the United States. Sporadic disease accounts for approximately 85%, inherited forms for 15%, and infectious disease less than 1% of the prion diseases.

Prion disease caused by extraneous infectious PrP^{Sc} protein is most interesting, as it shows the ability of a protein to act as an infectious agent in the absence of DNA or RNA. Humans can acquire prion disease through the ingestion of bovine PrP^{Sc} conformation prions in contaminated meat from cattle with bovine transmissible spongiform encephalitis (BSE; mad cow disease). The disease, variant Creutzfeldt–Jakob Disease (vCJD), has a different phenotype than the classic sporadic CJD. The median age of onset for vCJD is 28 years, and 68 years for sporadic CJD. The duration of the illness is approximately 14 months for vCJD and 5 months for sporadic CJD. The Centers for Disease Control (CDC) has identified a total number of 195 cases of vCJD as of August 2006, of which 162 were in the United Kingdom, 20 in France, and 2 in the United States. The incubation period from time of infection to onset of the disease is approximately 10 years. Infection by BSE appears to be age selective. As the peak of the United Kingdom outbreak occurred between 1994 and 1996 in patients with a median age of 28, the infection occurred around 1984–1986 at a median age of the infected individuals of 18.

A second significant infectious route is iatrogenic. Between 1985 and 1996 there were 136 vCJD cases reported worldwide in patients treated with human pituitary-derived growth hormone and 136 cases of patients receiving cadaveric *dura mater* transplants. A small number of iatrogenic CJDs have been caused with other procedures such as corneal transplants, blood transfusion, and treatment with human gonadotrophin.

Two mechanisms are suggested for amyloid plaque formation initiated by an infective prion (Clin. Corr Figure 3). In the Nucleation-Polymerization Mechanism (*a*), PrP^{c} (green) is in rapid equilibrium with the PrP^{Sc} conformation (brown) (step 1), but the polymerization into an amyloid fiber is slow (step 2) in the absence of an initiator molecule. The introduction of a PrP^{Sc} infective prion (orange) nucleates the polymerization process (step 3). The process is propagated by fragments from the newly generated polymer (step 5).

In the Template-Directed Mechanism (*b*), the prion, PrP^{Sc}, serves as a template to promote the change in conformation of endogenous PrP^{c} to PrP^{Sc} (steps 1 and 2). Once converted to the PrP^{Sc}, the PrP^{Sc} rapidly polymerize into insoluble fibrils.

Chaperone Proteins Assist the Protein Folding Process

Cells contain proteins that facilitate the folding process. These include *cis–trans*-prolyl isomerases, protein disulfide isomerases, and chaperone proteins. ***cis–trans*-prolyl isomerases** interconvert cis and trans peptide bonds of proline residues. This allows the correct prolyl peptide bond conformation to form for each proline as required by the native conformation. **Protein disulfide isomerases** catalyze the breakage and formation of disulfide cystine linkages so incorrect linkages are not stabilized and the correct arrangement of linkages for the native conformation is rapidly achieved.

Chaperone proteins were discovered as **heat shock proteins (hsps)**, a family of proteins whose synthesis is increased at elevated temperatures. The chaperones do not change the final outcome of the folding process but prevent protein aggregation prior to completion of folding and prevent formation of metastable dead-end or nonproductive intermediates. Chaperones of the hsp 70-kDa family bind to polypeptides as they are synthesized on the ribosomes, shielding the hydrophobic surfaces that would normally be exposed to solvent. This protects the protein from aggregation until the full chain is synthesized and folding can occur. Some proteins, however, cannot complete their folding process while in the presence of hsp70 chaperones and are delivered to the hsp60 family (GroEL in *Escherichia coli*) of chaperone proteins, also called **chaperonins**. The chaperonins are long cylindrical multisubunit structures that bind unfolded polypeptides in their molten-globule state within their central hydrophobic cavity. Chaperonins have an ATPase activity and hydrolyze ATP as they facilitate folding. The chaperonin hsp60-assisted folding in *E. coli* is presented in Figure 3.50. Chaperone proteins are also required for refolding of proteins after they cross cellular membranes. A system of chaperones facilitates protein transport into mitochondria and into and through the endoplasmic reticulum. Proteins cross the lipid bilayer of the mitochondrial and endoplasmic reticulum membranes in an unfolded conformation, and local chaperones are often required to facilitate their folding within the intracellular organelle.

Noncovalent Forces Lead to Protein Folding and Contribute to a Protein's Stability

Noncovalent forces cause a polypeptide to fold into a unique native conformation and then stabilize the native structure against denaturation. Noncovalent forces are weak bonding forces with strengths of 4–29 kJ/mol (1–7 kcal/mol). This may be compared to covalent bonds that have a bonding strength of at least 210 kJ/mol (50 kcal/mol) (Table 3.16). Even though individually weak, the large number of noncovalent contacts within a protein provides a large energy factor that promotes protein folding.

Hydrophobic Interaction Forces

Important noncovalent forces that cause a polypeptide to fold into its native conformation are the **hydrophobic interaction forces**. Their strength is not due to any intrinsic attraction between nonpolar groups but rather to the properties of water that surround the

TABLE 3.16 • Strength of Bonds Found in Protein Structures

	Bond Strength	
Bond Type	($kJmol^{-1}$)	($kcal\ mol^{-1}$)
Covalent	>210	>50
Noncovalent	2.5–29	0.6–7
Hydrophobic (i.e., two benzyl side chain groups of Phe)	8–13	2–3
Hydrogen	4–290	1–7
Ionic (low dielectric environment)	4–25	1–6
van der Waals	<4	<1

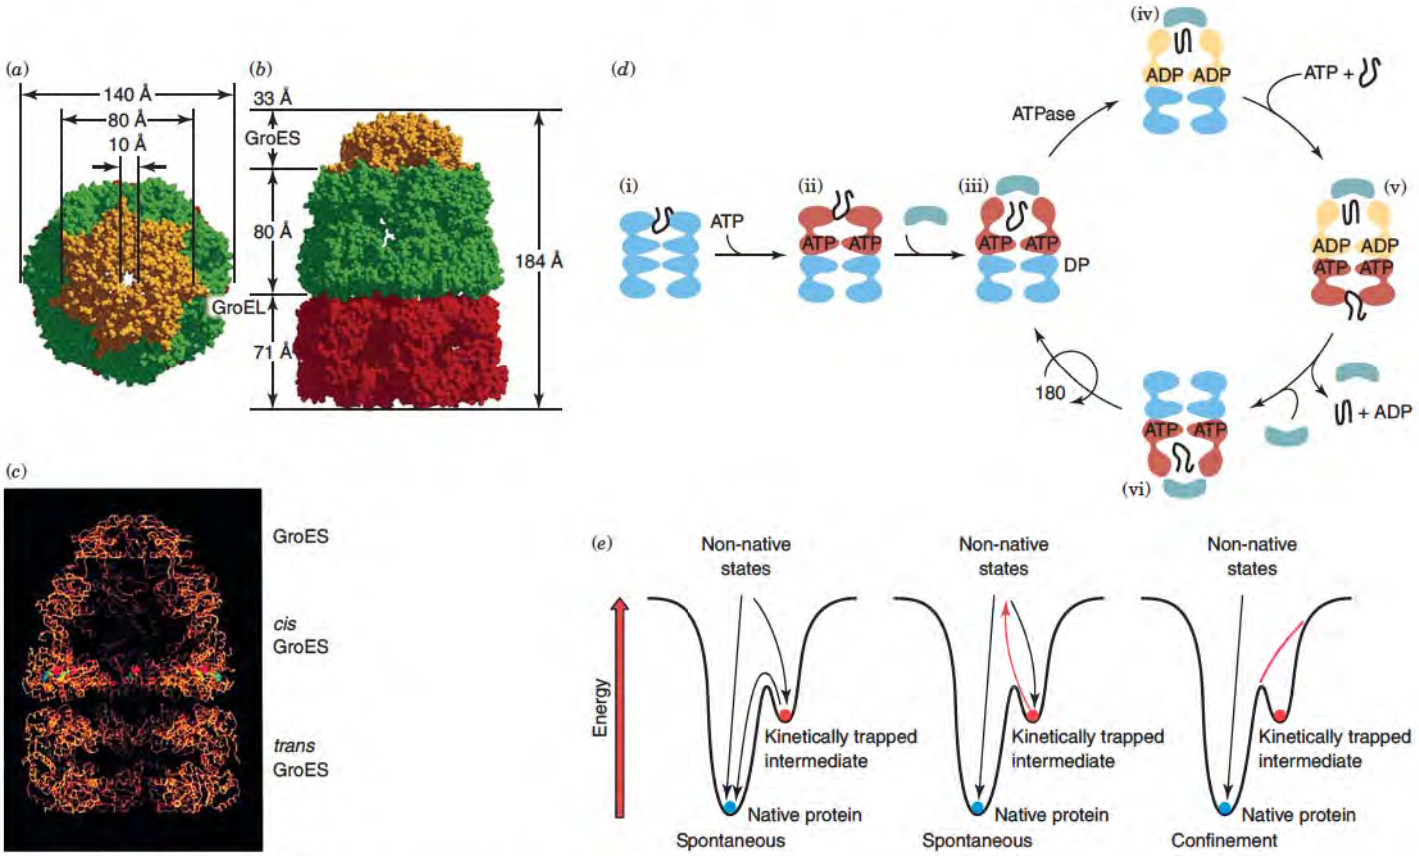

Figure 3.50 The GroEL-GroES Chaperonin system for protein folding. (*a*) Space-filling model of the entire chaperonin complex in a top view looking down from the GroES cap protein. The GroES is bound to the cis side of GroEL. GroES has 7 polypeptide subunits of 10 kD molecular weight and the GroEL cis and trans cylinder structures are each composed of 7 polypeptide subunits (total 14) each of 60 kD. (*b*) As (*a*) but in a side view, with the trans GroEL ring in red, the cis GroEL ring in green, and the GroES cap in gold. (*c*) Ribbons drawing of a slice through the center of the chaperonin complex showing internal cavities of the cis and trans cylindrical sections where denatured proteins enter and their folding occurs. (*d*) Simplified scheme for GroEL facilitated protein folding: (i) The denatured protein (black curved line) enters the GroEL and binds in the cavity with high affinity (black curved line), (ii) the ATP binds to one ring producing an altered conformation, (iii) the ATP-bound ring binds GroES to sequester the denatured protein in the folding chamber and a massive conformational change in the GroES-bound ring pulls open the denatured protein to untangle its nonproductive conformation and then releases the protein within the expanded cavity to fold spontaneously, (iv) the protein folds inside the chamber and ATP is hydrolyzed, (v) the ATP binds to the trans ring which releases GroES and the folded protein, and (vi) a new protein gets encapsulated. (*e*) Free-energy diagrams for protein folding. Left: Folding of protein in the absence of chaperonin results in a kinetically trapped intermediate. Middle: In chaperonin folding the pulling and release on chaperonin chamber expansion (annealing) untangles trapped intermediate and gives protein additional chances to fold without being trapped. Right: In addition the GroEL cavity smoothes the energy landscape to prevent the formation of certain kinetically trapped intermediates.

Copyright (2002) AAAS.

nonpolar groups. A nonpolar side chain or a region of a protein molecule dissolved in water induces a solvation shell of water in which water molecules are highly ordered. When two nonpolar side chains come together, the surface area exposed to solvent is reduced and some of the highly ordered water molecules in the solvation shell are released to bulk solvent. The entropy of the system (i.e., net disorder of the water molecules in the system) is increased. The increase in entropy is thermodynamically favorable and is the driving force causing nonpolar moieties to come together in aqueous solvent. A favorable free energy change of 8 kJ/mol (2 kcal/mol) for association of two phenylalanine side chains in water is due to this gain in entropy (Figure 3.51).

In transition from random to regular secondary conformation such as an α-helix or β-structure, approximately one-third of the water of solvation about the unfolded polypeptide is lost to bulk solvent. This approximates 2–4 kJ/mol (0.5–0.9 kcal/mol) for each peptide residue. Another one-third of the original solvation shell is lost when a polypeptide attains its native conformation. This brings different segments of folded polypeptide chain into close proximity with the release of water of solvation between these segments.

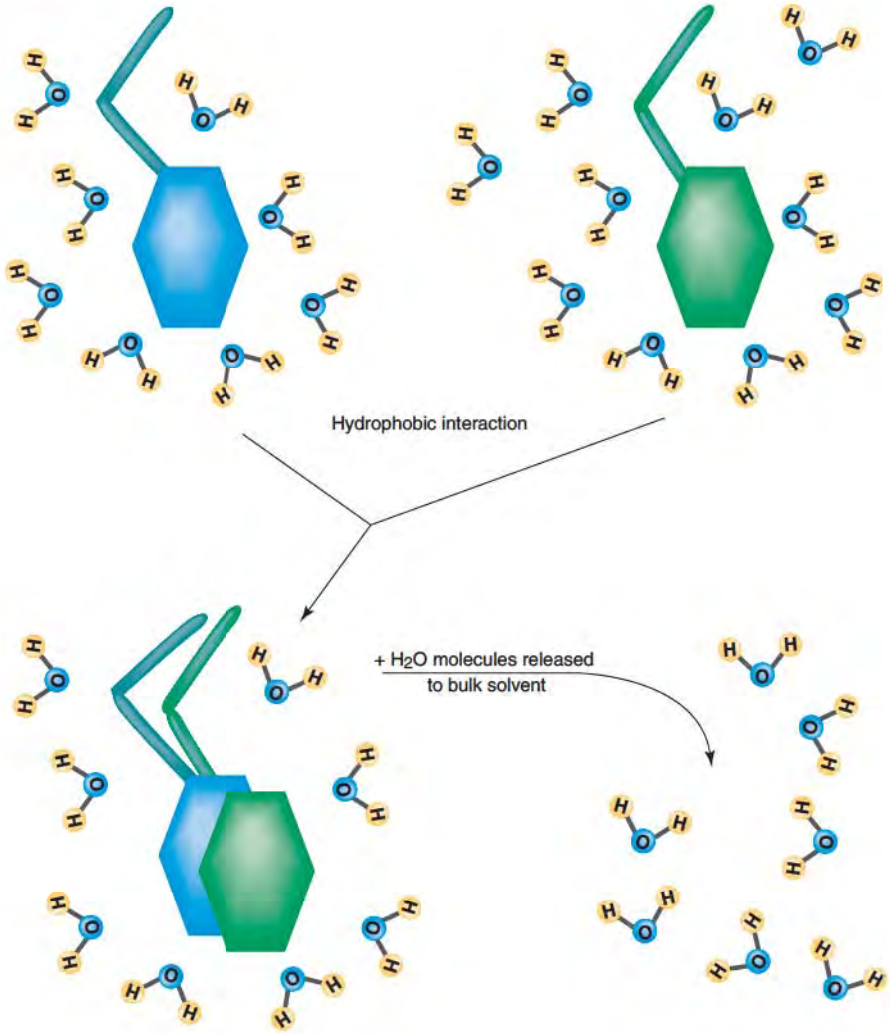

Figure 3.51 **Formation of hydrophobic interaction between two phenylalanine side-chain groups.**

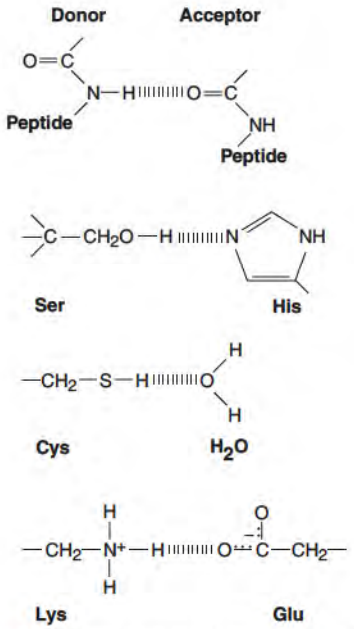

Figure 3.52 **Some common hydrogen bonds found in proteins.**

Hydrogen Bonds

Hydrogen bonds are formed when a hydrogen atom covalently bonded to an electronegative atom is shared with a second electronegative atom. The atom to which the hydrogen atom is bonded is designated the hydrogen **donor atom**. The atom with which the hydrogen atom is shared is the hydrogen **acceptor atom**. Typical hydrogen bonds found in proteins are shown in Figure 3.52. α-Helical and β-strand conformations are extensively hydrogen bonded.

The strength of a hydrogen bond depends on the distance between donor and acceptor atoms. High bonding energies occur when this distance is between 2.7 and 3.1 Å. Of lesser importance, but not negligible, is the dependence of hydrogen-bond strength on geometry. Bonds of higher energy are geometrically collinear, with donor, hydrogen, and acceptor atoms lying in a straight line. The dielectric constant of the medium around the hydrogen bond may also be reflected in the bonding strength. Typical hydrogen bond strengths in proteins are 4–29 kJ/mol (1–7 kcal/mol). Although they contribute to thermodynamic stability of a protein's conformation, their formation may not be a major driving force for folding. This is because peptide bonds and other hydrogen-bonding groups form hydrogen bonds to the water solvent in the denatured state, and these bonds must be broken before the polypeptide can fold. In calculating the net contribution of hydrogen-bonding forces to the folding, the energy required to break the hydrogen bonds to water must be subtracted from that gained from the formation of new hydrogen bonds between atoms in the folded protein.

Electrostatic Interactions

Electrostatic interactions (**ionic** or **salt linkages**) between charged groups are important in the stabilization of protein structure and in binding of charged ligands and substrates to

proteins. Electrostatic forces are repulsive or attractive depending on whether the interacting charges are of the same or opposite sign. The strength of an electrostatic force (E_{el}) is directly dependent on the charge (Z) of each ion and inversely dependent on the dielectric constant (D) of the solvent and the distance between the charges (r_{ab}) (Figure 3.53).

Water has a high dielectric constant ($D = 80$), and charge interactions in water are relatively weak compared to those in the interior of a protein where the dielectric constant is low. However, most charged groups remain on the surface where they do not interact with other charged groups from the protein because of the high dielectric constant of water, but are stabilized by hydrogen bonding and polar interactions with water. These interactions generate the dominant forces that place most charged groups of a protein on the outside of the folded structures.

$$E_{el} \approx \frac{Z_A \cdot Z_B \cdot \varepsilon^2}{D \cdot r_{ab}}$$

Figure 3.53 Strength of electrostatic interactions.

van der Waals Forces

van der Waals forces are the weakest of the noncovalent forces. They have an attractive term (A) inversely dependent on the sixth power of the distance between two interacting atoms (r_{ab}), and a repulsive term (B) inversely dependent on the 12th power of this distance (Figure 3.54). The A term contributes at its optimum distance an attractive force of less than 4 kJ/mol (1 kcal/mol) per atomic interaction due to the induction of complementary partial charges or dipoles in the electron density of adjacent atoms when the electron orbitals of the two atoms approach to a close distance. As the atoms come even closer, however, the repulsive component (term B) of the van der Waals force predominates as the electron orbitals of the adjacent atoms begin to overlap. The repulsive force is commonly called **steric hindrance**.

$$E_{VDW} = -\frac{A}{r_{ab}^6} + \frac{B}{r_{ab}^{12}}$$

Figure 3.54 Strength of van der Waals interactions.

The distance of maximum favorable interaction between two atoms is the **van der Waals contact distance**, which is the sum of van der Waals radii for the two atoms (Figure 3.55). The van der Waals radii for atoms found in proteins are given in Table 3.17.

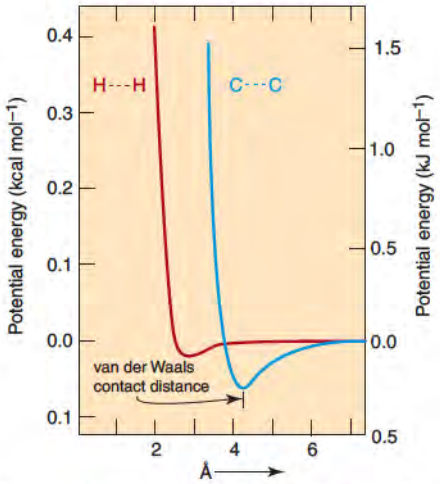

Figure 3.55 van der Waals–London dispersion interaction energies between two hydrogen atoms and two carbon (tetrahedral) atoms. Negative energies are favorable and positive energies unfavorable.
Redrawn from Fersht, A. *Enzyme Structure and Mechanism.* San Francisco: Freeman, 1977, 228.

The van der Waals repulsive forces between atoms of a peptide bond are weakest at the specific φ and ψ angles compatible with the α-helix and β-strand conformations. Thus, the absence of a van der Waals repulsive force is critical for secondary structure formation in proteins. In attaining the native conformation, the number of weak van der Waals interactions involved is in the thousands. The total contribution to the stability of a folded structure is substantial.

A special type of interaction (π-electron–π-electron) occurs when two aromatic rings approach each other with electrons of their aromatic rings interacting favorably (Figure 3.56). This interaction can result in attractive forces of up to 25 kJ/mol (6 kcal/mol).

TABLE 3.17 • Covalent Bond Radii and van der Waals Radii for Selected Atoms

Atom	*Covalent Radius (Å)*	*van der Waals Radius (Å)*[a]
Carbon (tetrahedral)	0.77	2.0
Carbon (aromatic)	0.69 along double bond	1.70
	0.73 along single bond	
Carbon (amide)	0.72 to amide N	1.50
	0.67 to oxygen	
	0.75 to chain C	
Hydrogen	0.33	1.0
Oxygen (—O—)	0.66	1.35
Oxygen (=O)	0.57	1.35
Nitrogen (amide)	0.60 ro amide C	1.45
	0.70 to hydrogen bond H	
	0.70 to chain C	
Sulfur, diagonal	1.04	1.70

[a]The van der Waals contact distance is the sum of the rwo van der Waals radii for the two atoms in proximity.

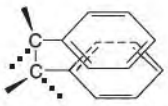

Figure 3.56 π-Electron–π-electron interactions between two aromatic rings.

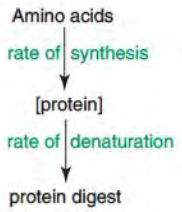

Figure 3.57 Steady-state concentration of a protein is due to its rates of synthesis and denaturation.

Denaturation Leads to Loss of Native Structure

Denaturation occurs when a protein loses its native secondary, tertiary, and/or quaternary structure. The peptide bonds are not broken by conformational denaturation. The **denatured state** is always correlated with loss of a protein's function. Loss of function is not necessarily synonymous with denaturation since small conformational changes can lead to loss of function without loss of the folded native structure. For example, a change in position of a single side chain in the active site of an enzyme or in protonation of a side chain may result in loss of enzyme activity but not to a loss of the native conformation.

Although conformational differences between denatured and native structures may be substantial, the free energy difference between such structures is typically as low as 20–40 kJ/mol (5–10 kcal/mol) (the energy of three or four noncovalent bonds). Thus, loss of a single hydrogen bond or electrostatic or hydrophobic interaction can lead to destabilization of a folded structure. Such a change in stability of a noncovalent bond can, in turn, be caused by a change in pH, ionic strength, or temperature. Presence of prosthetic groups, cofactors, and substrates also affects stability of its native conformation.

The statement that breaking of a single noncovalent bond can cause denaturation apparently conflicts with the observation that an amino acid sequence can often be extensively varied without loss of a protein's structure. The key to the resolution of this apparent conflict is the word "*essential*." Many noncovalent interactions are not essential for the structural stability of the native conformation of a protein. However, substitution or modification of an essential amino acid that provides a critical noncovalent interaction without a compensating stabilizing interaction dramatically affects the stability of a native protein conformation.

The cellular concentration of a protein is controlled by its rate of synthesis and of degradation (Figure 3.57). Under many circumstances the denaturation of a protein is the rate-controlling step in its degradation. Cellular enzymes and organelles that digest proteins "recognize" denatured proteins and eliminate them rapidly. In experimental situations, protein denaturation occurs on addition of urea, guanidine hydrochloride, or detergents (e.g., sodium dodecyl sulfate) that weaken hydrophobic bonding in proteins and stabilize the denatured state. Addition of a strong base, acid, or organic solvent or heating to temperatures above 60°C are also common ways to denature a protein.

3.8 • DYNAMIC ASPECTS OF PROTEIN STRUCTURE

Although high-resolution X-ray diffraction yields atomic coordinates for each atom in a protein, experimental evidence from NMR, fluorescence spectroscopy, and the temperature dependence of the X-ray diffraction reveals that the atoms in a protein molecule have a fluid-like dynamic motion and do not exist in one static position. Rather than an exact location, the atomic coordinates obtained by X-ray diffraction represent the time-averaged position for each atom. The time for position averaging is the duration of data collection, which may be up to several hours. Thus the active conformation may differ from the average conformation. An X-ray structure also shows small defects in packing of the folded structure, indicating the existence of holes in the structure that allow the protein space for flexibility. The concept that each atom in a protein is in constant motion, like molecules within a fluid, although constrained by its covalent bonds and the secondary and tertiary structure, is an important aspect of protein structure.

Calculations of theoretical **molecular dynamics** describe the changes in the coordinates of atoms in a protein structure and in the position of regions of the structure due to summation of the movements of atoms in that region. The computation is based on the solving of Newton's equations of motion simultaneously for all the atoms of the protein and the solvent that interacts with it. The energy functions used in the equation include representations of covalent and noncovalent bonding energies due to electrostatic forces, hydrogen bonding, and van der Waals forces. Individual atoms are randomly assigned a velocity from a theoretical distribution and Newton's equations are used to relax the system at a given temperature. The calculation is a computationally intensive activity, even when limited to less than several hundred picoseconds

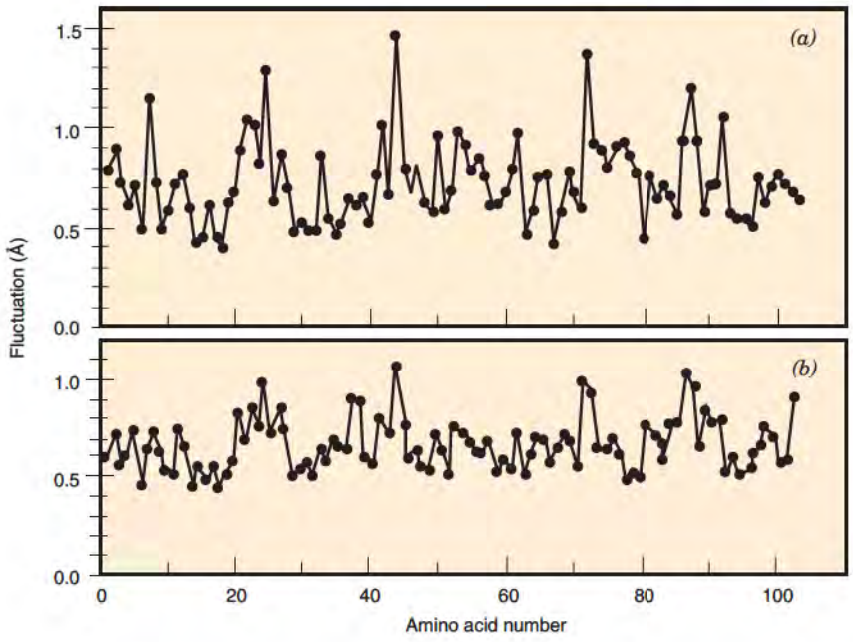

Figure 3.58 Fluctuation of structure of cytochrome c. (*a*) Calculated fluctuation on a picosecond time scale of α-carbons within each amino acid residue in folded structure of cytochrome c. (*b*) Experimentally observed fluctuation of each α-carbon of the amino acid residues determined from the temperature dependency of the X-ray diffraction pattern for the protein. Cytochrome-c has 103 amino acid residues. The *x*-axis plots amino acid residues in cytochrome-c from 1 to 103, and the *y*-axis the fluctuation distances in angstroms. (1 ps = 10^{-12} s) of protein dynamic time. Such calculations indicate that the average atom in a protein oscillates over a distance of 0.7 Å on the picosecond scale. Some atoms or groups of atoms move smaller or larger distances than this calculated average (Figure 3.58).

Net movement of any segment of a polypeptide over time represents the sum of forces due to rapid atomic oscillations, and the local jiggling and elastic movements of covalently attached groups of atoms. These movements within the closely packed interior of a protein frequently allow the buried planar aromatic rings of tyrosines to flip. The small amplitude fluctuations provide the "lubricant" for large motions in proteins such as domain motions and quaternary structure changes, like those observed in hemoglobin on O_2 binding (p. 358). The dynamic behavior of proteins is the basis for conformational changes induced by substrate, inhibitor, or drug on binding to an enzyme and receptor, generation of allosteric effects in hemoglobins, electron transfer in cytochromes and in the formation of supramolecular assemblies such as viruses. The movements may also have a functional role in the catalytic action of enzymes.

3.9 • CHARACTERIZATION, PURIFICATION, AND DETERMINATION OF PROTEIN STRUCTURE AND ORGANIZATION

Separation of Proteins on Basis of Charge

In **electrophoresis**, protein dissolved in a buffer solution at a particular pH is placed in an electric field. Depending on the relationship of the buffer pH to the pI of the protein, the protein moves toward the cathode (−) or the anode (+) or remains stationary (pH = pI). Supports such as polymer gels (e.g., polyacrylamide, agarose, and cellulose acetate) are used. The inert supports are saturated with buffer solution, a protein sample is placed on the support as a line or spot, an electric field is applied across the support, and the charged proteins migrate as zones in the support toward the oppositely charged pole.

A technique of extremely high resolution is **isoelectric focusing**, in which mixtures of polyamino-polycarboxylic acid ampholytes with a defined range of pI values are used to establish a pH gradient across the applied electric field. A charged protein migrates through the pH gradient in the electric field until it reaches a pH region in the gradient equal to its pI value. At this point the protein becomes stationary and may be visualized (Figure 3.59). Proteins that differ by as little as 0.0025 in their pI values are separated on the appropriate pH gradient.

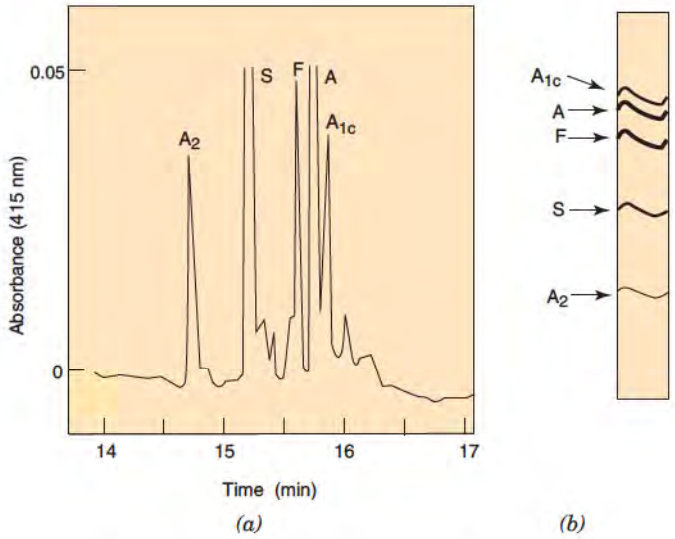

Figure 3.59 Isoelectric focusing of hemoglobins from a patient heterozygous for HbS and β-thalassemia. The figure shows the separation by isoelectric focusing of HbA_{1c} (HbA glycosylated on NH_2-end, see Clin. Corr. 3.5), normal adult HbA, fetal HbF, sickle-cell HbS (see Clin. Corr. 6.2; p. 214), and minor adult HbA_2. (*a*) Isoelectric focusing carried out by capillary electrophoresis with ampholyte pH range between 6.7 and 7.7 and detection of bands at 415 nm. (*b*) Isoelectric focusing carried out on gel with Pharmacia Phast System; ampholyte pH range is between 6.7 and 7.7.

Ion-exchange column chromatography is used for the preparative separation of proteins by charge. Ion-exchange resins consist of insoluble materials (agarose, polyacrylamide, cellulose, and glass) that contain charged groups (Figure 3.60). Negatively charged resins bind positively charged molecules and are **cation-exchange resins**. Positively charged resins bind anions strongly and are **anion-exchange resins**. The degree of retardation of a protein (or an amino acid) by a resin depends on the magnitude of the charge on the protein at the particular pH of the experiment. Molecules with the same charge as the resin are eluted first in a single band, followed by those with an opposite charge to that of the resin, in an order based on the protein's charge density (Figure 3.61). When it is difficult to remove a molecule from the resin because of the strength of the attractive interaction between the bound molecule and resin, systematic changes in pH or in ionic strength are used to weaken the interaction. For example, an increasing pH gradient through a cation-exchange resin reduces the difference between the solution pH and the pI of the bound protein. This decrease between pH and pI reduces the magnitude of the net charge on the protein and decreases the strength of the charge interaction between the protein and the resin. An increasing gradient of ionic strength also decreases the charge interactions, as the ions compete with the proteins for binding, and elutes tightly bound electrolytes from the resin.

Capillary Electrophoresis

Electrophoresis within a fused silica capillary tube has a high separation efficiency, utilizes very small samples, and requires only several minutes for an assay. A long capillary tube is filled with the electrophoretic medium, a sample is injected in a narrow band near the anode end of the tube, and the molecules of the sample are separated by their mobility toward the negatively charged pole. The fused silica wall of the capillary has a negative charge and an immobile cationic layer is fixed to it. An adjacent diffuse layer of cations moves toward the cathode in the applied electric field and causes a flow of solvent toward the cathode. This electro-osmotic flow creates a "current" that carries analyte molecules toward the cathode, irrespective of the charge of the analyte (Figure 3.62). Molecules with a high positive charge-to-mass ratio move with the current and have the highest mobility, followed by neutral molecules. Anionic molecules are repelled by the cathode and will move against the electro-osmotic flow. However, the electro-osmotic current toward the cathode overcomes any negative migration, and anions also migrate toward the cathode but at a slower rate than the cationic or neutral molecules.

In zone electrophoresis separations are made in the presence of a single buffer. Capillary electrophoresis may be performed in the presence of ampholytes to separate proteins by isoelectric focusing, in the presence of a porous gel to separate proteins by molecular weight or in the presence of a micellar component to separate by hydrophobicity. Detectors that utilize UV light, fluorescence, Raman spectroscopy, electrochemical detection, or mass spectroscopy make the capillary method sensitive and versatile.

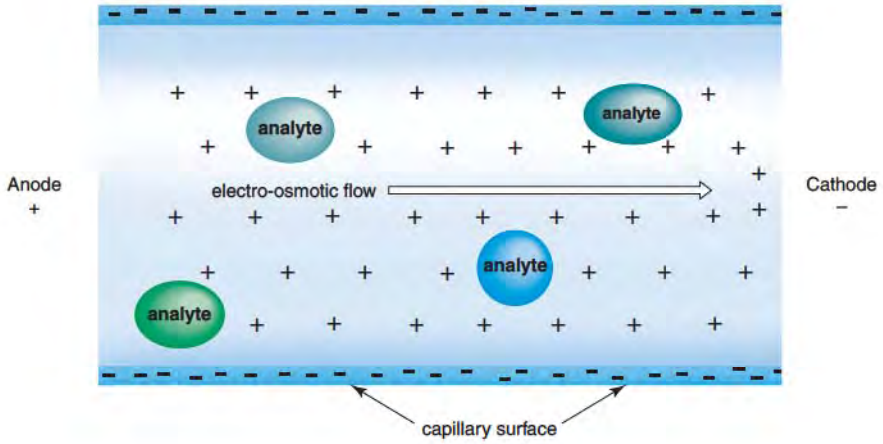

Figure 3.62 Generation of electro-osmotic flow toward the cathode in capillary electrophoresis.

Separation of Proteins Based on Molecular Mass or Size

Ultracentrifugation: Definition of Svedberg Coefficient

A protein subjected to centrifugal force moves in the direction of the force at a velocity dependent on its mass. The rate of movement is measured with an appropriate optical detection system, and from the rate, the sedimentation coefficient is calculated in **Svedberg units** (units of 10^{-13}s). In the equation (Figure 3.63), v is the measured velocity of protein movement, ω the angular velocity of the centrifuge rotor, and r the distance from the center of the tube in which the protein is placed to the center of rotation. Sedimentation coefficients between 1 and 200 Svedberg units (S) have been found for proteins (Table 3.18). Equations have been derived to relate the sedimentation coefficient to the molecular mass of a protein. One of the more simple equations is shown in Figure 3.64, in which R is the gas constant, T the temperature, s the sedimentation coefficient, D the diffusion coefficient of the protein, v the partial specific volume of the protein, and ρ the density of the solvent. The quantities D and v must be measured in independent experiments. The equation assumes a spheroidal geometry for the protein. Because this assumption may not be true and independent measurements of D and v are difficult, usually only the sedimentation coefficient for a molecule is reported. A protein's sedimentation coefficient is a qualitative measurement of its molecular mass.

$$s = \frac{v}{\omega^2 r}$$

Figure 3.63 Equation for calculation of the Svedberg coefficient.

$$\text{Molecular weight} = \frac{RTs}{D(1 - \bar{v}\rho)}$$

[a] $s_{20,} \times 10^{-13}$, is sedimentation coefficient in Svedberg units, referred to water at 20°C, and extrapolated to zero concentration of protein.

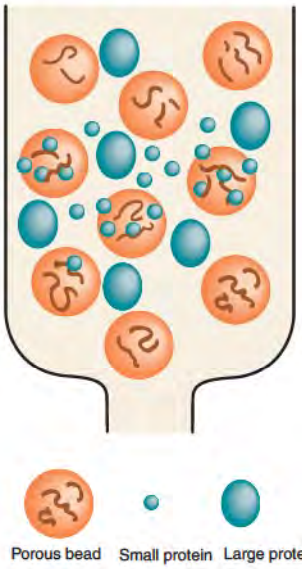

Figure 3.65 Molecular exclusion chromatography. A small protein can enter the porous gel particles and will be retarded on the column with respect to a larger protein that cannot enter the porous gel particles.

solvent volume through which to travel in the column than large proteins, which are sterically excluded from the pores. Accordingly, a protein mixture is separated by size. The larger proteins are eluted first, followed by the smaller proteins, which are retarded by their accessibility to a larger solvent volume (Figure 3.65). As with ultracentrifugation, an assumption is made as to the geometry of an unknown protein in the determination of molecular mass. Elongated nonspheroidal proteins as well as glycoproteins often give anomalous molecular masses when analyzed using a standard curve determined with proteins of spheroidal geometry.

Polyacrylamide Gel Electrophoresis in the Presence of a Detergent

If a charged detergent is added to a protein electrophoresis assay and electrophoresis occurs through a sieving support, separation of proteins is based on protein size and not charge. A common detergent is **sodium dodecyl sulfate (SDS)** and a common sieving support is **cross-linked polyacrylamide**. The dodecyl sulfates are amphiphilic C12 alkyl sulfates, which stabilize a denatured protein by forming a charged micellar SDS solvation shell around its polypeptide chain. The inherent charge of the polypeptide chain is obliterated by the negatively charged SDS molecules, and each protein-SDS solubilized aggregate has an identical charge per unit volume. Negatively charged particles move through the polyacrylamide gel toward the anode. Polyacrylamide acts as a molecular sieve and the protein–micelle complexes are separated by size; proteins of larger mass are retarded. A single band in an SDS polyacrylamide electrophoresis is often taken to demonstrate a pure protein. The conformation of the native structure is not a factor in the calculation of molecular mass, as molecular mass is determined by comparison to known standards that are similarly denatured. The detergent dissociates the quaternary structure of a multimeric protein and releases the constituent subunits. Only the molecular mass of the subunits of such a protein are determined by this method.

HPLC Techniques Separate Amino Acids, Peptides, and Proteins

In high-performance liquid chromatography (HPLC), a liquid solvent containing a mixture of molecules to be identified is passed through a column densely packed with a small-diameter insoluble beadlike resin. In column chromatography, the smaller and more tightly packed the resin beads, the greater the resolution of the separation technique. In HPLC, the resin is so tightly packed that the liquid must be pumped through the column at high pressure. Therefore HPLC uses precise high-pressure pumps with metal plumbing and columns rather than the glass and plastics used in gravity chromatography. Resin beads are coated with charged groups to separate compounds by ion exchange or with hydrophobic groups to retard hydrophobic nonpolar molecules. In hydrophobic chromatography, tightly associated nonpolar compounds are eluted from the hydrophobic beads in aqueous solvents containing various percentages of an organic reagent. The higher the percentage of organic solvent in the effluent, the faster the nonpolar component is eluted from the hydrophobic resin. This latter type of chromatography over nonpolar resin beads is called **reverse-phase HPLC** (Figure 3.66). HPLC separations have extremely high resolution and reproducibility.

Affinity Chromatography

Proteins have a high affinity for their substrates, prosthetic groups, membrane receptors, or specific noncovalent inhibitors and for antibodies made against them. These high-affinity compounds can be covalently attached to an insoluble resin, and the modified resin used to purify its conjugate protein in column chromatography. In a mixture of proteins eluted through the resin, the one of interest is selectively retarded.

General Approach to Protein Purification

A protein must be purified prior to determination of its chemical composition, structure, and function. As living cells contain thousands of genetically distinct proteins as well as lipids, polysaccharides, and polynucleotides, the purification of a specific protein from the other cellular constituents may be difficult. The first task is the development of a simple

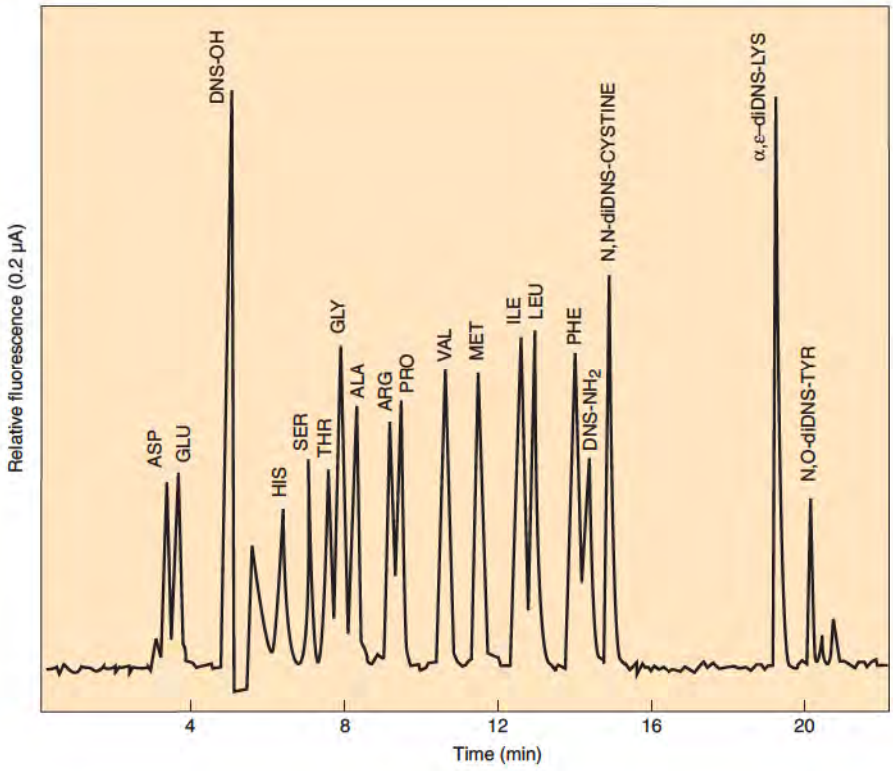

Figure 3.66 Separation of amino acids utilizing reverse-phase HPLC. The *x*-axis is time of elution from column. Amino acids are derivatized by reaction with dansyl chloride (DNS) so that they emit a fluorescence that is used to assay them as they are eluted from the column. assay for the protein. Whether it utilizes the rate of transformation of substrate to product, antibody–antigen reaction, or a physiological response in an animal assay system, a protein assay must give a quantitative measure of activity per unit of protein concentration. This quantity is known as the sample's **specific activity**. The aim of a purification procedure is to increase a sample's specific activity to the value expected for the pure protein. A typical protocol for purification of a soluble cellular protein involves disruption of the cell membranes, followed by differential centrifugation in a density gradient to isolate the protein from subcellular particles and high molecular weight aggregates. Further purification may utilize selective precipitation by inorganic salts such as ammonium sulfate (salting out) or by organic solvent. Final purification includes a combination of techniques that separate based on molecular charge, molecular size, and/or affinity.

Proteomic Techniques Determine All the Proteins Expressed in a Cell or Tissue in a Single Assay

The number of unique genes in the human genome is estimated to be about 25,000. Given that multiple protein products may be produced from a single gene by alternate splicing and posttranslational modifications generate additional forms, the number of unique proteins present in the human probably approaches 1 million. **Proteomics** is the science of determining exactly which proteins are produced in a cell or tissue, under a specific set of conditions.

Any cell or tissue may express thousands of different proteins simultaneously. To understand the properties of a cell or tissue, the type of proteins expressed and how the pattern of expressed proteins changes with development, differentiation, and disease is determined. Techniques have been developed to assay expressed mRNAs in cells and tissues in a single assay by hybridizing to DNA microarrays. More recently, techniques have been developed to analyze the active gene products, the proteins expressed by cells and tissues by use of **2-D electrophoresis.** In this, the proteins are first extracted from cells or tissues and then spotted onto a polyacrylamide gel in an electrophoresis apparatus. The proteins are separated in the first direction on the basis of their differences in pI. The gel is then turned by 90° and sodium dodecyl sulfate (SDS) added to buffer. The proteins are separated in the second

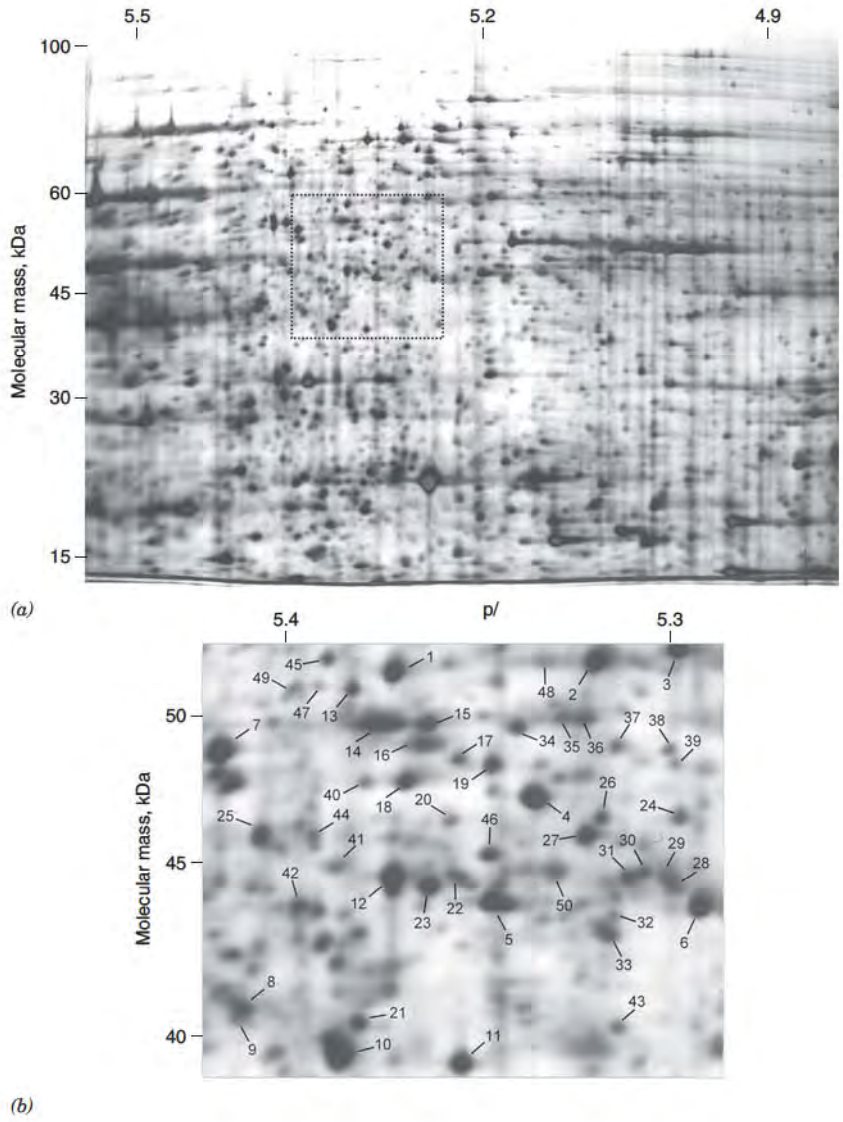

Figure 3.67 A two-dimensional (2-D) display of expressed proteins from cultured cells. (*a*) Soluble proteins from cellular extract (500 μg) loaded on the gel and separated by isoelectric focusing (between pH 4.9 and 5.5) in the horizontal direction and by molecular mass in the vertical direction (electrophoresed in the presence of SDS detergent). More than 1500 proteins are observed in the gel by silver staining. (*b*) A region from the gel expanded to show detail. Numbered proteins were analyzed by protease hydrolysis and mass spectrometry to determine their partial amino acid sequences, leading to their identification. Reproduced with permission from Gygi, S. P., Corthals, G. L., Zhang, Y., Rochon, Y., and Aebersold, R. *Proc. Natl. Acad. Sci. USA* 97: 9390, 2000.

direction on the basis off differences in their molecular mass (see Gel Electrophoresis in the Presence of Detergent). The resulting gel is stained for protein, and the intensity of each of the thousands of protein spots measured in order to determine whether a particular protein is expressed and its concentration (Figure 3.67).

Determining the identity of each of the protein spots in a 2-D gel is not a trivial task. The 2-D gel pattern, if carried out under standard conditions, may be compared to patterns obtained by reference laboratories that have determined the identity of the majority of spots in the 2-D pattern from a particular cell type. These reference 2-D patterns are available over the Internet. More definitively, a spot may be extracted from the gel and the protein partially hydrolyzed into smaller peptide fragments by proteolytic enzyme digestion (e.g., trypsin or chymotrypsin), and the peptide fragments subjected to mass spectroscopy. The mass spectroscopy rapidly determines the amino acid sequence of many of the small fragments. This technique is called peptide **mass fingerprinting**. Utilizing these sequences to search protein sequence or gene sequence databases leads to the identification of the protein extracted from the 2-D gel. Robotic instruments now perform each of the steps in protein spot extraction and identification. In this way, the thousands of expressed proteins may be identified.

The technique currently fails to identify low abundance proteins in cells or tissues. In addition, certain types of proteins are difficult to analyze due to low solubility, low molecular charge, or very low molecular mass. For example, integral membrane proteins are highly hydrophobic and are not soluble in the standard isoelectric focusing solvents.

CLINICAL CORRELATION 3.7

Use of Amino Acid Analysis in Diagnosis of Disease

Elevated concentrations of amino acids are found in plasma or urine in a number of clinical disorders. An abnormally high concentration in urine is called an aminoaciduria.

Aminoacidurias in Humans

Amino Acid(s) Elevated	*Aminoaciduria*	*Clinical Correlation*

Determination of Amino Acid Composition of a Protein

Determination of the amino acid composition is an essential component in the study of a protein's structure and physiological properties. A protein is hydrolyzed to its constituent amino acids by heating it at 110°C in 6 N HCl for 18–36 h, in a sealed tube under a vacuum to prevent degradation of oxidation-sensitive side chains by oxygen in air. Tryptophan is destroyed in this method, and alternative procedures are used for its analysis. Side chain amides of asparagine and glutamine are hydrolyzed to aspartate and glutamate and free ammonia; they are included within the glutamic acid and aspartic acid content in the analysis.

Common procedures for amino acid identification use cation-exchange chromatography or reverse-phase HPLC to separate them and then react with ninhydrin, fluorescamine, dansyl chloride, or similar chromophoric or fluorophoric reagents for quantitation. With some types of derivatization, amino acids are identified at concentrations of 0.5×10^{-12} mol (pmol). Analysis of the amino acid composition of physiological fluids (i.e., blood and urine) is utilized in diagnosis of disease (Clin. Corr. 3.7).

Determination of Amino Acid Sequence

The ability to clone genes has led to the ability to determine the amino acid sequence of a protein from its DNA or mRNA sequence. This is often a much faster method for obtaining an amino acid sequence. Sequencing of a protein, however, is required for the determination of modifications to the protein structure that occur after its biosynthesis, to identify a part of the protein sequence in order that its gene can be cloned, and to identify a protein as the product of a particular gene. Determination of the primary structure of a protein requires a purified protein and determination of the number of chains in it. Individual chains are purified by the same techniques used in purification of the whole protein. If disulfide bonds join the chains, these bonds have to be broken (Figure 3.68).

Polypeptides are most commonly sequenced by the **Edman reaction** or by **mass spectroscopy**. In the Edman reaction, the polypeptide chain is reacted with phenylisothiocyanate, which reacts with the NH_2-terminal amino group. Acidic conditions catalyze intramolecular cyclization that cleaves the NH_2-terminal amino acid as a phenylthiohydantoin derivative (Figure 3.69). This amino acid derivative may be separated chromatographically and identified against standards. The remaining polypeptide is isolated, and the Edman reaction is repeated to identify the next NH_2-terminal amino acid. Theoretically, this can be repeated

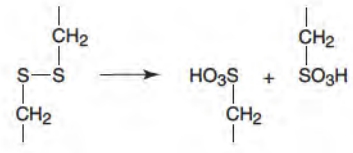

Figure 3.68 Breaking of disulfide bonds by oxidation to cysteic acids.

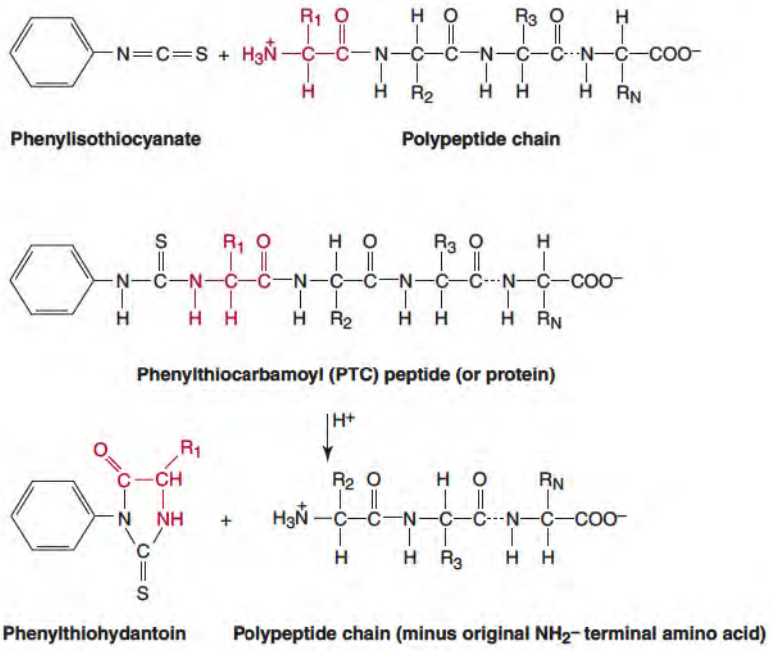

Figure 3.69 **Edman reaction.**

until the sequence of the entire polypeptide is determined but under favorable conditions can only be carried out for 30 or 40 amino acids into the polypeptide chain, when impurities generated from incomplete reactions in the reaction series make further **Edman cycles** infeasible. Polypeptides longer than 30 or 40 amino acids are hydrolyzed into smaller fragments and sequenced in sections. For sequencing by mass spectroscopy, it is also necessary to break long polypeptide chains into smaller fragments.

Enzymatic and chemical methods are used to break polypeptide chains into smaller fragments (Figure 3.70). **Trypsin** preferentially cleaves the peptide bond on the COOH-terminal side of lysine and arginine within polypeptide chains. **Chymotrypsin** cleaves the peptide bond on the COOH-terminal side of large apolar side chains. Other enzymes cleave polypeptide chains on the COOH-terminal side of glutamic and aspartic acid. **Cyanogen bromide** cleaves peptide bonds on the COOH-terminal side of methionine residues (Figure 3.70). After **partial hydrolysis**, the segments are separated, and the sequence of each is determined by the Edman reaction or mass spectroscopy. To place the sequenced peptides correctly into the complete sequence, another sample of the original polypeptide is subjected to partial hydrolysis by a different hydrolytic reagent from that used initially, and the fragments separated and sequenced. This generates overlapping sequences, which permit the determination of the complete sequence (Figure 3.71).

X-Ray Diffraction Techniques Are Used to Determine the Three-Dimensional Structure of Proteins

X-ray diffraction enables determination of the structure of proteins at near atomic resolution. The approach requires formation of a protein crystal, which contains solvent and is thus a concentrated solution, for use as the target. Our understanding of the detailed components of protein structure derived from this crystalline state correlate well with other physical measurements of protein structure in solution (e.g., by NMR spectroscopy; p. 133).

The generation of protein crystals can be the most time-consuming aspect of the process. Proteins have molecular dimensions at least an order of magnitude greater than a small molecule, and the packing of large protein molecules into the crystal lattice generates a crystal with large "holes" or solvent channels. A protein crystal typically contains 40% to 60% solvent, and it may be considered a concentrated solution rather than the hard crystalline solid obtained with most small molecules. The presence of solvent and unoccupied volume in the crystal permits the infusion of inhibitors and substrates into the protein molecules in the crystalline state.

A **dynamic flexibility** within regions of the protein structure may be seen as disorder in the X-ray diffraction pattern. Disorder describes the situation in which the observed electron density can be fitted by more than a single local conformation. Two explanations must be distinguished. The first involves the presence of two or more static molecular conformations, which are present in a stoichiometric relationship. The second involves the actual dynamic range of motion exhibited by atoms or groups of atoms in localized regions of the molecule. These explanations can be distinguished by lowering the temperature of the crystal to where dynamic disorder is "frozen out;" in contrast, the multiple static conformations are not temperature dependent and persist. Analysis of dynamic disorder by its temperature dependency using X-ray diffraction is an important method for studying protein dynamics (Section 3.8).

Crystallization techniques have so advanced that crystals are obtainable even from less abundant proteins. Interesting structures have been reported for proteins in which specific residues have been substituted, of antibody–antigen complexes, and of viral products such as the protease required for the infection of the human immunodeficiency virus (HIV) that causes acquired immunodeficiency syndrome (AIDS). Approximately 50,000 structures have been solved by X-ray diffraction and the details are stored in the **Protein Data Bank**, which is accessible on the Internet.

Diffraction of X-rays by a crystal occurs with incident radiation of a characteristic wavelength (e.g., copper, $K\alpha = 1.54$ Å). The X-ray beam is diffracted by the electrons that surround the atomic nuclei in the crystal, with an intensity proportional to the number of electrons around the nucleus. Thus, the technique establishes the **electron distribution** of the molecule and infers the nuclear distribution. Actual positions of atomic nuclei can be determined directly by diffraction with **neutron beam radiation**, an interesting but very expensive technique as it requires a nuclear reactor or particle accelerator. With the highest resolution now available for X-ray diffraction determination of protein structure, the diffraction from C, N, O, and S atoms can be observed. That from hydrogen atoms is not observed due to the low density of electrons, that is, a single electron around a hydrogen nucleus. The diffracted beam is typically detected on photographic film or electronic area detectors. This permits recording of the amplitude (intensity) of radiation diffracted in a defined orientation. Determination of the **phase**

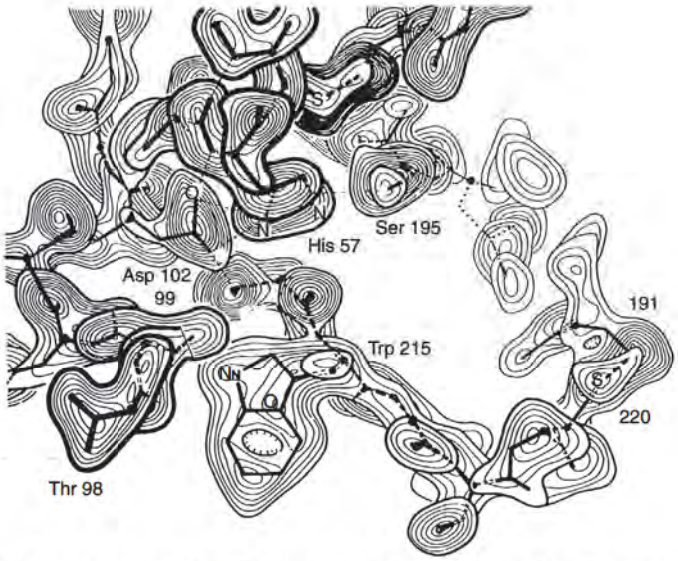

Figure 3.72 Electron-density map at 1.9-Å resolution of active site region of proenzyme form of trypsin. Active site amino acid residues are fitted onto an electron density map.
Reproduced with permission from Kossiakoff, A. A., Chambers, J. L., Kay, L. M., and Stroud, R. M. *Biochemistry* 16: 654, 1977. Copyright (1977) by American Chemical Society.

angles has historically required the placement of heavy atoms (such as iodine, mercury, or lead) in the protein molecule. Modern procedures can often solve the phase problem without use of heavy atoms.

It is convenient to compare X-ray crystallography with light microscopy to understand the processes involved. In light microscopy, incident radiation is reflected by an object under study and the reflected beam is recondensed by the objective lens to produce an image of the object. The analogy is appropriate to incident X-rays but no material exists that can serve as an objective lens for X-ray radiation. In place of the objective lens, amplitude and phase angle measurements of the diffracted radiation are mathematically reconstructed by **Fourier synthesis** to yield a three-dimensional **electron-density map** of the diffracted object. A few hundred reflections are required for a low-resolution electron-density map. For example, 400 reflections were used to obtain a 6-Å map of myoglobin. At this resolution one can clearly locate the molecule within the unit cell of the crystal and study the overall packing of the subunits in a multimeric protein. However, a trace of the conformation of the polypeptide chain is made with difficulty. Many more reflections are required to obtain higher-resolution maps. For myoglobin, where 400 reflections were utilized to obtain the 6-Å map, 10,000 reflections were needed for a 2-Å map, and 17,000 reflections for a 1.4-Å map. Much of the work is now partially automated using computers. A slice through a three-dimensional electron-density map of trypsinogen is shown in Figure 3.72. The known primary structure is fitted to the electron-density pattern by **refinement**, the computer-intensive process of aligning a sequence to the electron-density map until the best fit is obtained.

X-ray diffraction provides incomplete evidence of a protein's mechanism of action. Rather, it provides an average structure of a molecule whose atoms are normally undergoing rapid fluctuation in solution (Section 3.8). Indeed, the average structure may not be the active structure for the protein in solution. On the time scale of diffraction data collection, the structures of reactive enzyme–substrate complexes, intermediates, and reaction transition states cannot be observed. These structures must be inferred from the static pictures of an inactive form of the protein or from complexes with inactive analogs of its substrates (Figure 3.73).

Newer methods for X-ray diffraction use synchrotron radiation to generate an X-ray beam, at least 10,000 times more intense than that of standard X-ray generators, which enables the collection of diffraction data on a millisecond time scale. Application of these techniques will enable determination of short-lived structures and solve mechanistic and dynamic structural questions not addressable by the standard technology.

A CLOSER LOOK 3.2

Ultraviolet and Visible Light Absorbance Show a Linear Dependency on Concentration and Path Length

The Beer–Lambert law is an empirical equation that shows the linear relationship between the concentration of a chromophore and absorbance at a particular wavelength of UV or visible light. The equation is

$$A = \varepsilon_\lambda * l * c$$

where A is the light absorbance at wavelength λ, ε_λ is the molar absorptivity or extinction coefficient of the chromophore at wavelength λ, l is the path length of the light through the solution, and c is the concentration of chromophore. The extinction coefficient is a constant of the chromophore molecule at a set temperature and solution conditions. If ε_λ is in units of $M^{-1}cm^{-1}$, then l is in cm, c is in M, and A is in absorbance units.

Spectroscopic Methods for Evaluating Protein Structure and Function

Ultraviolet Light Spectroscopy

Side chains of tyrosine, phenylalanine, and tryptophan, and peptide bonds absorb ultraviolet (UV) light. The efficiency of absorption for each **chromophore** is related to its **molar extinction coefficient** (ε) (A Closer Look 3.2). A typical spectrum is shown in Figure 3.74. Absorbance between 260 and 300 nm is primarily due to aromatic side chains (Figure 3.75). When the tyrosine side chain is ionized at high pH (this R group has a $pK'_a \approx 10$), the absorbance is shifted to a higher wavelength (red shifted) and its molar absorptivity is increased (Figure 3.75). Peptide bonds absorb in the far-UV (180–230 nm). A peptide bond in α-helix conformation interacts with the electrons of peptide bonds above and below it to create an **exciton system** in which electrons are delocalized. The result is a shift of the absorption maximum for an isolated peptide bond to either a lower or a higher

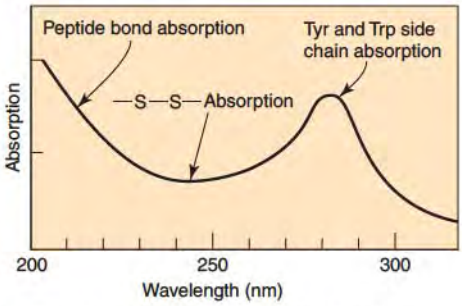

Figure 3.74 Ultraviolet absorption spectrum of the globular protein α-chymotrypsin.

Redrawn from d'Albis, A., and Gratzer, W. B. In Bull, A. T., Lagnado, J. R., Thomas J. O., and Tipton, K. F. (Eds.), *Companion to Biochemistry.* London: Longmans, 1974, 175.

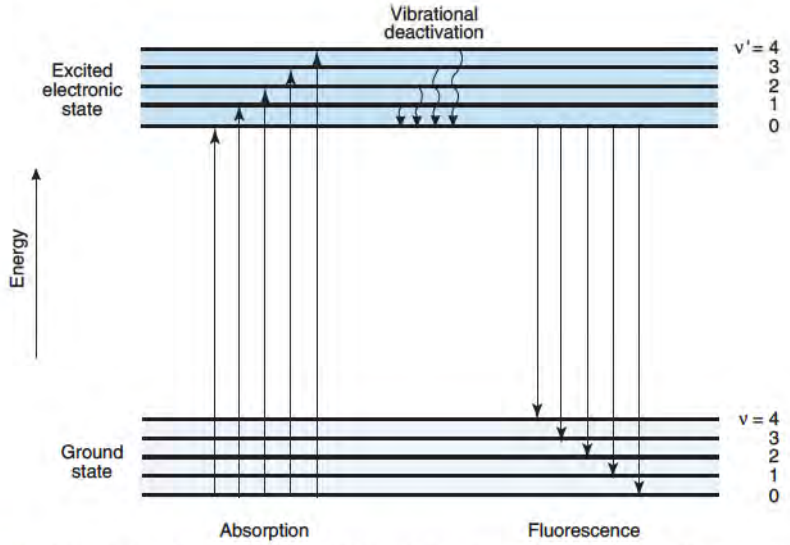

Figure 3.77 Absorption and fluorescence electronic transitions. Excitation on light absorption is from zero vibrational level in ground state to various higher vibrational levels in the excited state. Fluorescence emission is from the zero vibrational level in excited electronic state to various vibrational levels in the ground state. The fluorescence emission is at a higher wavelength (less energy) than the absorption wavelength.
Redrawn from d'Albis, A., and Gratzer, W. B. In Bull, A. T., Lagnado, J. R., Thomas, J. O., and Tipton, K. F. (Eds.), *Companion to Biochemistry.* London: Longmans, 1974, 166.

wavelength (Figure 3.76). Ultraviolet spectroscopy can provide information on a protein's secondary and tertiary structure. As a protein is denatured, differences in the absorption characteristics of the peptide bonds appear because of disruption of the exciton system. In addition, the absorption maximum for an aromatic chromophore is at a lower wavelength in an aqueous environment than in a nonpolar environment.

The **molar absorbancy** of a chromophoric substrate often changes on binding to a protein and can be used to measure its binding constant. Changes in chromophore extinction coefficients during enzyme catalysis are used to provide the kinetic parameters for the reaction.

Fluorescence Spectroscopy

The energy of an excited electron produced by light absorption is lost most commonly as thermal energy in a collision process. In some chromophores, the excitation energy is dissipated by fluorescence. The **fluorescent emission** is always at a longer wavelength of light (lower energy) than the absorption wavelength of the fluorophore as vibrational energy levels, formed during the light absorption (excitation), are lost prior to fluorescence (Figure 3.77). If another molecule is present to absorb light energy emitted by the **fluorophore**, the emitted fluorescence is not observed but transferred to the absorbing molecule. The **acceptor molecule**, in turn, either emits its own characteristic fluorescence or loses its excitation energy by an alternative process. If the acceptor molecule loses its excitation energy by a nonfluorescent process, it is a **quencher** of the **donor molecule's** fluorescence. The efficiency of the **excitation transfer** is dependent on the distance between and orientation of donor and acceptor molecules.

Fluorescence emission spectra for phenylalanine, tyrosine, and tryptophan side chains are shown in Figure 3.78. The emission wavelengths for phenylalanine overlap with the absorption wavelengths for tyrosine. In turn, the emission wavelengths for tyrosine overlap with the absorption wavelengths for tryptophan. Because of these overlaps in emission and absorption wavelengths, primarily only tryptophan fluorescence is observed. Excitation transfers occur over distances up to 80 Å, which are typical diameters of globular domains. On denaturation, the distances between donor and acceptor groups increase and the efficiency of energy transfer to tryptophan decreases. Accordingly, an increase in tyrosine and/or

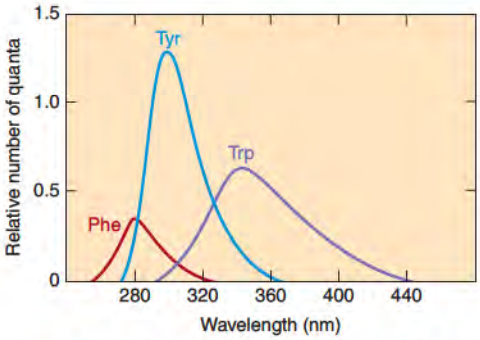

Figure 3.78 Characteristic fluorescence of aromatic groups in proteins. Redrawn from d'Albis, A., and Gratzer, W. B. In Bull, A. T., Lagnado, J. R., Thomas, J. O., and Tipton, K. F. (Eds.), *Companion to Biochemistry.* London: Longmans, 1974, 478.

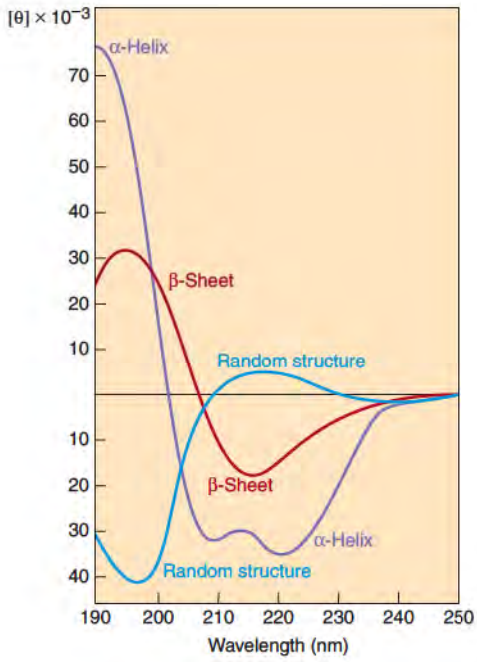

Figure 3.79 Circular dichroism spectra for polypeptide chains in α-helix, β-sheet and random conformations. Redrawn from d'Albis, A., and Gratzer, W. B. In Bull, A. T., Lagnado, J. R., Thomas, J. O., and Tipton, K. F. (Eds.), *Companion to Biochemistry*. London: Longmans, 1974,190.

phenylalanine and loss of tryptophan fluorescence is observed on denaturation of a protein. Since excitation transfer processes in proteins are distance and orientation dependent, the fluorescence yield is dependent on the conformation of the protein. This type of analysis detects changes due to conformational changes and binding interactions.

Circular Dichroism Spectroscopy

Circular dichroism (CD) is caused by differences in light absorption between the clockwise and counterclockwise component vectors of a beam of polarized light traveling through a solution of an optically active molecule such as an L-amino acid. A spectrum is generated when the circular dichroism is determined through a range of wavelengths. Aromatic amino acids in a protein and the polypeptide chain generate an optical rotation and CD spectrum (Figure 3.79). Because of the differences between spectra for α-helical, β-sheet, and random structures, circular dichroism has been a fairly sensitive assay for the amount and type of secondary structure and is commonly utilized to follow protein folding and denaturation.

Nuclear Magnetic Resonance

With **two-dimensional (2-D) NMR** and powerful NMR spectrometers the conformation in solution of small proteins of about 150 amino acids or less can be determined. Multidimensional NMR and triple resonance can extend the sensitivity to more than 250 residues.

Conventional NMR techniques use radiofrequency (rf) radiation to study the environment of atomic nuclei that are magnetic. The requirement for magnetic nuclei is absolute and based on an unpaired spin state in the nucleus. Thus, the naturally abundant carbon (^{12}C), nitrogen (^{14}N), and oxygen (^{16}O) do not absorb, while ^{13}C, ^{15}N, and ^{17}O do absorb. The information derived from absorption bands enables the determination of the identity and number of nearest-neighbor groups that can affect the response of absorbing species through bonded interactions, but it gives no information on through-space (nonbonded) interaction due to the native conformation of the protein. To determine through-space interactions and protein tertiary structure requires the use of **nuclear Overhauser effects (NOEs)** and the application of the two-dimensional technique.

The major difference between two-dimensional and one-dimensional (1-D) NMR is the addition of a second time delay rf pulse. The technique requires identification in the spectrum of proton absorbance from a particular position in the protein structure. Through-space

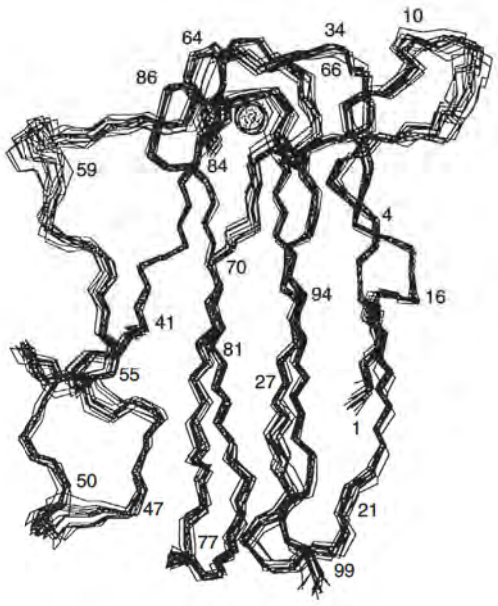

Figure 3.80 NMR structure of plastocyanin from the French bean. Structure shows superposition of eight structures of the polypeptide backbone for the protein, calculated from constraints of NMR spectrum.
From Moore, J. M., Lepre, C. A., Gippert, G. P., Chazin, W. J., et al. *J. Mol. Biol.* 221: 533, 1991. Figure generously supplied by P. E. Wright.

interactions can be observed at a maximum distance of about 5 Å. On the generation of distance information for interresidue pairs through the protein structure, protein conformations consistent with the spectra are generated. In this calculation, a distance matrix is constructed containing ranges of distances (minimum and maximum) for as many interresidue interactions as may be measured. Possible structures are generated from the data consistent with the constraints imposed by the NMR spectra. Computational refinements of the initially calculated structures can optimize covalent bond distances and bond angles. The method generates a family of structures, the variability showing either the imprecision of the technique or the dynamic "disorder" of the folded structure (Figure 3.80). Such computations have yielded structures that do not significantly differ from the time-averaged structure observed with X-ray diffraction methods.

Other enhancements of NMR, for determination of protein structure, include the ability to synthesize proteins that contain isotopically enriched (e.g., containing ^{13}C or ^{15}N) amino acids and the development of paramagnetic shift reagents to study localized environments on paramagnetic resonances, such as the lanthanide ion-reporting groups.

Bibliography

Bioinformatics and Proteomics Software Portals

The journal *Nucleic Acids Research* annually compiles and summarizes the Web-accessible biological databases (*Nucleic Acids Research* 36: January 2008) and web sites with tools for analysis of biological data (*Nucleic Acids Research* 36: July 1, 2008).

The National Institutes of Health Entrez site has access to sequence, genomic, and protein expression databases and analysis tools (http://www3.ncbi.nlm.nih.gov/Entrez).

The Expert Protein Analysis System (ExPASy) site of the Swiss Institute of Bioinformatics contains tools for protein study and links to other sites and to databases for the study and analysis of proteins (http:// http://ca.expasy.org).

The web site of the European Bioinformatics Institute also offers references to databases and a comprehensive package of analysis tools (http://www.ebi.ac.uk).

The Swiss PDB viewer (Deep View) can be downloaded and allows viewing of three-dimensional structures. The software and manual are available through the DeepView site (http://spdbv.vital-it.ch). An excellent tutorial by Gale Rhodes can be accessed at http://spdbv.vital-it.ch/TheMolecularLevel/SPVTut/index.html.

Protein Explorer is available at http://www.umass.edu/microbio/chime/pe_beta/pe/protexpl.

Cn3D, is available at the National Center for Biotechnology Information (NCBI) at the NIH web site http://www.ncbi.nlm.nih.gov/Structure/CN3D/cn3d.shtml.

The molecular Viewers downloads protein structures stored at the Protein Data Bank (PDB) by the RCSB (http://www.rcsb.org/pdb/home/home.do).

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. All of the following are correct about a peptide bond except
- **A.** it exhibits partial double bond character.
- **B.** it is more stable in the *cis* configuration than in the *trans* configuration.
- **C.** it has restricted rotation around the carbonyl carbon to nitrogen bond.
- **D.** it is planar.
- **E.** in proline, the nitrogen is attached to the side chain.

2. In an α-helix,
- **A.** side-chain groups can align to give a polar face.
- **B.** each peptide bond forms two hydrogen bonds.
- **C.** there are 3.6 amino acids per turn.
- **D.** all of the above.
- **E.** none of the above.

3. Chaperone proteins
- **A.** all require ATP to exert their effect.
- **B.** cleave incorrect disulfide bonds, allowing correct ones to subsequently form.
- **C.** guide the folding of polypeptide chains into patterns that would be thermodynamically unstable without the presence of chaperones.
- **D.** of the Hsp70 class are involved in transport of proteins across mitochondrial and endoplasmic reticulum membranes.
- **E.** act only on fully synthesized polypeptide chains.

4. Proteins may be separated according to size by
- **A.** isoelectric focusing.
- **B.** polyacrylamide gel electrophoresis.
- **C.** ion exchange chromatography.
- **D.** molecular exclusion chromatography.
- **E.** reverse-phase HPLC.

5. Similar arrangements of secondary structural motifs are often observed in the fold structure of protein domains. Which of the following is correct?
- **A.** Superfolds are similar structures from proteins related by function or evolution from the same primordial gene.
- **B.** Folds must be either all α or all β.
- **C.** There is only one type of β domain.
- **D.** If a protein has more than one domain, all domains are identical.
- **E.** A common fold has a central β-barrel with the strands connected by α-helices around the outside.

6. Unstructured proteins
- **A.** are those proteins that have been denatured by heat.
- **B.** do not have any biological functions.
- **C.** can be induced to have a defined structure by binding to other proteins or to DNA or RNA.
- **D.** have no secondary or tertiary structure.
- **E.** have regions that are very rich in aromatic amino acids.

Questions 7 and 8: Abnormalities in the synthesis or structure of collagen cause dysfunctions in cardiac organs, bone, skin, joints, and eyes. Problems may result from abnormal collagen genes, abnormal posttranslational modifications of collagen, or deficiency of cofactors needed by enzymes responsible for posttranslational modifications. Scurvy, a lack of vitamin C, is an example of the last type.

7. In collagen:
- **A.** intrachain hydrogen bonding stabilizes the native structure.
- **B.** three chains with polyproline type helical conformation can wind about one another to form a superhelix because of the structure of glycine.
- **C.** the φ angles contributed by proline are free to rotate.
- **D.** regions of superhelicity comprise the entire structure except for the N- and C-termini.
- **E.** crosslinks between triple helices form after lysine is converted to allysine.

8. The formation of covalent cross-links in collagen
- **A.** occurs during synthesis of the peptide chain.
- **B.** uses hydroxyproline.
- **C.** involves glycine residues.
- **D.** requires conversion of some ε-amino groups of lysine to δ-aldehydes.
- **E.** all of the above.

Questions 9 and 10: Glycoproteins, with carbohydrate molecules covalently bound to one or more amino acids, participate in many normal and disease-related functions, for example, antigenic determinants of blood groups, cell–cell recognition, and functioning of collagen. Usually the carbohydrate is added to the protein by enzymatic reactions. A glycosylated hemoglobin, HbA_{1c}, however, is formed nonenzymatically in red blood cells. In prolonged hyperglycemia as in patients with diabetes mellitus, the concentration of HbA_{1c} rises and it can be used to follow the effectiveness of treatment.

9. Glycoproteins
- **A.** are found in cells but not in plasma.
- **B.** in a plasma membrane typically have the carbohydrate portion on the cytosolic side.
- **C.** may have the carbohydrate portion covalently linked to the protein at an asparagine.
- **D.** that are carbohydrate to hydroxyl linked always have the linkage to hydroxylysine.
- **E.** of a given type always have identical carbohydrate chains.

10. With glycoproteins,
- **A.** the carbohydrate is added as the polypeptide chain is transported through the endoplasmic reticulum and Golgi network.
- **B.** the amount of carbohydrate present is always a small percentage ($< 5\%$) of the weight of the protein.
- **C.** the carbohydrate portion consists only of a single sugar on each amino acid.
- **D.** the most common type of linkage is to an α-amino group of a polypeptide chain.
- **E.** changes in composition would have no effect on biological function.

Questions 11 and 12: Many pathological hyperlipoproteinemias result from abnormalities in the rates of synthesis or clearance of lipoproteins in the blood. They are usually characterized by elevated levels of cholesterol and/or triacylglycerols in the blood. Type I has very high plasma triacylglycerol levels (> 1000 g/dL) because of an accumulation of chylomicrons. Type II (familial hypercholesterolemia) has elevated cholesterol, specifically in the form of LDL. Another abnormality of lipoproteins is hypolipoproteinemia in which lipoproteins are not formed because of the inability to make a particular apoprotein.

11. All lipoprotein particles in the blood have the same general architecture which includes
- **A.** a neutral core of triacylglycerols and cholesteryl esters.
- **B.** amphipathic lipids oriented with their polar head groups at the surface and their hydrophobic chains oriented toward the core.
- **C.** most surface apoproteins containing amphipathic helices.
- **D.** unesterified cholesterol associated with the outer shell.
- **E.** all of the above.

12. In abetalipoproteinemia chylomicrons, VLDL and LDL are absent from the blood. Which of the following is correct?
- **A.** In this disease, no apolipoproteins are synthesized.
- **B.** If the blood from these individuals were centrifuged, the lipid bands would be found primarily in the upper half of the tube.
- **C.** Failure to synthesize apolipoprotein ApoB-100 and ApoB-48 would account for the pattern shown in this disease.
- **D.** Apolipoproteins are composed mostly of β structure.
- **E.** All of the above.

Problems

13. In a plot of equivalents of OH^- versus pH, pH is ~2 when 0.5 equiv has been used, pH is ~6 for 1.5 equiv and pH is ~9.5 for 2.5 eq. What amino acid has been titrated? In each case, the point indicated is the midpoint of a steep part of the curve.

14. After purification, the Edman reaction was used to sequence a dodecapeptide, yielding the following data: the C-terminal amino acid is isoleucine; the N-terminal amino acid is methionine; and the peptide fragments are Ala-Ala-Ile, Leu-Arg-Lys-Lys-Glu-Lys-Glu-Ala, Met-Gly-Leu, and Met-Phe-Pro-Met. What is the sequence of this peptide?

Answers

1. **B** This would put both side chains on the same side of the bond, and this is less favorable. C is a consequence of A. D: All atoms attached to the carbon and nitrogen of the bond are in a common plane. E: Proline has an imino group.
2. **D** A: They could also align to give a nonpolar face. B: One is to the fourth residue above the bond, and the other is to the fourth residue below. C: This is one of the characteristics of a right-handed α-helix.
3. **D** Proteins cross the membrane in an unfolded state and refold once they cross the membrane. A: The hsp60 family of chaperones is ATP linked, but the hsp70 family is not. B: Disulfide isomerases catalyze this reaction. C: The final product is thermodynamically stable; chaperones prevent unfavorable intermediate interactions. E: Hsp70 chaperones react with nascent polypeptide chains as they are synthesized by the ribosome. The protein may then be delivered to an hsp60 chaperone for facilitation of final folding.
4. **D** Another method that separates on the basis of size is SDS PAGE. A–C separate molecules on the basis of charge. E: Reverse-phase HPLC effects separations based on polarity.
5. **E** This α/β structure is found in pyruvate kinase, for example. A: This is called a family; superfolds are found in proteins unrelated in function or origin. B: See E. C: There are several different types. D: A protein may have multiple different domains, and the different domains may, in some cases, have different functions.
6. **C** Their unstructured domains allow them to bind with a variety of partners. A: These proteins naturally lack a stable folded conformation. B: They play a variety of roles such as scaffold proteins, cyclin-dependent kinases, and many others. D: They may have regions of secondary structure. E: They tend to be rich in polar and charged amino acids and low in aromatic ones.
7. **B** Close contacts in the interior of the triple helix are possible only when the R group at that position is very small, that is, hydrogen. A: Hydrogen bonding in collagen is interchain. C: The φ angle is part of the proline ring and is not free to rotate. D: Although the statement is true of type I collagen, the superhelical regions in other collagen types may be broken by regions of globular domains. E: The conversion and crosslinking are extracellular.
8. **D** These then react with each other or with unmodified ε-amino groups of lysine. A: It is posttranslational. B and C: This is not the role of hydroxyproline or glycine.
9. **C** In the N-linked type, asparagine is in the sequence Asn-X-Thr(Ser). A: Most plasma proteins, except albumin, are glycoproteins. B: Carbohydrate is on the outside of the cell for functions like cell–cell recognition. D: This link is in collagen only. Other O-linked carbohydrates have the linkage to serine or threonine. E: Carbohydrate structure is not determined by genes and is variable.
10. **A** The carbohydrate content is not directed by genes but is a co- or posttranslational event. B: The content is highly variable, for example, glycophorin in erythrocyte membrane has 60% carbohydrate. C: The attached carbohydrate can be a single carbohydrate or as many as 15 carbohydrate residues. D: This is a type VI linkage found in HbA_{1c} but is not the most common type. E: There could be a profound change in function.
11. **E** All lipoproteins share these characteristics. C: The polar face interacts with water and the hydrophobic face is oriented toward the core. D: Cholesterol's hydroxyl group is sufficiently polar that it orients toward the outer shell.
12. **C** Apo B-100 is a primary apolipoprotein of LDLs and VLDLs. Apo B-48, a truncated form of B-100, is found in chylomicrons. A: Since the various apolipoproteins come from different genes, one would not expect all genes to be affected. B: The missing lipoproteins are the ones found in the upper part of the tube on centrifugation. D: Apolipoproteins associated with lipid have a high content of amphipathic α-helices.
13. This is a titration curve for an acid with three dissociable groups. The points indicated represent half-titration of each of these groups, and the pHs are the pK values for each group. With these pK values, the amino acid must be histidine.
14. You must have the correct N- and C-terminal amino acids and the correct total number (12) of amino acids in the peptide. Using these values and overlapping the fragments, you should get the sequence Met-Phe-Pro-Met-Gly-Leu-Arg-Lys-Glu-Ala-Ala-Ile. Notice that the Lys-Glu fragment does not give any additional information for the sequencing.

Key Concepts

- DNA replication, recombination, and repair involve transesterification, the switching of partners across a phosphodiester bond. All three processes rely on complementary base pairing.
- DNA replication requires a template, a set of enzymes, and the proper precursors. It is semiconservative, with parental strands separating so that each can be a template for the synthesis of a complementary strand. The double helix opens at a replication fork followed by a priming step, the sequential addition of complementary nucleotides, and the sealing of adjacent fragments. The process is extremely accurate.
- Replication is very similar in bacteria and mammalian cells, but the differences allow antibiotics to selectively inhibit bacterial growth.
- Replication is highly regulated as part of the cell cycle. Telomerase preserves the ends of chromosomes.
- Recombination is essential for proper chromosome segregation into daughter cells. A key intermediate is a DNA structure called a Holliday Junction. Errors in recombination can lead to cancer.
- Changes in a single base pair of the 6 billion base pairs in the human genome can lead to disease. There are an estimated 10,000–50,000 damaging events, such as radiation and chemical reactions, to DNA per cell per day. There are several different mechanisms to repair damaged DNA. Base-excision repair and nucleotide excision repair are very accurate processes that remove damaged base(s). Defects in DNA repair mechanisms can cause cancer.
- Some repair mechanisms introduce errors into the DNA as a cost of allowing cells to deal with damage that blocks replication.

4.1 • COMMON FEATURES OF REPLICATION, RECOMBINATION, AND REPAIR

In addressing the "three R's" of DNA—replication, recombination, and repair—it is useful to consider some unifying similarities among them. The fundamental mechanisms of replication, recombination, and repair are conserved throughout evolution. Because these processes act on the same substrate, DNA chains, they share fundamental chemical mechanisms of making and breaking phosphodiester bonds. The chemistry of DNA is largely that of its phosphodiester bonds. The theme of a nucleophilic attack on a phosphodiester bond, leading to a switch in the partners across the bond, is common to all three processes. The double-stranded nature of cellular DNA and the complementarity of the two strands also play a major role in all three processes. Because the genetic information is present in two copies, each strand can serve as a template for synthesis or repair of the opposite strand. The antiparallel nature of the two strands is critical in all processes that act on DNA. The three processes share many enzymes. Requirements of accuracy and regulation, however, lead to specialization of groups of enzymes for a particular task. Recognizing similarities and differences will make understanding replication, recombination, and repair easier.

As the carrier of genetic information, DNA in a cell must be duplicated, maintained, and passed down to daughter cells with extraordinary accuracy. The scale of the problem is large. The common bacterium *Escherichia coli* (*E. coli*) has a genome containing 4.6 million base pairs (bp). The human genome consists of two copies of 23 chromosomes, totaling approximately 6×10^9 bp. Individual human chromosomes each contain a single DNA molecule, ranging from 34 million bp for the smallest chromosome to 263 million bp for the largest.

Overall accuracy of replication is extremely high: During a single cycle of replication, an average of only one error is introduced per billion bp. However, even with this extraordinary accuracy, a handful of errors are introduced into an average human cell at each cell division. These errors are mutations, heritable changes in the DNA sequence. Mutations are often harmful; they can affect cell viability or trigger the uncontrolled growth characteristic of cancer. Some serious diseases can result from the change of a single base pair in the 6×10^9 bp human genome. Eukaryotes have the additional task of ensuring that all parts of the genome are replicated only once during each cell cycle, to avoid chromosomal abnormalities and imbalances in gene expression.

Accurate replication, critical as it is, is not enough. DNA is subject to continuing attack by both chemical and physical agents including water, activated oxygen species that arise as by-products of normal cellular metabolism, chemicals in foods and in the environment, and radiation. There are systems that recognize and repair DNA damage, and thereby help maintain the integrity of the genome. In spite of all of this care, accumulation of mutations can lead to cell death, aging, and cancer.

Figure 4.1 Semiconservative DNA synthesis. The two parental strands separate, and each is a template for synthesis of a complementary daughter strand. Therefore, the two daughter duplexes each have one parental strand and one newly synthesized strand.

4.2 • DNA REPLICATION: FUNDAMENTAL MECHANICS

The Basics

Replication leads to doubling of the DNA, preserving the genetic information that is carried as the sequence of bases. Replication requires a **template** to provide sequence information. The basic mechanism of DNA replication was obvious as soon as the complementary, double-stranded structure of DNA was recognized. Because each strand is the complement of the other, with an A in one strand always paired with a T in the other and likewise for C and G, the two strands can be separated and each can be used as a template for synthesis of a new complement. This is called **semiconservative replication**, because half of the parental DNA molecule (one strand) is conserved in each new double helix, paired with a newly synthesized complementary strand (Figure 4.1).

A template alone is not sufficient for DNA synthesis. **DNA polymerases** catalyze the addition of mononucleotides to a growing chain. DNA polymerases do not start a strand by

Figure 4.2 Template and primer. The substrate for addition of a nucleotide is a primer (light tan) hydrogen bonded to a template (dark tan). The template provides information about which nucleotide to add. The primer provides a free 3′-hydroxyl group to which nucleotides can be added. The two strands run antiparallel.

joining the first two nucleotides together; rather, they add nucleotides to an existing primer that provides a 3′-hydroxyl group (Figure 4.2, Table 4.1). The requirement for a primer is not due to the chemistry of phosphodiester bond formation, as demonstrated by the ability of **RNA polymerases** to start polynucleotide chains *de novo* (without primers). Rather, it probably evolved because it increases the overall accuracy of replication. Proofreading (see p. 143) during polymerization of the first few nucleotides is not likely to be effective because there are few base pairs to stabilize the double helix and allow recognition of correct base pairing. In most organisms, the initial primer is made of ribonucleotides by an enzyme called **primase**. The first few nucleotides are marked for eventual removal because they are ribonucleotides; their subsequent removal leaves a gap that can be resynthesized more accurately because the resynthesis is done by elongation of a longer strand of DNA. During growth of the DNA chain, the growing chain itself, base paired to the template, serves as a primer for addition of the next nucleotide.

TABLE 4.1 • Requirements for DNA Replication

Template	Provides sequence information
Primer	Provides free 3′-OH to which nucleotides are added
Precursors	5′-Deoxynucleoside triphosphates (5′-dNTPs)
Enzymes	DNA polymerases, sliding clamps, helicases, primases, single-stranded DNA-binding proteins, nucleases, ligases

Chemistry of Chain Elongation

The chemistry of DNA replication, repair, and recombination is largely that of the **phosphodiester bonds** that link neighboring nucleotides in a DNA chain. Figure 4.3 depicts the

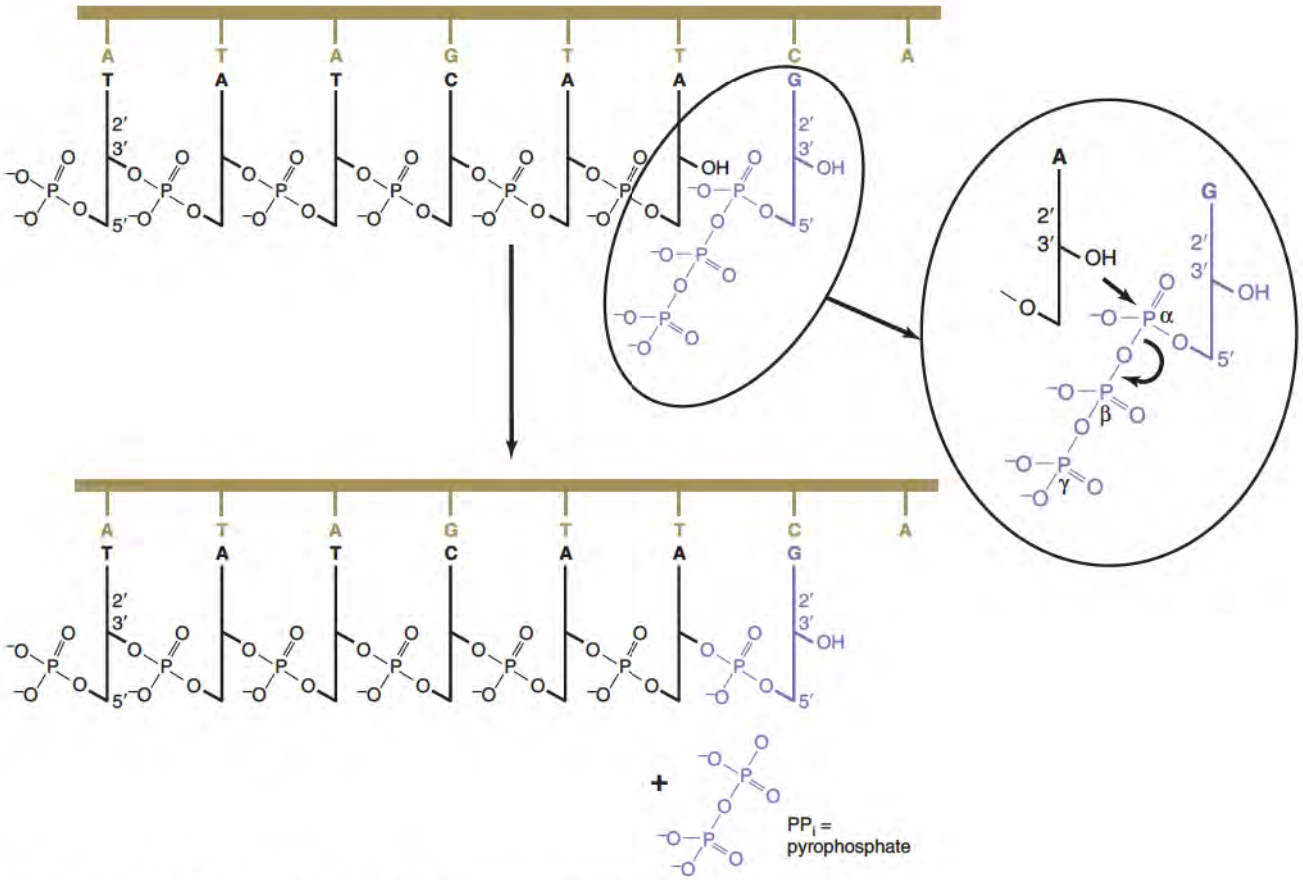

Figure 4.3 Formation of a phosphodiester bond. An incoming nucleoside triphosphate that forms correct hydrogen bonds with the template in the active site of a DNA polymerase is depicted in purple. The 3′-OH of the primer attacks the innermost (α) phosphate of the incoming nucleotide, displacing the two terminal phosphates as pyrophosphate (insert). This results in the elongation of the primer by one nucleotide. This cycle is repeated as long as template is available.

CLINICAL CORRELATION 4.1

Chemotherapy Can Target Precursors of DNA Synthesis

Because tumor cells replicate at higher rates than most normal tissues, much chemotherapy is directed at inhibiting DNA replication. Cells that are actively dividing are more sensitive to these drugs than are quiescent cells; this provides a therapeutic window. In addition to rapidly dividing cancer cells, the targets of chemotherapy, there are normal but rapidly dividing cells in the intestinal tract, bone marrow, and hair follicles; the sensitivity of these rapidly dividing normal cells explains many of the limiting side effects of chemotherapy.

One way to inhibit replication is to interfere with the pools of deoxyribonucleotides needed for DNA synthesis. Hydroxyurea is an antimetabolite that inhibits ribonucleotide reductase, the key enzyme needed to make deoxyribonucleotides from ribonucleotides. This decreases the concentrations of the dNTPs and thereby inhibits DNA synthesis, without dramatically altering the pool of rNTPs needed for transcription. Hydroxyurea is used primarily against melanoma and myeloproliferative diseases such as chronic myelogenous leukemia; it can be used in combination with radiation therapy that damages DNA, because by lowering pools of dNTPs it can also inhibit DNA repair. The main side effect is myelosuppression due to the inhibition of DNA synthesis in bone marrow, which leads to fewer red blood cells, white blood cells, and platelets.

formation of a phosphodiester bond between a short chain of DNA (a **primer**) and an incoming nucleotide. This process is repeated for each nucleotide added to the growing chain.

Addition of a nucleotide to a growing chain is not a spontaneous process, because the decrease in entropy is large. For this reason, nucleotide precursors of DNA are 5′-deoxyribonucleoside triphosphates (5′-dNTPs; Clin. Corr. 4.1). The phosphodiester bond connecting the first (α) phosphate (attached to the 5′ carbon of the sugar) and the outer two (β and γ) phosphates undergoes nucleophilic attack by the 3′-OH of the growing DNA chain (Figure 4.3). The bond is not hydrolyzed, but rather **transesterified;** the phosphodiester bond that had joined the α-phosphate to the β-phosphate now joins the α-phosphate to the 3′-end of the growing chain. The terminal two phosphates are released as inorganic pyrophosphate, which is hydrolyzed by phosphodiesterases present in cells. Cleavage of pyrophosphate renders the reaction essentially irreversible. Much of the chemistry of replication, repair, and recombination involves transesterification reactions.

DNA Polymerases

DNA polymerases catalyze the addition of nucleotides during chain elongation. They require both **templates** and **primers** and use 5′-dNTP precursors (Figure 4.3). The very powerful laboratory techniques of DNA sequencing and the polymerase chain reaction (p. 257) are based on the requirement for both template and primer to allow DNA polymerization. Cells contain several DNA polymerases that carry out specialized functions, including various aspects of replication and coping with damage to the template (Table 4.2). DNA polymerases

TABLE 4.2 • DNA Polymerases

Function	*E. coli Enzyme*	*Eukaryotic Enzyme*
Priming	DnaG primase[a]	Pol α/primase[b]
Synthesis of continuous (leading) strand	Pol III	Pol δ
Synthesis of initial part of Okazaki fragment		Pol α/primase
Synthesis of most of Okazaki fragment	Pol III	Pol δ

Damage bypass	Pol IV, Pol V	Pol ϵ, Pol ξ, Pol η, Pol ι
Damage bypass, DNA repair	Pol II	Pol ϵ?
Base excision repair	Pol I	Pol β
Mitochondria DNA replication	—	Pol γ

[a] DnaG is not considered a DNA polymerase; it makes an RNA primer.

[b] In eukaryotes, the primase component of the pol α/primase complex makes the initial RNA primer, which is extended 20–30 nt by the DNA polymerase α component using dNTPs.

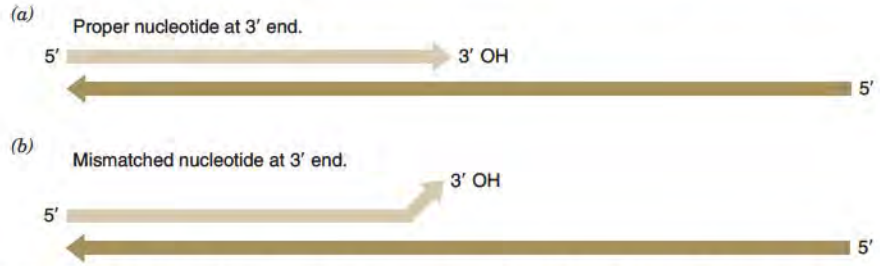

Figure 4.4 Proofreading. (*a*) When the proper nucleotide is added to the 3′-end of a primer, the result is a good substrate for addition of a nucleotide, but a poor substrate for the 3′ to 5′ exonuclease. (*b*) On the rare occasions when an incorrect nucleotide is added to the primer, the resulting primer with a mismatch at the 3′-end is a poor substrate for addition of a nucleotide, but a good substrate for the 3′ to 5′ proofreading exonuclease that removes the mismatched nucleotide. This leaves the primer shorter but ready for the correct nucleotide to be incorporated.

that participate in replication help to ensure accuracy in two ways: by the initial selection of the proper nucleotide to add and by enzymatic proofreading.

The initial selection is based on the fit of the incoming nucleotide into the active site of the polymerase. An incoming nucleotide that makes the proper hydrogen bonds with the nucleotide on the template strand can be added to the growing chain. An incoming nucleotide that does not make the correct hydrogen bonds is not aligned properly for catalysis. Conformational changes in the DNA polymerase itself are critical in assuring this accuracy, which leads to error rates in the range of 10^{-4} to 10^{-6}. Although good for most processes, this is not nearly as accurate as required for replication.

The second way DNA polymerases increase accuracy is by **proofreading**. This is carried out by a 3′- to 5′-**exonucleolytic activity** that removes mispaired nucleotides from the 3′ end of the growing chain. Proofreading is integral to many replicative DNA polymerases, but may also be carried out by an associated protein in the replication complex. A primer with a properly base-paired terminal nucleotide is a good substrate for the addition of the next nucleotide, but a poor substrate for the 3′- to 5′-exonuclease (Figure 4.4). A primer with a mismatched terminal nucleotide is a poor substrate for addition of a nucleotide but a good substrate for 3′- to 5′-exonuclease. This combination results in removal of virtually all mismatched nucleotides before the next nucleotide is added. It also leads to removal of some properly incorporated nucleotides, but that is a price that must be paid for the increased accuracy provided by proofreading. The ability to discriminate between properly and incorrectly incorporated nucleotides is compromised when the growing chain is very short, because the strength of base pairing between a short chain and template is weak. This is the most likely explanation for the evolution of DNA polymerases unable to start chains *de novo,* and for the use of ribonucleotides to prime DNA synthesis.

Some mutated DNA polymerases are actually more accurate than the normal polymerase. This is paradoxical if one assumes that there is an evolutionary advantage to ever-increasing accuracy. However, there are reasons to expect that beyond a certain level, higher accuracy is not advantageous and may in fact be disadvantageous. First, extremely accurate proofreading is energetically costly. To ensure that virtually all misincorporated bases are removed, a polymerase would also have to remove a large number of correctly incorporated bases that have moved slightly with respect to the template due to normal thermal fluctuations. This would greatly slow replication and utilize much additional energy in the form of dNTPs. Second, the ability of DNA repair systems to deal with residual errors reduces the advantages of ever more accurate polymerases. It has also been argued that a low level of mutations provides the raw material for evolution, producing a population with some genetic variation that is better able to survive changing conditions.

Despite their very high accuracy, polymerases can incorporate nucleotide analogs. Nucleoside analogs are often used in chemotherapy to kill rapidly growing cancer cells or viruses responsible for serious illnesses. Analogs that are phosphorylated to nucleotides can be incorporated into DNA, where they can inhibit further synthesis or lead to a high level of mutation. Differences between bacterial or viral polymerases and host polymerases in their ability to incorporate nucleotide analogs can provide a therapeutic window within which physicians can preferentially target infected cells (Clin. Corr. 4.2).

CLINICAL CORRELATION 4.2

Nucleoside Analogs and Drug Resistance in HIV Therapy

Acquired Immune Deficiency Syndrome (AIDS) is caused by infection with the retrovirus Human Immunodeficiency Virus (HIV). A key step in the HIV life cycle is synthesis of a DNA copy of the viral RNA genome, catalyzed by a reverse transcriptase. Reverse transcriptase is a major target of chemotherapy because it is not essential for normal cells.

Zidovudine (AZT; 3′-azido-2′,3′-dideoxythymidine) was the first drug approved for treatment of HIV infection. It is a nucleoside analog with an azido group on the sugar. It can be phosphorylated into the triphosphate form, which competes with dTTP for incorporation into the reverse transcript. Once incorporated, it terminates the growing chain of the transcript because the azido group on the 3′ carbon of the sugar is not a substrate for nucleotide addition. AZT is much less efficient at competing with the more accurate cellular DNA polymerases, providing a therapeutic window in which the effect is primarily on viral replication. Nevertheless, side effects include toxicity to bone marrow, which contains rapidly dividing cells, and myopathy that might be related to toxicity to mitochondria, which contain their own DNA polymerase, pol δ. Other nucleoside analogs have been used to treat HIV infection. Didanosine (DDI; 2′, 3′ dideoxyinosine) and zalcitabine (dideoxycytidine)also function as chain terminators after incorporation of their phosphorylated derivatives by the HIV reverse transcriptase.

Reverse transcriptases do not carry out proofreading, thus their error rate is much higher than that of cellular DNA polymerases. This high error rate complicates the treatment of AIDS, because the population of viruses carried by any one patient contains many mutants, and mutations continue to increase with time. Some of these mutants are likely to be resistant to any given therapeutic agent. Thus, many drugs initially reduce the viral load, but later become ineffective due to the selective growth of viruses in which the drug target is mutated to an insensitive form. Combination therapy, with multiple drugs that target different viral proteins, is an attempt to circumvent this problem.

There are interesting animations of HIV life cycle at www.galaxygoo.org/biochem/hiv/hiv_lifecycle.html and at http://www.roche-hiv.com/portal/eipf/pb/hiv/Roche-HIV/hivlifecycle#.

Separating Parental Strands: The Replication Fork

Both prokaryotes and eukaryotes solve problems of replication in fundamentally similar ways. Separation of the two parental strands of DNA allows each to serve as a template for a new complementary strand. The separation of parental strands creates a structure called a **replication fork** (Figure 4.5). This separation requires considerable input of energy. Melting double-stranded DNA into two single strands normally occurs only at elevated temperatures (over 90°C). To separate the parental strands at physiological temperatures, cells use enzymes called **helicases.** Helicases bind to single-stranded DNA and rachet along it in a fixed direction, with each step requiring hydrolysis of ATP. This "pushes apart" the parental DNA to form a replication fork (Figure 4.5).

In the absence of additional proteins, parental strands would quickly reanneal behind the helicase, because the complementary strands are close and aligned in proper register. Reannealing is prevented by **single-stranded DNA-binding proteins (SSBs)** (Figure 4.5). SSBs keep the strands apart, reduce potential secondary structure (hairpins that might impede polymerization), and align the template strands for rapid DNA synthesis. SSBs are important not only in replication, but also in recombination and repair.

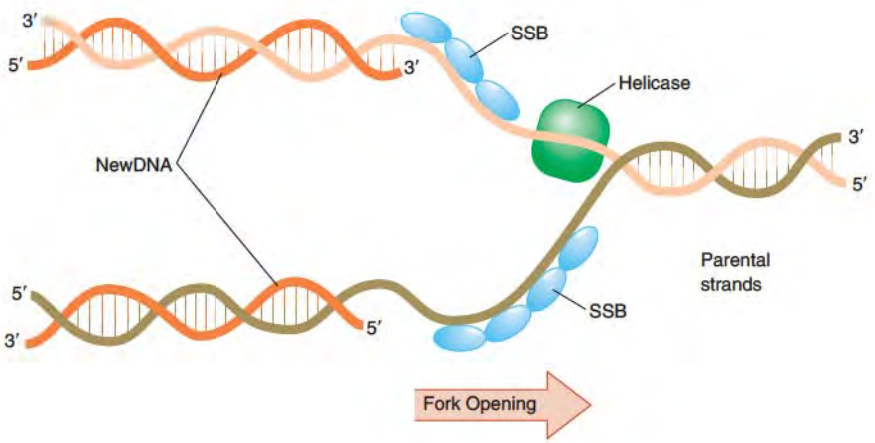

Figure 4.5 Separation of parental strands at a replication fork DNA synthesis occurs at a structure called a replication fork, at which parental strands are separated. A helicase is needed to separate parental strands and allow the fork to progress. Single-stranded DNA-binding proteins (SSBs) are needed to keep the strands apart. The parental strands twist around each other approximately every 10.5 base pairs and must untwist to separate; this creates topological problems. Note that one of the growing strands is oriented with its 3′-end toward the fork, while the other is oriented with its 5′-end toward the fork.

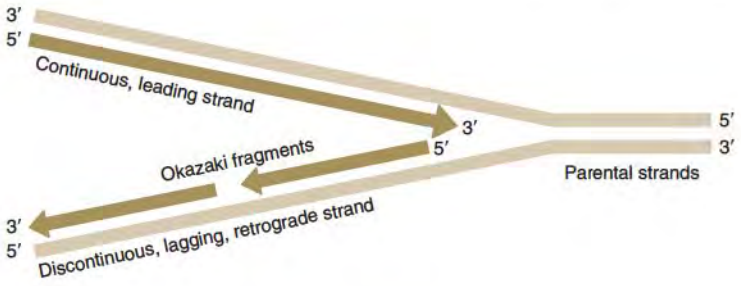

Figure 4.6 Solving the polarity problem: Semi-discontinuous DNA synthesis. Both growing strands are elongated at their 3′-ends. The one with its 3′-end toward the fork can grow continuously; it is called the continuous or leading strand. Because no DNA polymerase can add nucleotides to the 5′-end of a growing chain, the strand with its 5′-end toward the fork is made as a series of short pieces, called Okazaki fragments, each synthesized in 5′ to 3′ direction and later joined. This is called the discontinuous, retrograde, or lagging strand.

Solving the Polarity Problem: Semi-discontinuous DNA Synthesis

Antiparallel strands at a replication fork present an immediate problem for the process of replication; one daughter strand is oriented with the 3′-end toward the fork and the other strand has its 5′-end oriented toward the fork (Figure 4.5). The strand with its 3′-OH oriented toward the fork can be elongated simply by sequential addition of new nucleotides to this end (see Figure 4.3, p. 141); this strand is called the **continuous**, **leading**, or **anterograde** strand. The other strand presents the problem: No DNA polymerase catalyzes the addition of nucleotides to the 5′-end of a growing chain. Yet when viewed on a larger scale, replication appears to proceed along both strands in the direction of fork movement. This problem is solved by synthesizing one strand as a series of short pieces, each made in the normal 5′ to 3′ direction, and later joining them (Figure 4.6). The strand made in pieces is called the **discontinuous**, **lagging**, or **retrograde** (backward-going) strand; the small pieces from which the discontinuous strand is made are called **Okazaki fragments** in honor of Reiji Okazaki, who first demonstrated this process. Okazaki fragments in human cells average about 130–200 nucleotides in length. In *E. coli*, they are about 10 times larger. The overall process is called **semi-discontinuous** synthesis, because one strand is synthesized continuously and the other discontinuously.

Replication Fork Movement

Priming

DNA polymerases require primers. The **continuous** (leading) **strand** needs only a single priming event, which occurs during replication initiation (p. 155). But each Okazaki fragment of the discontinuous (retrograde, lagging) strand requires a separate primer. These primers are short stretches of RNA, synthesized by a special enzyme called a **primase.** In eukaryotic cells, the RNA primers are about 8–10 nucleotides long. They provide a free 3′-OH to which the first deoxyribonucleotide can be covalently added (Figure 4.7). Therefore, each Okazaki fragment carries a short stretch of RNA at its 5′-end, covalently attached to the DNA.

Strand Elongation

DNA chains grow by repeated addition of nucleotides to the 3′-OH ends of the chains by the mechanism shown in Figure 4.3, page 142. This reaction is catalyzed by a DNA polymerase.

Primer Removal

The RNA primers are removed from the 5′-ends of Okazaki fragments by enzymes with **RNA Hybridase (RNase H)** activity. RNase H catalyzes hydrolysis of an RNA chain hydrogen bonded to a DNA chain (that is, an RNA–DNA hybrid). In eukaryotes, a special flap endonuclease (FEN1) also participates in this process; FEN1 cuts at a bend where the RNA portion has been peeled away from the template. All of the ribonucleotides are removed, leaving only DNA.

Gap Filling

Removal of RNA primers leaves a **gap** (Figure 4.7). Synthesis must fill the gap with deoxyribonucleotides, leaving only a **nick.** Note the terminology: A gap means that at least one nucleotide is missing. A nick is an interruption in the phosphodiester backbone with no missing nucleotides. The gap is filled with deoxyribonucleotides by a DNA polymerase,

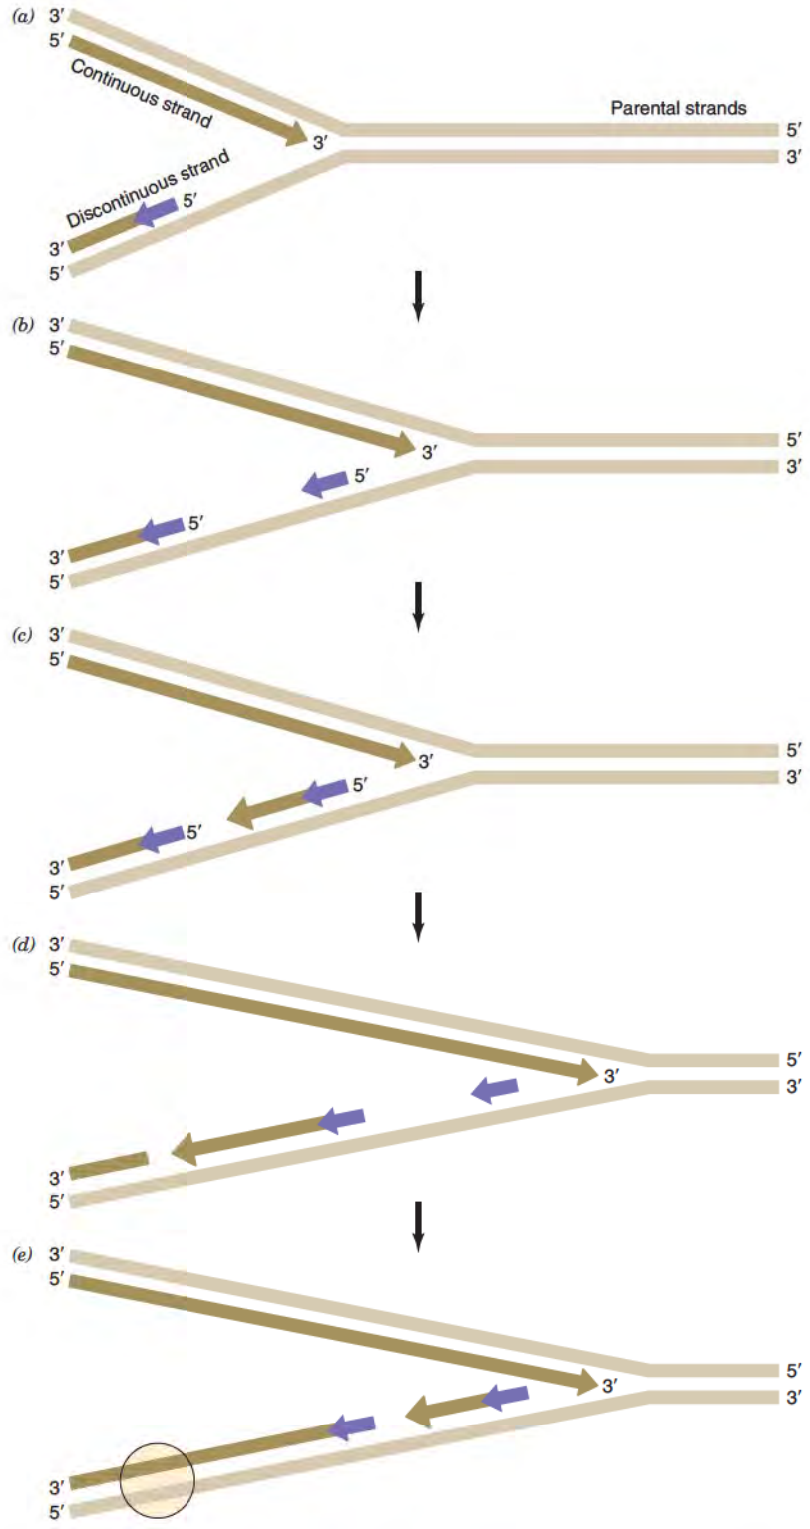

Figure 4.7 DNA synthesis at a replication fork. (*a*) The continuous strand is elongated at its 3′-end by repeated nucleotide additions as shown in Figure 4.2. A previously made Okazaki fragment with a short RNA primer is shown on the other side. (*b*) Using the parental strand as template, primase synthesizes an RNA primer (purple). (*c*) DNA polymerase covalently extends the 3′-end of the RNA primer, incorporating deoxyribonucleotides (tan) as shown in Figure 4.2. (*d*) As the growing Okazaki fragment approaches the previously synthesized fragment, the RNA primer on the older fragment is removed, and the gap is filled by a DNA polymerase elongating the newer Okazaki fragment. Meanwhile, the fork opens further and primase has synthesized a new primer. (*e*) When the gap has been filled and only a nick remains, a DNA ligase seals the two fragments together (within the circle). This process will be repeated, with the new primer elongated, the old primer removed, the gap filled, and the nick sealed.

using the more recently synthesized Okazaki fragment as primer. The Okazaki fragment provides a secure primer–template combination that allows accurate proofreading.

Ligation

The remaining nick is sealed by a **DNA ligase**. Sealing a nick requires formation of a new phosphodiester bond. It therefore requires energy, supplied by coupling the reaction to the splitting of ATP in eukaryotes or NAD^+ in prokaryotes. In both cases the first step is the covalent attachment of an AMP residue to the enzyme (Figure 4.8). This AMP is then

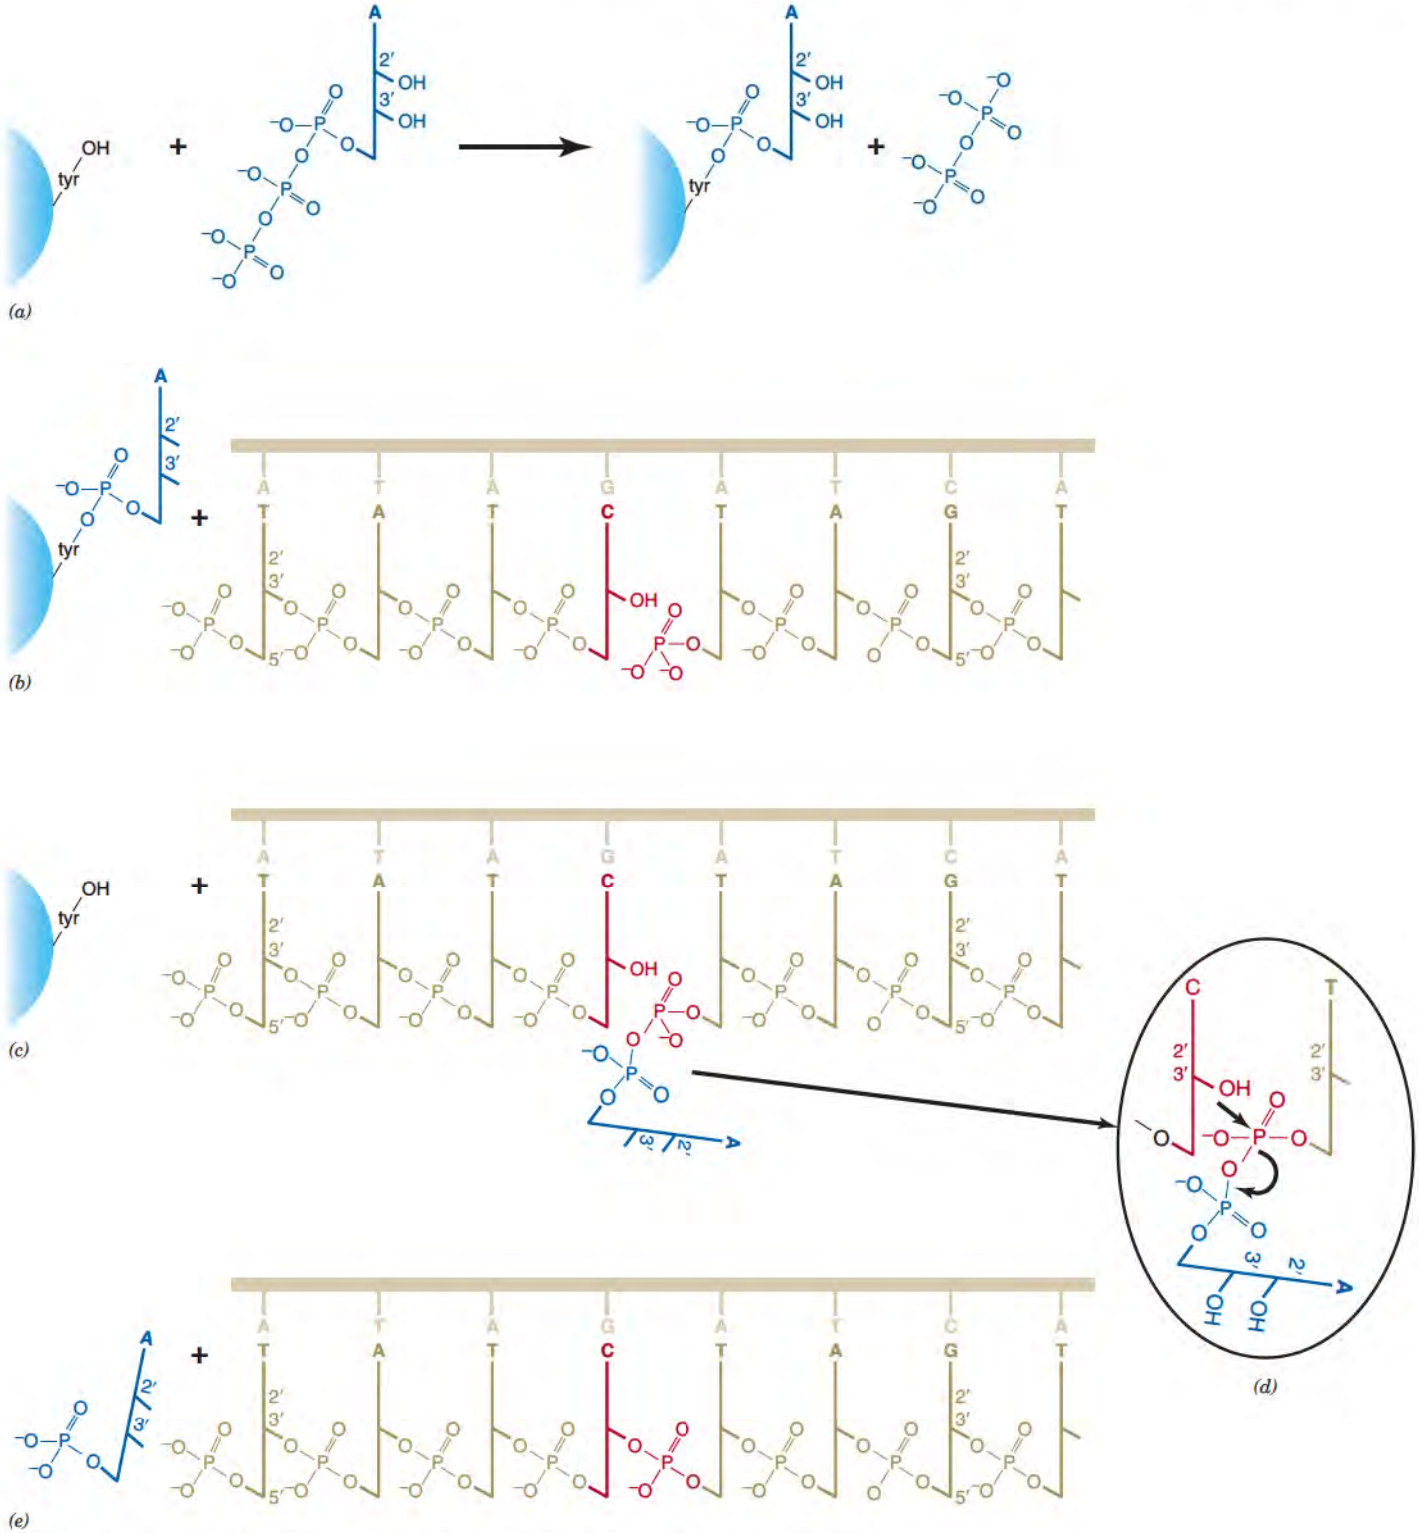

Figure 4.8 DNA ligase mechanism. (*a*) DNA ligase first catalyzes addition of an AMP residue to a tyrosine on the enzyme. In eukaryotes, the AMP donor is ATP (split to AMP + pyrophosphate, as shown here); in prokaryotes, it is NAD + (split to AMP + NMN). (*b*) The ligase-AMP complex binds to a nicked DNA duplex (broken backbone shown in red). (*c*) Ligase transfers the AMP onto the free 5′ phosphate of the nucleotide at the nick. (*d*) Inset: The 3′-OH at the other side of the nick attacks the α phosphate of the nucleotide at the nick to form a new phosphodiester bond, sealing the DNA backbone and releasing AMP. This attack is similar to that which occurs during DNA synthesis (compare Figure 4.2), but with an AMP as the group that leaves, rather than a pyrophosphate. (*e*) The result is a sealed phosphodiester backbone, at a net "cost" of an ATP split into an AMP + PPi (or an NAD split into AMP + NMN).

transferred to the 5′-end of the nick. The AMP serves as a good leaving group that is displaced by the 3′-OH at the other side of the nick; this last step is comparable to the reaction that adds a nucleotide to a growing chain but with an AMP as the leaving group instead of a pyrophosphate.

Untwisting Parental Strands

The above discussion and diagrams were simplified by depicting the DNA strands as straight lines (Figure 4.7, p. 146). But parental strands wrap around each other approximately once every 10.5 bp (Figure 4.5, p. 144). Cells cannot ignore this twisting. In the bacterium *E. coli,* for example, the genome can replicate in approximately 40 minutes. To untwist the 4.6 million bp DNA completely in 40 minutes requires rotation at approximately 11,000 revolutions per minute (rpm)! Clearly, the entire chromosome, compactly folded and carrying large replication and transcription complexes, cannot simply rotate at these speeds without whipping the contents of the cell into a froth.

Another problem caused by the double-helical nature of DNA is **topological**. In circular DNA (such as the *E. coli* chromosome, mitochondrial DNA, and many viruses and plasmids) or long linear DNA whose ends are not free to rotate around each other (such as in our chromosomes, bound at intervals to the nuclear matrix), the number of times one strand wraps around the other, called the **linking number**, is fixed. The linking number cannot be altered without breaking at least one of the two strands. In DNA molecules, the wrapping is of two types, the Watson–Crick **twisting** of one strand around the other approximately every 10.5 bp and the coiling of the double helix on its axis (**writhing** or **supercoiling**). Topologically, twisting and writhing are equivalent and can be interconverted; it is only the total number of times one strand wraps around the other, the linking number, that must remain constant as long as both strands are intact.

One way to allow untwisting and reduction in linking number would be to nick a parental strand ahead of the replication fork. This relieves the topological constraint and allows the parental strands to rotate around each other. A nick presents a serious danger, however, because if the replication fork reached the nick, the strand separation would transform it into a double-strand break in DNA. A double-strand break presents a serious threat to genome stability; if unrepaired, it is lethal. Enzymes called **topoisomerases** solve the unlinking problem in a safer manner by catalyzing changes in the linking number that allow the untwisting and eventual separation of parental strands. Topoisomerases act by forming a transient interruption in the DNA backbone and then resealing it. This interruption is not formed by hydrolysis of the sugar–phosphate bond, but by a transesterification reaction that creates a phosphate–enzyme bond as a transient intermediate (Figure 4.9). Rejoining of the backbone phosphodiester bond displaces the enzyme. Thus there is no net loss or creation of phosphodiester bonds, just a switch in partners across the bond. This means that "nicking" and "resealing" can occur without the need for coupling with a high-energy intermediate (e.g., hydrolysis of ATP or NAD^+). It also avoids the presence of free nicks in DNA.

There are two main classes of topoisomerases: Type I topoisomerases make a transient break in one strand (forming a protein–DNA bond) and allow the other strand to pass through. This changes the linking number in steps of one. Type II topoisomerases make transient breaks in both strands (slightly staggered) and allow a double helix to pass through, changing the linking number in steps of two. Both play important roles in DNA replication and are important targets of chemotherapy.

Sliding Clamps and Processivity

When an enzyme binds to a polymer, carries out a single step of a reaction (for example a polymerase adding a single nucleotide or an exonuclease removing a single nucleotide), and then dissociates from the substrate, the process is called **distributive**. In contrast, when an enzyme binds and carries out many additions (or excisions) before dissociating, the process is **processive**. Because it takes a finite time for an enzyme to dissociate from a template and then reassociate, distributive enzymes tend to work more slowly than processive enzymes.

For rapid synthesis of new DNA, processive polymerases are advantageous. To increase processivity, replicative DNA polymerases are associated with accessory proteins called **sliding clamps** that hold them in contact with the growing DNA chain. In mammalian cells,

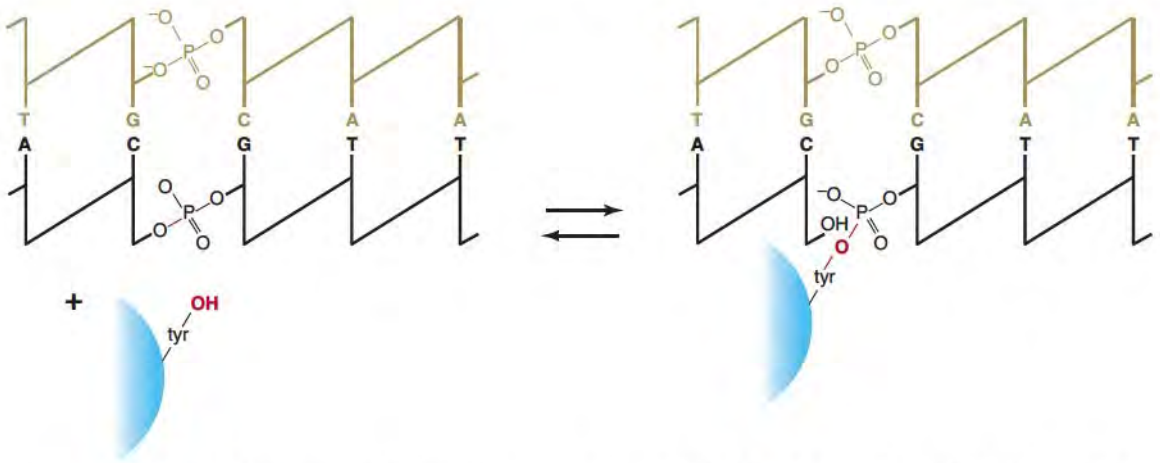

Figure 4.9 Topoisomerase mechanism. Topoisomerase I (mammalian nicking-closing enzyme is depicted here) catalyzes a transesterification reaction that results in a phosphodiester bond between the 3′ carbon of one residue on the DNA chain and a tyrosine residue on the topoisomerase (right panel). (Other topoisomerases form a phosphodiester bond with the 5′ carbon.) This breaks the continuity of the sugar–phosphate backbone and releases the other portion of DNA chain to rotate around (or pass through) its partner; this allows changes in linking number. Then the 5′-OH that was left at the other side of the interruption attacks the phosphodiester bond between nucleotide and protein, reforming the DNA backbone and freeing the protein (left panel). Note that because this is a series of transesterification reactions, no high-energy cofactor is needed.

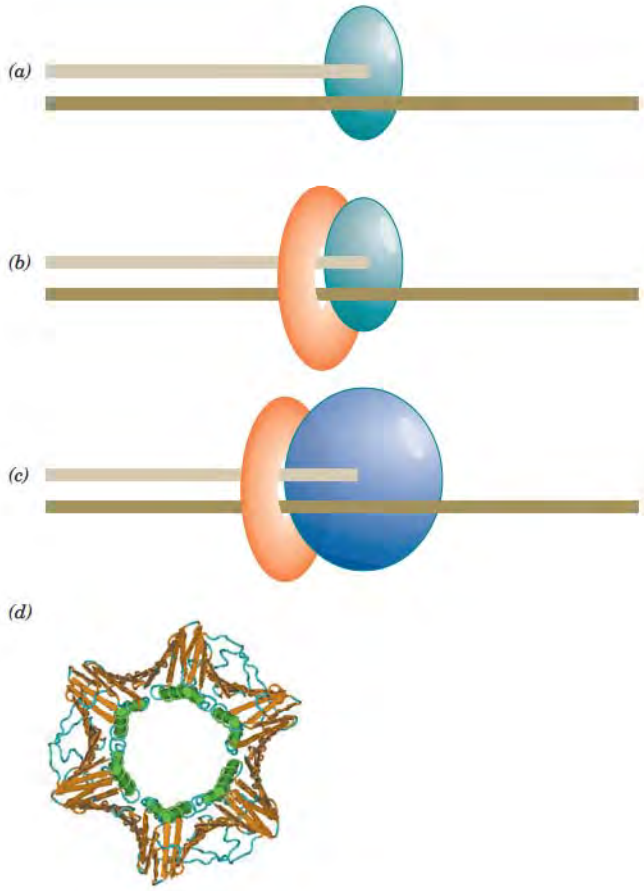

Figure 4.10 Sliding clamps. (*a*) A clamp-loading protein binds to DNA. (*b*) The clamp-loader assembles the sliding clamp from its subunits. (*c*) DNA polymerase associates with the assembled clamp and becomes processive. (*d*) The structure of the sliding clamp in mammalian cells, a trimer of PCNA subunits. DNA passes freely through the large hole in the center of the complex.

the sliding clamps are made of a protein called proliferating cell nuclear antigen (PCNA), with three PCNA molecules encircling the DNA double helix (Figure 4.10). Assembling this ring around the DNA requires accessory enzymes called **clamp-loading factors**. Binding to a sliding clamp makes a DNA polymerase more processive; this increases the speed of synthesis and its accuracy.

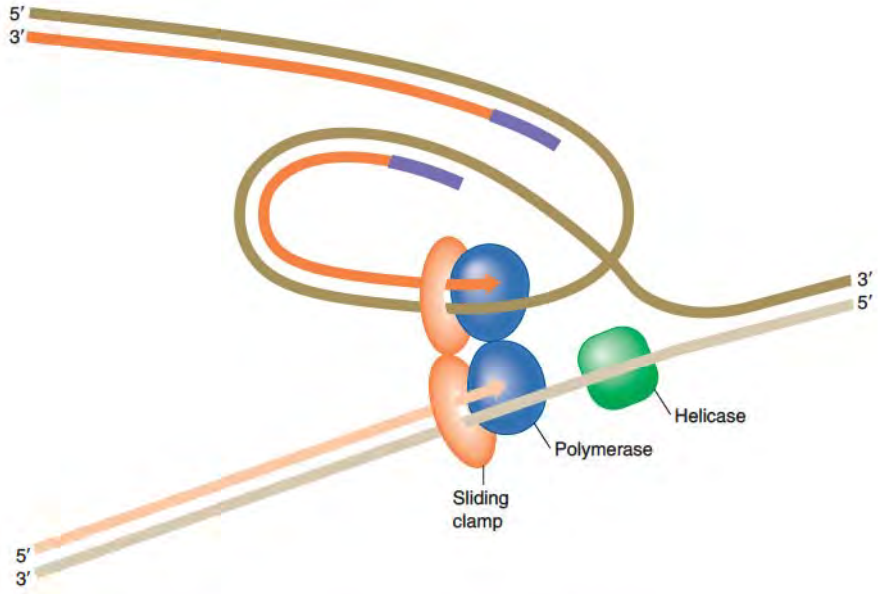

Figure 4.11 Replication of both strands in a replisome. By binding two replicative polymerases together and looping the discontinuous strand so that it can pass through the complex, both strands can be made in one place. DNA feeds through the complex, rotating as it passes through; the large protein complexes do not have to rotate around the DNA.

Choreography in Three Dimensions: The Replisome

The complex choreography described above occurs within the very confined volume of a bacterial cell or the nucleus of a eukaryotic cell, a volume that also contains many other molecules carrying out their functions. The idea of two huge replication complexes circling rapidly around the DNA at each replication fork is untenable. It is much easier for the very thin, cylindrical DNA to rotate around its own axis and move through a large replication complex. The polymerases working on the leading and lagging strands are assembled into a large complex called a **replisome** (Figure 4.11). As the DNA feeds through the replisome, both strands are synthesized. The continuous strand feeds straight through the replisome as it is being elongated at its 3′-end. The discontinuous strand binds to allow synthesis of an Okazaki fragment and is then released to allow the finishing steps (primer removal, gap filling, and ligation) while the template further along the molecule binds the replisome to allow synthesis of the next Okazaki fragment.

Termination of Replication in Circular Genomes

Termination of replication of a circular genome generally occurs 180° away from the origin. Two converging replication forks meet, and the last portion of the genome is synthesized. Topological unlinking of the two new chromosomes must occur. This is a key function of type II topoisomerases. In some small viruses like SV40, termination occurs wherever replication forks meet; there is no special sequence involved. The *E. coli* genome contains special termination sequences that constrain termination to occur within a defined region, by preventing replication forks from proceeding past the region.

Termination of Replication in Linear Genomes: Telomeres

Human cells, and eukaryotic cells in general, have linear chromosomes. There are special difficulties in replicating the ends of linear chromosomes. What exactly is the problem in replicating the ends of linear chromosomes? Although the continuous strand can theoretically be synthesized to the very end of its template, the discontinuous strand cannot. There is no place to synthesize a primer to which the nucleotides opposite the end of the template can be added (Figure 4.12*a*). Even were there a primase that could start at the very end of the template, removal of the RNA would leave a short gap. Although the failure to complete the lagging strand at the end of the chromosome would not be a problem in a single generation, over many cycles of replication chromosome ends would be shortened until essential genes were lost and the cell died. Therefore, it is essential to prevent continued loss of DNA at the ends of chromosomes.

A second problem that eukaryotes face is that the ends of DNA molecules tend to trigger recombination (discussed in the following). To avoid both problems, the ends of eukaryotic

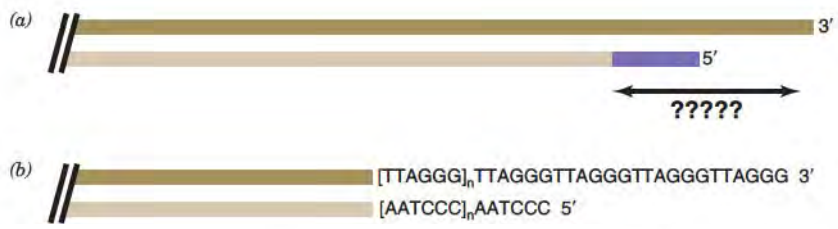

Figure 4.12 **Human telomeres.** (*a*) The telomere replication problem. The 3′-end of one parental strand, the template for the discontinuous (retrograde) daughter strand, is shown in dark tan, the daughter strand is shown in light tan, and an RNA primer is in purple. The problem is that there is no place to synthesize a primer that would allow the daughter strand to be completed (region shown with????), so the daughter strand will be shorter than the parental strand. Removal of the last RNA primer makes it even shorter. (*b*) A telomere consists of many tandem repeats of a 6 nt sequence, TTAGGG in humans, with the G-rich strand extending beyond the C-rich strand by about 12–18 nt.

linear chromosomes are special structures called **telomeres**, which contain many repeats of a six-nucleotide, G-rich repeated sequence. Human telomeres contain thousands of the repeat TTAGGG. The 3′-end of the chromosome extends about 18 nucleotides beyond the 5′-end (Figure 4.12*b*), leaving three repeats as an overhang. The overhanging 3′-end folds back on itself, forming non-Watson–Crick G-G hydrogen bonds, and binds proteins that define its length and protect the chromosome ends from undergoing recombination.

Epigenetics

An important epigenetic marking in mammalian DNA is the methylation of C residues on both strands of many CpG sequences. This can alter gene regulation and silence some genes (Chapter 8). Patterns of methylation can be inherited by daughter cells, but how? During replication, the new strand is made in unmethylated form, with unmodified C residues incorporated. Methylation is restored by DNA methyltransferases that recognize the hemimethylated DNA resulting from semiconservative replication (the C on the old strand remains methylated; that on the new strand is not) and methylate the newly incorporated C.

4.3 • DNA REPLICATION: ENZYMES AND REGULATION

Prokaryotic Enzymes of Replication

Enzymes that carry out the movement of a replication fork in *E. coli* are shown in Figure 4.13. The main replicative DNA polymerase in *E. coli* is **DNA polymerase III (pol III)**. Pol III is a multi-subunit complex that synthesizes the continuous strand and most of the lagging

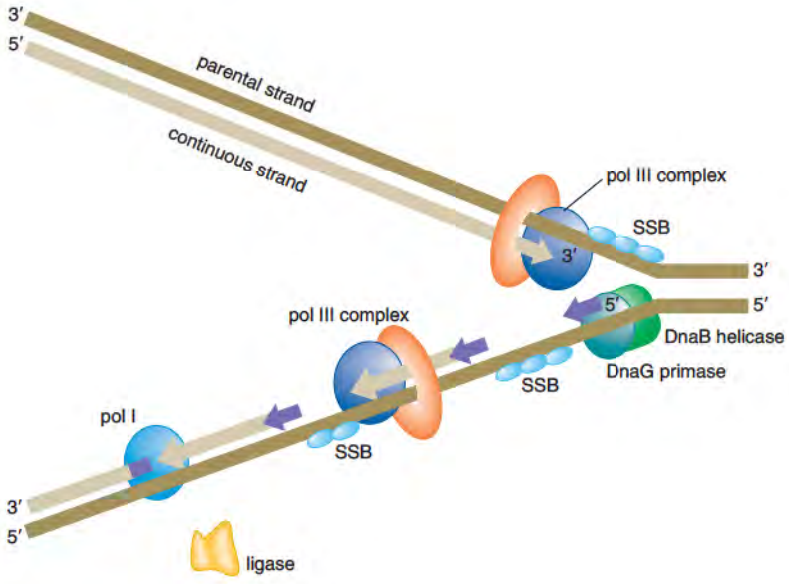

Figure 4.13 **Replication enzymes in *E. coli*.** The continuous strand (top) is elongated by pol III associated with a sliding clamp. The DNA helicase/primase complex (DnaB/DnaG) moves along the template for the discontinuous strand (bottom); it pauses to allow DnaG to synthesize an RNA primer every 1000 to 2000 nt. Pol III elongates the primer until it reaches the primer of the previously synthesized Okazaki fragment. At that time, pol III releases the DNA, and pol I binds to the end of the Okazaki fragment. Pol I removes the RNA primer one nucleotide at a time using its 5′ endonuclease activity and simultaneously fills the gap in a process called nick translation. When there is a remaining nick with deoxyribonucleotides on both sides, DNA ligase can seal the nick.

strand. The core polymerase contains a θ subunit that catalyzes phosphodiester bond formation, an β subunit that is the 3′ to 5′ proofreading exonucleases, and a β subunit. The sliding clamp in *E. coli* consists of two β subunits that are assembled onto the DNA by the γ complex (the clamp loader) in a step that requires the hydrolysis of ATP. The β subunits form a ring around the double helix that slides along it (Figure 4.10, p. 149), tethering the pol III complex to make the DNA synthesis a highly processive process. This complex can synthesize DNA until it runs out of template or hits certain types of damage in DNA.

On the lagging strand, the complex releases the DNA when it encounters the previous Okazaki fragment. Two molecules of pol III are held together by the τ subunit, allowing synthesis of both leading and lagging strands in one large replisome.

On the lagging strand the DNA primase (called DnaG) forms a complex with the DnaB helicase (DnaB). DnaB causes the complex to travel along the template for the discontinuous strand, pushing the parental strands apart in a movement that requires ATP hydrolysis. The single-stranded DNA that results from helicase action is coated with **single-stranded DNA-binding protein (SSB)** that prevents reannealing of parental strands and prevents hairpins and other secondary structures from forming in the single stranded DNA. The helicase/primase complex stops approximately once per 1000–2000 bp and the DnaG primase synthesizes a short RNA primer. The RNA primer is elongated into an Okazaki fragment of about 1000–2000 bp by DNA polymerase III with its associated sliding clamp. Elongation stops when the polymerase complex encounters the RNA primer from the previously synthesized Okazaki fragment, and the DNA dissociates from the pol III complex.

In *E. coli*, RNA primer removal and gap filling are both catalyzed by a single enzyme, **DNA polymerase I (pol I)**. Pol I contains a 5′- to 3′-exonuclease activity that removes the RNA primer from the 5′-end of the previously synthesized Okazaki fragment, thereby functioning as an RNase H. It also contains a DNA polymerase activity that catalyzes addition of deoxyribonucleotides to the 3′-end of the more recently made Okazaki fragment until the gap created by removal of the primer is filled (Figure 4.13). An intrinsic 3′-to 5′-proofreading exonuclease increases accuracy of gap filling. Pol I coordinates primer removal and gap filling by excising a ribonucleotide from the primer and elongating the newer Okazaki fragment with a deoxyribonucleotide. It repeats these steps until the primer is removed. Pol I is capable of continuing down the DNA, removing deoxyribonucleotides and replacing them, an activity called nick translation. This would be a wasteful procedure, but it is limited by the fact that pol I acts in a distributive manner, coming off the substrate frequently. As long as there is still at least one ribonucleotide remaining, DNA ligase cannot act on the substrate but pol I can bind again and replace the ribonucleotide. When the gap has been filled and only a nick remains, dissociation of pol I allows **DNA ligase** to bind to the nick and catalyze formation of a phosphodiester bond, sealing the Okazaki fragment to the growing chain.

As noted in the preceding, the circular *E. coli* chromosome is under **topological constraint**. Yet the parental double helix must be completely unwound for replication and the completed chromosomes to separate into daughter cells. Replication requires the removal of positive supercoils, because the linking number of the parental strands must be reduced from a large positive number (approximately 440,000, because they are twisted around each other once per 10.5 bp) to zero to allow the daughter chromosomes to separate. **Topoisomerases** are, therefore, crucial for DNA replication.

E. coli has both type I and type II topoisomerases. The *E. coli* type I topoisomerase is called the omega protein (ω). Omega acts unidirectionally, removing only negative supercoils. Therefore, ω is not sufficient to allow replication to occur. **DNA gyrase**, a type II topoisomerase, is essential for DNA replication. DNA gyrase acts as a "power swivel" to remove positive supercoils or introduce negative supercoils; the direction is identical. Gyrase is a heterotetramer with two "swivelase" subunits encoded by gyrA and two ATPase subunits encoded by gyrB. The swivelase subunits catalyze transesterification reactions that break and reform the phosphodiester backbone, creating and resealing a transient nick on both strands (a transient double-strand break). Hydrolysis of ATP is coupled with gyrase action not to form new phosphodiester bonds but rather to trigger the conformational changes that allow a double helix to pass through the transient double-strand break, resulting in unidirectional reduction in linking number. Antibiotics that target one or the other subunit of DNA gyrase

CLINICAL CORRELATION 4.3

Topoisomerases as Antibiotics

Antibiotics that target either subunit of DNA gyrase rapidly stop *E. coli* DNA replication, because preventing the reduction in linking number of the parental strands prevents the strands from untwisting. There are two modes of targeting topoisomerases. Topoisomerase inhibitors such as coumermycin A1 and novobiocin prevent catalytic activity; they target the ATPase subunits encoded by gyrB.

Topoisomerase poisons such as Nalidixic acid freeze the covalent DNA–protein links; these complexes are lethal if converted into double-strand breaks, as would happen during replication. Nalidixic acid is used against urinary tract infections; it targets the swivelase subunits encoded by gyrA. Ciprofloxacin, another topoisomerase poison, is one of the most effective oral antibiotics in clinical use today; it is used to prevent and treat anthrax and many other bacterial infections.

Froelich-Ammon, S. J., and Osheroff, N. Topoisomerase poisons: Harnessing the dark side of enzyme mechanism. *J. Biol. Chem.* 270:21429, 1995.

rapidly stop *E. coli* replication (Clin. Corr. 4.3). *E. coli* has a second type II topoisomerase activity, topo IV, which is important in chromosome segregation into daughter cells.

Eukaryotic Enzymes of Replication

Eukaryotes require the same types of enzymatic activities as do prokaryotes, because replication follows essentially the same pathway. But differences between bacterial and human enzymes in the details of their specificity and mechanisms are used in antibacterial therapy to target pathogen replication and spare the host cells.

The continuous strand at a replication fork is synthesized by **DNA polymerase δ (pol δ)**, associated with the **sliding clamp** called **proliferating cell nuclear antigen (PCNA)**. PCNA was first detected as an antigen in nuclei of replicating cells, hence its name. Three subunits of PCNA are assembled to form a ring around DNA (Figure 4.10, p. 149), to which pol δ attaches. Assembly of this ring requires a **clamp-loading factor** called Replication Factor C (RFC).

The situation on the lagging strand is slightly more complicated in eukaryotes than in *E. coli* (Figure 4.14). A helicase activity in eukaryotes separates the parental strands, and a single-strand DNA-binding protein called **replication protein A (RPA)** binds to the exposed single strands. In eukaryotes, the primase forms a complex with **DNA polymerase α (pol α)** that initiates Okazaki fragment synthesis. This **pol α/primase** complex synthesizes a primer of approximately 10 ribonucleotides, and then switches from primase to DNA polymerase activity and elongates the primer with approximately 15–30 deoxyribonucleotides. The product of this dual reaction is a short stretch of DNA covalently attached to the RNA primer. Once the Okazaki fragment has reached this length, the pol α/primase complex dissociates from DNA. RFC binds to this elongated primer and serves as a **clamp loader** to assemble the PCNA **sliding clamp**. Then pol β binds to the PCNA and completes the Okazaki fragments to a final length of about 130–200 bp.

Primer removal is carried out in two steps by RNase H and FEN1. **Rnase H** degrades the RNA primer, leaving a single ribonucleotide attached to the end of the Okazaki fragment. **Flap endonuclease 1 (FEN1)** removes the last ribonucleotide (and possibly some deoxyribonucleotides) by peeling back one or a few nucleotides to form a small "flap" and then cleaving the phosphodiester bond at the angle to release the flap. If there is a mismatch within the first few nucleotides of the Okazaki fragment, as a result of misincorporation by pol α, the mismatch would destabilize the 5′-end and create a larger flap that could be excised by FEN1. This increases accuracy of the replication process by removing errors introduced by pol α.

The gap that remains is filled by pol δ extending the 3′-end of the more recently synthesized Okazaki fragment (Figure 4.14). The pol δ/PCNA complex releases the DNA when it encounters dNTPs at the 5′-end of the previously synthesized Okazaki fragment. The remaining nick is sealed by DNA ligase. The pol δ/PCNA complex of the replisome must then reattach to the next partly synthesized Okazaki fragment to repeat this process. As in *E. coli*, two molecules of the main replicative polymerase, pol δ in this case, are held together in a replisome, or "replication factory" in which both strands are synthesized (Figure 4.11, p. 150).

Eukaryotic DNA is packaged into **nucleosomes** that contain approximately 200 bp of DNA. Dissociation of nucleosomes is required for replication and probably limits the rate of DNA synthesis. When a single nucleosome is dissociated, about 200 bp of parental DNA are available to be separated; primer synthesis can occur somewhere in the exposed single-stranded DNA. This would explain the limited size of the Okazaki fragments in human cells.

Humans have both type I and type II topoisomerases. The human type I topoisomerase, called nicking-closing enzyme (Figure 4.9, p. 149), can remove both positive and negative supercoils; it functions during DNA replication and transcription. Type II topoisomerase is critical at the termination step and for segregation of chromosomes, which would otherwise be tangled together as the many replication bubbles are completed. Topo II is an abundant protein that also plays a role in attaching DNA to special sites in the nuclear matrix during interphase. Human type II topoisomerase is not a gyrase, in that it does not introduce negative supercoiling. Cancer chemotherapy often targets topoisomerases, using poisons that lead to double-strand breaks during replication (see Clin. Corr. 2.7). Rapidly replicating cells are more sensitive to these drugs than quiescent cells.

This page intentionally left blank

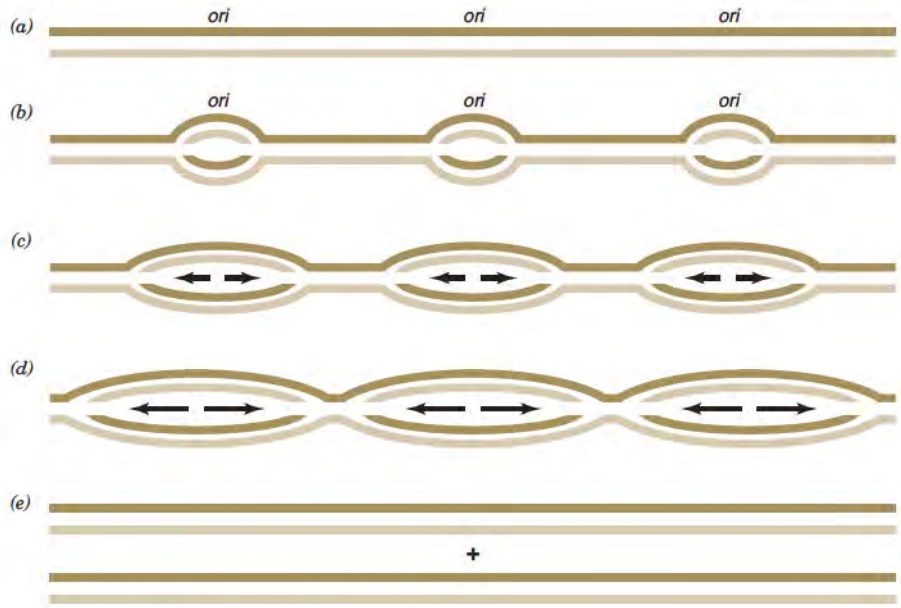

Figure 4.15 Tandem replicons and bidirectional replication in eukaryotes. (*a*) There are multiple origins of replication (ori) tandemly arrayed along each eukaryotic chromosome. In humans they are spaced at approximately 50,000- to 100,000-bp intervals. (*b*) Initiation occurs at each ori. Adjacent clusters of oris tend to function together. (*c*) Two diverging replication forks are established at each ori, so replication is bidirectional. The structures formed are called replication bubbles. (*d*) Replication bubbles enlarge as replication continues, until they are in close proximity. At that stage, termination of replication joins adjacent bubbles and unlinks parental DNA. Topoisomerase II is essential for termination of replication and segregation of the chromosomes. (*e*) The resulting duplicated chromosomes can then segregate into two daughter cells.

Initiation of Replication

In the previous discussion, we addressed progression of a replication fork. But, how does a replication fork get started? And how is initiation controlled so that the entire genome is copied once and only once? Replication begins from specific sites called **origins of replication.** Known origins contain multiple, short, repeated sequences that bind specific initiator proteins, and AT-rich regions at which the initial separation of parental strands occurs. The *E. coli* chromosome has a single origin of replication, origin of chromosomal replication (oriC), a region of approximately 245 bp. There are thousands of origins in eukaryotic cells (Figure 4.15), which allow those cells to replicate the large amount of DNA in the limited time of one cell cycle. In yeast the origins are termed **Autonomously Replicating Sequences (ARS).** In humans, specific sequences that serve as origins have not been identified.

In *E. coli*, oriC is bound by an **initiator protein** called **DnaA. DnaC** then associates and acts like a "matchmaker" to allow **DnaB**, the helicase, to bind and begin separating the parental strands to create a replication fork. A replication bubble is formed at each origin and a pair of replication forks is established that move away from the origin, one in each direction (Figure 4.15). Thus, replication is **bidirectional**.

The **Origin Recognition Complex (ORC)** in eukaryotes assembles at multiple origins (Figure 4.16). Assembly of an ORC at an origin is necessary but not sufficient for initiation to occur. A second complex called **minichromosome maintenance proteins (MCM)**, which has a weak helicase activity, must also bind, forming a pre-replicative complex; Cdc6 (the protein encoded by *Cdc6*) is required for this binding. Once the ORC/MCM complex bound at an origin is activated, it catalyzes the initial separation of parental strands to form a small **replication bubble** (Figure 4.16). **SSBs** (the human SSB is RPA) bind and hold the separated strands apart. The **MCM** complex may then function as a helicase to allow replication fork unwinding. Activation of the ORC/MCM complex is regulated by **cyclins** and **cyclin-dependent protein kinases** (see p. 1005). Phosphorylation of Cdc6 by a **cyclin-dependent kinase** inactivates it and prevents reassembly of the complex; this is one of the ways in which reinitiation of replication, which would be disastrous for the cell, is prevented.

The initiation of DNA synthesis uses most of the same mechanisms and enzymes as the movement of a replication fork (compare Figure 4.14, p. 154, and Figure 4.16). In eukaryotes, the polα/primase complex initiates synthesis of an RNA primer and then switches to elongating it with dNTPs. This short polynucleotide is elongated by a DNA polymerase δ in the same way as on the discontinuous (retrograde) strand at a replication fork. The replisome elongating this first strand can continue synthesis and forms the leading strand of the fork on one side of the replication bubble (Figure 4.16). On that half of the bubble, synthesis of the first Okazaki fragment on the retrograde strand is initiated by the same mechanism as is used in moving the replication fork (compare Figure 4.13, p. 151). However, as this

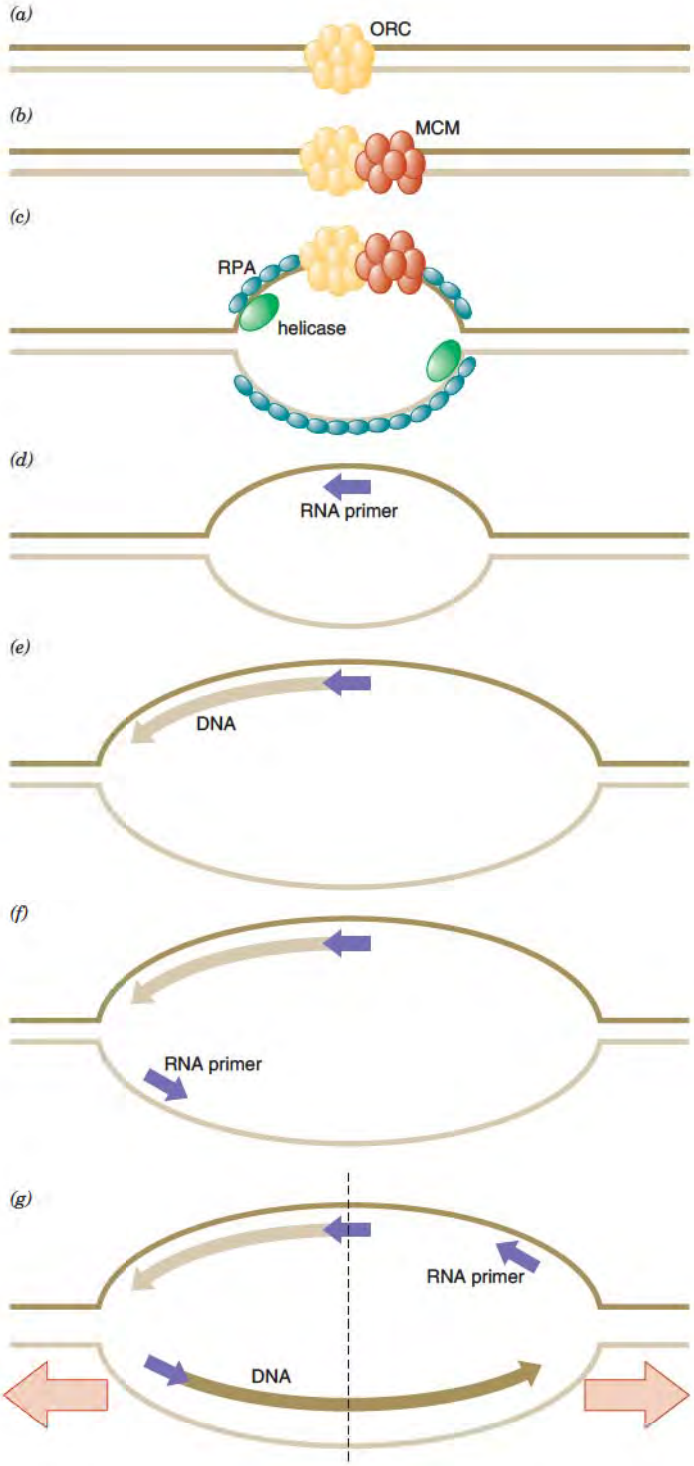

Figure 4.16 Initiation of replication at a eukaryotic replication origin. (*a*) The origin recognition complex (ORC) binds to an origin. (*b*) An MCM complex binds to this; cell division cycle 6 protein (cdc6) is important in this assembly. (*c*) The initiator complex is activated and the helicase activity opens the parental strands to form a very small bubble. SSB binds to the exposed single strands, helicases are loaded onto the DNA, and the bubble is enlarged. (*d*) Polα/primase synthesizes the first RNA primer and, after about 10 nt, switches to elongating it with deoxyribonucleotides. (In this and subsequent panels, the focus is on processes occurring on DNA, and proteins are not shown.) (*e*) After about 15–30 deoxyribonucleotides are added, polα/primase leaves and the chain is elongated by DNA polymerase δ, which incorporates deoxyribonucleotides. To this stage, the process is like that occurring on the discontinuous (retrograde) strand (compare Figure 4.14). However, the elongating strand will not encounter a previous Okazaki fragment; it can continue elongating, becoming the continuous (leading) strand on the leftward-moving replication fork. (*f*) An RNA primer is synthesized on the discontinuous side of this replication fork, as in normal fork progression. (*g*) This primer is elongated as previously described. However, this elongating strand will not encounter a previous Okazaki fragment and can continue elongating, becoming the continuous (leading) strand on the rightward-moving replication fork. An RNA primer can be synthesized on this fork by the normal mechanism (compare Figure 4.14). The result is two replication forks diverging from the origin. The process is symmetrical around the axis indicated by the dotted line, with mirror-image forks diverging from origin.

first Okazaki fragment is elongated, it will not run into a previous fragment so it continues to grow in the 5′ to 3′ direction; as it passes the origin, it becomes the leading strand of the replication fork moving in the opposite direction (Figure 4.16). Both leading strands continue to be elongated in a highly processive manner, and Okazaki fragments are synthesized on the opposite sides. The result is a pair of replication forks diverging from the origin.

Telomerase

Telomeres, the specialized structures at the end of linear chromosomes in eukaryotes (Figure 4.12, p. 151), are maintained by **telomerases**, enzymes that add new six-nucleotide repeats to the 3′-ends of the telomeres. Telomerases are ribonucleoprotein

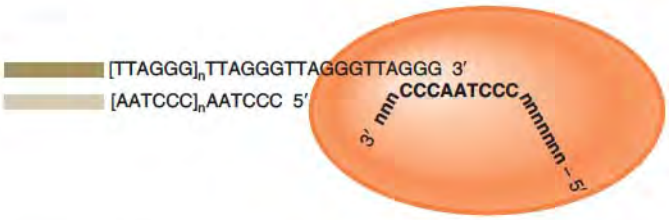

Figure 4.17 Telomerase. Telomerase is a ribonucleoprotein complex with a short RNA strand as an integral part; it catalyzes the addition of new 6-nt telomere repeats to the 3′-end of a DNA chain. Telomerase RNA partially base-pairs with the telomeric repeat and serves as the template for the reaction, while the protein component functions as a reverse transcriptase, synthesizing DNA using the RNA template. After a six-nucleotide repeat is added, the enzyme can dissociate and bind again, and add additional 6-nt repeats.

complexes containing a small RNA that serves as a template for addition of a new six-nucleotide repeat (Figure 4.17). A telomerase binds to the end of the 3′-strand with part of the telomerase RNA hydrogen bonded to the last few nucleotides of the chromosome. A six-nucleotide repeat is synthesized, using the RNA as a template. Then the telomerase can dissociate and reassociate to add another hexamer.

Telomeres do not have to remain exactly the same length; some shortening is not a problem, because the repeats do not encode proteins. Telomeres undergo cycles of shortening of the lagging strands due to the inability to complete synthesis (Figure 4.12*a*, p. 151) and lengthening by addition of new six-nucleotide repeats to the 3′-end by telomerase (Figure 4.17). Although the length of the telomere does not remain constant, progressive shortening is avoided by addition of repeats. Telomerases also reestablish the 3′-overhang characteristic of telomeres.

Cells that have differentiated and will divide only a limited number of times do not express telomerase. Thus, the telomeres shorten with each further division; this limits the number of times such cells can divide before the loss of telomeres triggers apoptosis, programmed cell death (see p. 1010). Telomerase expression is generally reactivated in tumor cells; this allows them to continue division indefinitely without chromosome shortening, and makes telomerase an attractive target for cancer chemotherapy. It should be noted that inactivating telomerase in a tumor would not lead to a rapid halt in tumor growth; the effect would be delayed by many cell cycles, until the chromosome ends shorten significantly. Thus, telomerase inhibitors are likely to be useful only in conjunction with other therapies.

Cell Cycle

In eukaryotes, there is a distinct and regulated pattern of activities that constitutes a **cell cycle** (Figure 4.18 and p. 157). The most striking morphological feature of the cell cycle is mitosis, the condensation, alignment, and separation of chromosomes followed by division of a cell into two cells. The phase of the cell cycle in which mitosis occurs is called **M-phase** (for mitotic phase). DNA replication takes place during the **S-phase** (for synthesis phase). **G1-phase** (Gap 1 phase) occurs between mitosis and S-phase, and **G2-phase** (Gap 2 phase) between S-phase and mitosis. G1-, S-, and G2-phases together are called interphase and constitute most of the total time of a cell cycle. A higher-than-normal fraction of cells in mitosis is a histological indicator of cancer (Clin. Corr. 4.4).

In eukaryotes, replication is regulated by determining whether to start DNA replication. Once started, cells generally proceed through the entire replication process. Initiation of replication at origins must be coordinated to ensure that all regions of all chromosomes are replicated in each cell cycle and that no region is replicated more than once. This is, obviously, a difficult challenge in a cell with thousands of origins. Failure to replicate the entire genome would lead to chromosome instability and loss of genetic information. If a portion of the chromosomal DNA is not replicated, the two progeny chromosomes cannot separate properly, or the chromosome could be broken during the attempt. Broken chromosomes are unstable and trigger recombination, which causes further problems. Either the lack of key genes in a cell missing a chromosome due to missegregation or the excessive expression of other genes in a cell with an extra copy of a chromosome can be disastrous. Trisomy 21, the presence of one extra copy of the smallest human chromosome, causes Down syndrome, and most other trisomies are lethal.

Different regions of the genome are replicated at different times during the S-phase of the cell cycle. Typically, regions that are actively transcribed are replicated early during

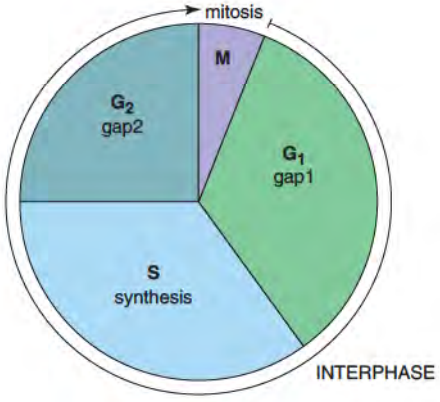

Figure 4.18 Cell cycle. In eukaryotic cells, DNA replication (S-phase) and mitosis (M-phase) are separated by two gaps, G1 and G2. The size of the segment represents the typical fraction of the cell division cycle time.

CLINICAL CORRELATION 4.4

Cancer and the Cell Cycle

Cancer is defined as the unregulated, excessive division of cells. It is recognized pathologically by a higher fraction of cells actively in the cell cycle than is expected for the normal tissue from which it arose. This includes a higher fraction of cells in mitosis, recognizable by microscopy, and a higher fraction of cells in S-phase.

Many kinds of drugs are used to disrupt replication. Antimetabolites interfere with synthesis of precursors of 5′-NTPs. Methotrexate inhibits dihydrofolate reductase, needed to maintain reduced tetrahydrofolate required for nucleotide synthesis. 5-Fluorouracil inhibits thymidylate synthase; when metabolized into its triphosphate, it can be incorporated into DNA and lead to strand breaks. Vinca alkaloids inhibit microtubule assembly and thereby interfere with mitosis and chromosome segregation. Topoisomerase inhibitors slow or stop the process of replication by preventing untwisting of parental strands. Topoisomerase poisons inhibit resealing of the phosphodiester bond, leaving covalent protein–DNA junctions that are converted into strand breaks; this class of antineoplastic agents includes etoposide and doxorubicin.

S-phase. Conversely, heterochromatic regions (where the chromatin is condensed and not actively transcribed) are typically replicated late in S-phase.

Although the details of the process are not yet clear, some general principles can be stated. The current model is referred to as licensing. A licensing factor must be bound to the origins to allow initiation of replication at that origin. This occurs before the start of S-phase and involves the MCM complex binding to the ORC at the many origins. This binding is facilitated by "matchmaker" proteins, including cell division cycle protein 6 (Cdc6) and chromatin licensing and DNA replication factor 1 (Cdt1). Assembly of this pre-replication complex only occurs during G1-phase, before DNA synthesis occurs. Once initiation of replication has occurred, the licensing factor is inactivated by phosphorylation and dissociation of Cdc6 and of the MCM complex. Cyclin-dependent kinase (CDK) and Dbf4-dependent kinase (DDK) are involved in the initiation of replication, catalyzing the recruitment of the replisome to the origin, activating the helicase activity that unwinds the parental strands, and inactivating the licensing factors. For that origin to be used again, a new licensing factor must bind, but the assembly of the complex cannot occur until the next G1-phase when new Cdc6 protein is available. Another block to re-replication is the protein geminin, which binds and inhibits Cdt1. This prevents premature reinitiation during a single cell cycle.

For cell viability, it is important that DNA be completely replicated before mitosis. Cells have regulatory mechanisms that ensure coordination of the events of the cell cycle at several checkpoints. Cells are most sensitive to DNA damage during the process of replication, because replication forks can encounter the damage before it has been repaired (Clin. Corr. 4.4). Cells have evolved sensors that recognize DNA damage and arrest the cell cycle at either the G1/S boundary or the G2/M boundary. If the cell is already in S-phase, the blockage of replication forks prevents further initiation events during S-phase. The damage sensors also induce synthesis of proteins that aid in DNA repair. PCNA, RFC, RPA, and pol ϵ appear to play important roles in recognition of damage that blocks replication and coordination of replication and repair functions. The interaction of PCNA with $p21^{cip1}$, an inhibitor of cyclin-dependent kinase, appears to inhibit replication but not repair; it may thus allow repair to proceed before replication continues. Defects in several genes important in this checkpoint response, including ATM, TP53, and CHK2, increase genomic instability and the risk for cancer.

Replication of RNA Genomes

Some viruses have an RNA genome. Such genomes are replicated with much lower accuracy, and they can accumulate variations relatively rapidly. A particularly important example of this is the **Human Immunodeficiency Virus (HIV)**, which causes **Acquired Immune Deficiency Syndrome (AIDS)**. The HIV viral RNA is reverse transcribed into DNA and then the DNA integrates into the chromosome. The HIV reverse transcriptase is a target for antiviral chemotherapy (see Clin. Corr. 4.2, p. 144).

Reverse transcription of the RNA genome of HIV is far less accurate than DNA synthesis, and the reduced accuracy leads to the rapid generation of a collection of variant viruses within an individual. A small fraction of these variants is likely to be resistant to any single drug being used to treat the infection. That fraction can continue to replicate in the presence of the therapeutic agent to become the dominant variants; this leads to loss of efficacy of the drug. Current combination therapies are designed to reduce the probability that a virus will be simultaneously resistant to all drugs in the combination. Current combination therapies target both the HIV reverse transcriptase and the HIV protease.

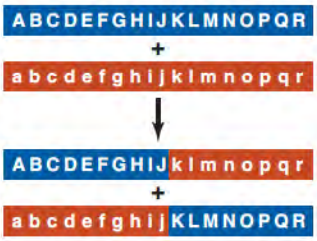

Figure 4.19 Homologous recombination. (*a*) The paternal chromosome is shown in blue with alleles shown in capital letters. The homologous maternal chromosome is shown in red with alleles shown in lower case. (*b*) After homologous recombination between genes j and k, both chromosomes contain DNA from both parents. There has been an equal, reciprocal exchange between them.

4.4 • RECOMBINATION

Recombination is the exchange of genetic information. There are two basic types: **homologous recombination** and **nonhomologous recombination**. Homologous recombination (also called **general recombination**) occurs between identical or nearly identical sequences, for example, between paternal and maternal chromosomes of a pair. Chromosomes are not passed down intact from generation to generation (Figure 4.19); rather, each chromosome

you inherit from your father contains portions from both of his parents, and likewise for chromosomes inherited from your mother. Occasionally and often triggered by damage to a chromosome such as a double-strand break, recombination occurs between different chromosomes. This can lead to cancer (Clin. Corr. 4.5).

Homologous recombination is reciprocal, transferring part of one chromosome to the other and vice versa. It shuffles the combination of genes before they are passed to the next generation, generating genetic diversity. This is a normal part of the process of chromosome alignment and segregation necessary to ensure that each germ cell gets a single haploid set of chromosomes during meiosis. The probability that a recombination event will occur between any two points on a chromosome is roughly proportional to the physical distance between them. This is the basis for genetic mapping. A 1% frequency of recombination between two genes or markers is defined as a genetic distance of one **centimorgan (cM)**. In humans, 1 cM is approximately 1,000,000 base pairs along the chromosome.

Homologous Recombination

There are three major models for homologous recombination (Table 4.3). They are related in many ways, and have a common intermediate called a **Holliday junction.** The simplest is the Holliday model; understanding its key points will make it easy to see the distinctions of the others.

Holliday Model

The key features of the **Holliday model** are (a) homology, (b) symmetry of both breaks and strand invasion, and (c) presence of a four-stranded "Holliday junction" as a key intermediate (Table 4.3). In this model, recombination is initiated by a pair of single-strand breaks at homologous positions in the two aligned DNA duplexes (Figure 4.20). The strands of each duplex partly unwind, and each "invades" the opposite duplex. That is, a portion of one strand from each duplex base pairs with the opposite duplex in a reciprocal, symmetrical fashion. These strands can be covalently joined to the opposite duplex, creating a joint molecule in which two strands cross between the DNA molecules.

Branch migration then occurs (Figure 4.20*c*); branch migration is the simultaneous unwinding and rewinding of the two duplexes such that the total number of hydrogen bonds remains constant but the position of the crossover moves. Because the number of hydrogen bonds remains constant and the thin, cylindrical DNA molecule is easy to rotate around its axis, branch migration requires little energy. Branch migration creates a region of **heteroduplex**, a region where one strand comes from one original duplex and the other comes from the other duplex. In humans, two individuals differ by approximately one base pair per thousand; therefore, a region of heteroduplex often contains at least one mismatched base pair.

The crossed strands are covalently joined to the other duplex (Figure 4.20*c*) The two DNA duplexes, joined by a single crossover point, can rotate as shown in Figure 4.20*e* and *h* to create a four-stranded Holliday junction. Its resolution into two duplexes can occur

TABLE 4.3 • Homologous Recombination

	Holliday Model	*Meselson-Radding Model*	*Double-strand Break Model*
Homology	Yes	Yes	Yes
Initiation	2 single strand nicks at homologous positions	1 single strand nick	1 double strand break, ends resected
Strand invasion	1 strand of each duplex invades the other-reciprocal	Single elongated nick invades other duplex	1 or 2 strands invade other duplex
Branch migration	Yes	Yes	Yes
Key intermediate	Holliday Junction	Holliday Junction	2 Holliday Junctions
Heteroduplex formed	Yes-symmetrical	Yes-asymmetrical	Yes-asymmetrical and long

CLINICAL CORRELATION 4.5

Recombination and Cancer

Errors in recombination can lead to gene duplications or deletions, triplet expansion, gene fusions, and chromosomal rearrangements. The frequency of recombinational events is increased by damage to DNA, in part due to disruptions of replication forks and in part due to breaks in the DNA. Recombination can occur between related but not identical sequences within a chromosome or between chromosomes. It can also occur by nonhomologous end joining following a double-strand break in DNA. Some forms of cancer are triggered by specific chromosomal rearrangements that result in gene fusions that form oncogenes. Both chronic myeloid leukemia (CML) and acute lymphocytic leukemia (ALL) can result from translocations between chromosomes 9 and 22 that create fusion proteins between the genes BCR and ABL. The BCR–ABL fusion protein is an active tyrosine kinase that functions as an oncogene.

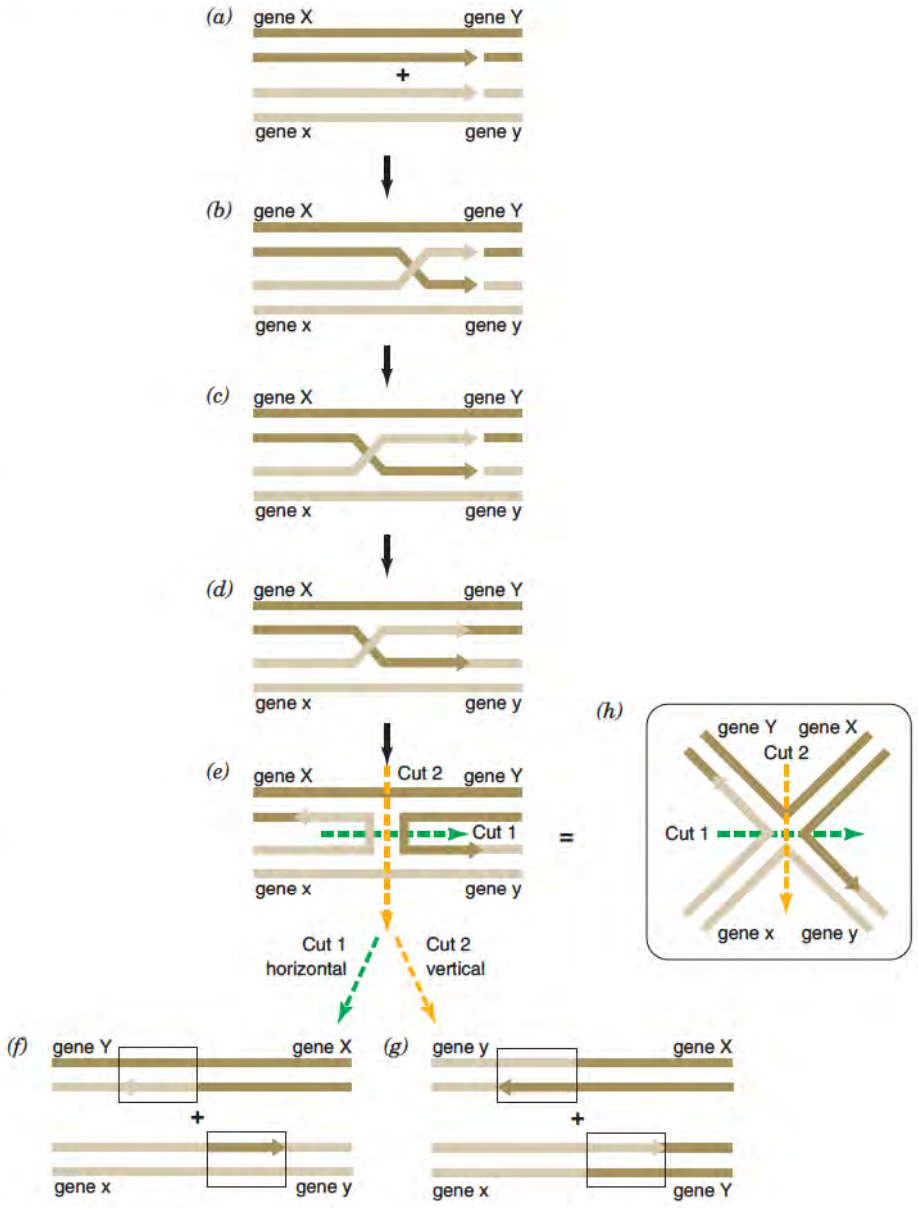

Figure 4.20 Holliday model of homologous recombination. (*a*) Synapsis (pairing): two homologous DNA molecules come together properly aligned. (X,x and Y,y represent different alleles of genes X and Y, one on either side of the crossover.) Single-strand breaks are made at homologous positions in strands of the same polarity in each duplex. (*b*) Strands partly unwind and reciprocally "invade" (base-pair with) the opposite molecule, forming a structure in which two intact strands are joined by two crossed strands. This is a symmetrical and reciprocal event. Regions in which one strand was from one duplex and the other from the homologous duplex are called heteroduplexes. (*c*) Branch migration occurs. (*d*) DNA ligase seals the nicks. Further branch migration can occur. All four strands are held together at one crossover point. (*e*) Rotation of this structure forms a Holliday intermediate shown in inset (*h*). (*f* and *g*) Resolution: Molecules are separated by a pair of symmetrical cuts in either of two directions (orange or green arrows). The ends are resealed by ligase. The direction of the cuts determines whether flanking regions are exchanged. (*f*) If crossed strands are cut (cut 1, horizontal), flanking genes remain as they were (XY/xy). You would not detect recombination between these loci. (*g*) If uncrossed parental strands are cut (cut 2, vertical), flanking genes or markers are exchanged (Xy/xY). This would be detected as a recombination event. Note that there is a region of heteroduplex in either case (boxed); mismatch repair in this region can lead to gene conversion.

in either of two ways, depicted as vertical or horizontal cuts in Figure 4.20*e*. If the crossed strands are cut (cut 1), markers flanking the region of heteroduplex remain linked together in the same phase as originally (X with Y and x with y; panel *f*); on a gross level, the chromosomes remain unchanged. If the intact strands are cut (cut 2), the flanking regions are exchanged between the two chromosomes, creating a new chromosome containing part from one parent and part from the other (X with y and X with y; Figure 4.20*g*). The heteroduplex may undergo mismatch repair (p. 170), converting one allele into another, a process called **gene conversion**.

Meselson–Radding Model

Once you understand the Holliday model, it is easy to understand the variant proposed by Meselson and Radding (Table 4.3). It is initiated by a single nick and a single invading strand, rather than a pair of nicks and reciprocal invasion (Figure 4.21*a*). The nicked strand serves as a template–primer combination that a DNA polymerase elongates, and this elongation displaces part of the invaded duplex (Figure 4.21*b*). The displaced strand invades the opposite, aligned duplex, forming a structure called a D-loop (Figure 4.21*c*). The single-stranded portion of the D-loop is degraded, and repair synthesis and resealing result

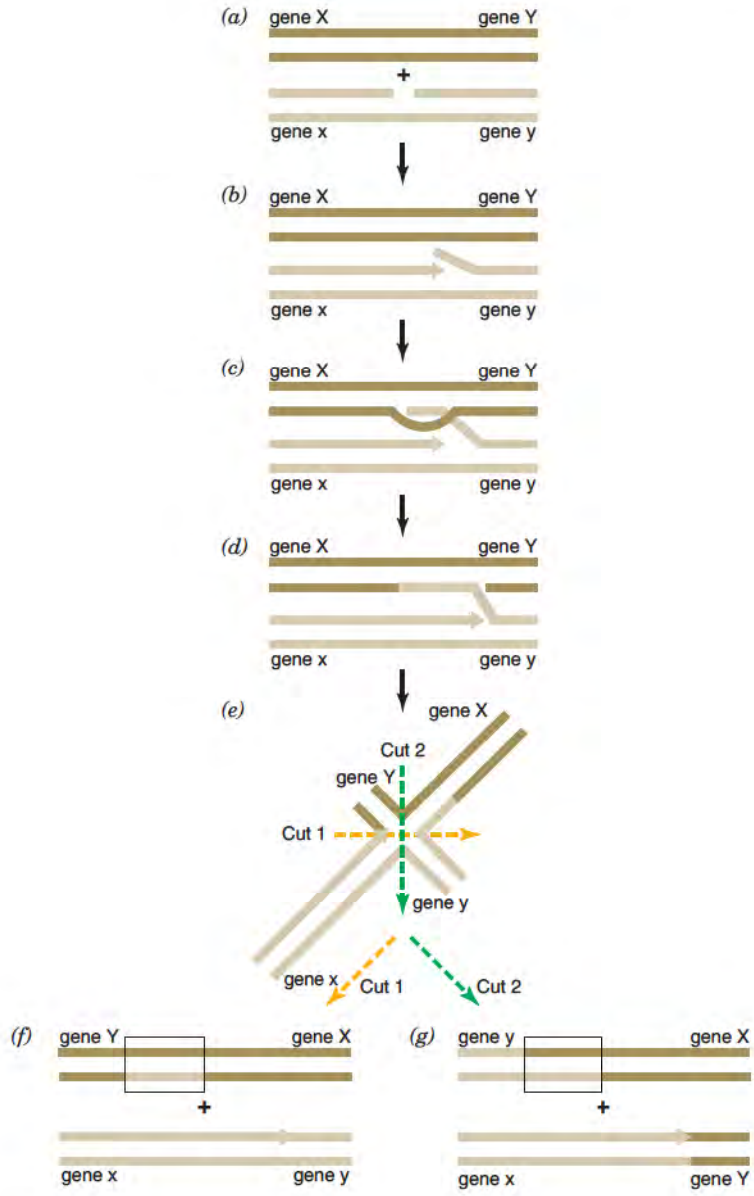

Figure 4.21 Meselson–Radding model of homologous recombination. This model is similar to the Holliday model, but initiation is by a single nick and a single invading strand. (*a*) Synapsis (pairing): Two homologous DNA molecules come together properly aligned. A single-strand break is made in one strand. (*b*) The 3′-OH-end is elongated by a DNA polymerase, displacing the 5′-end. (*c*) The free 5′-end invades the homologous duplex, forming a D-loop. (*d*) The D-loop is degraded, and repair synthesis and resealing by DNA ligase lead to a molecule in which one strand crosses between two duplexes. Branch migration occurs as one strand is elongated further (not shown). The elongating strand crosses over and is joined to the opposite duplex, leaving all four strands joined at a single crossover point, as in Figure 4.20. (*e*) Strands rotate to form a Holliday junction exactly as in Figure 4.20e and h. Resolution of the Holliday junction can occur in two ways, and the direction of the cut determines whether flanking regions are exchanged. Note that there is a region of heteroduplex in either case (boxed), but it is not reciprocal; it is only on one duplex. Mismatch repair in this region can lead to gene conversion.

in the crossing over of one strand. Branch migration occurs. The remaining nick is sealed and the strands can swivel to form a Holliday junction identical to that described for the Holliday model in the preceding (Figure 4.21*e*), which is resolved in exactly the same way, resulting in an exchange of flanking genes (cut 2: X with y and X with y; Figure 4.21*g*) or the original configuration of genes (cut 1: X with Y and x with y; Figure 4.21*f*). The key difference in the **Meselson–Radding model** is the asymmetrical heteroduplex that results from the invasion by one strand from one of the two duplexes. Mismatch repair can lead to gene conversion.

Double-Strand Break Model

The third model is the double-strand break model (Table 4.3). In this, recombination is initiated by a double-strand break in one duplex (Figure 4.22*a*). The ends are resected (Figure 4.22*b*), resulting in the loss of genetic information from one of the two duplexes. There are alternative forms of this model. In one, the two single-stranded segments of the broken duplex both invade the intact duplex, forming a joint molecule that has two Holliday junctions. The broken ends can be repaired by a polymerase, using the intact strand as a template, and a DNA ligase. Branch migration occurs as in the previous models. In an alternative model, the 3′-end of one of the two sides of the break invades the other

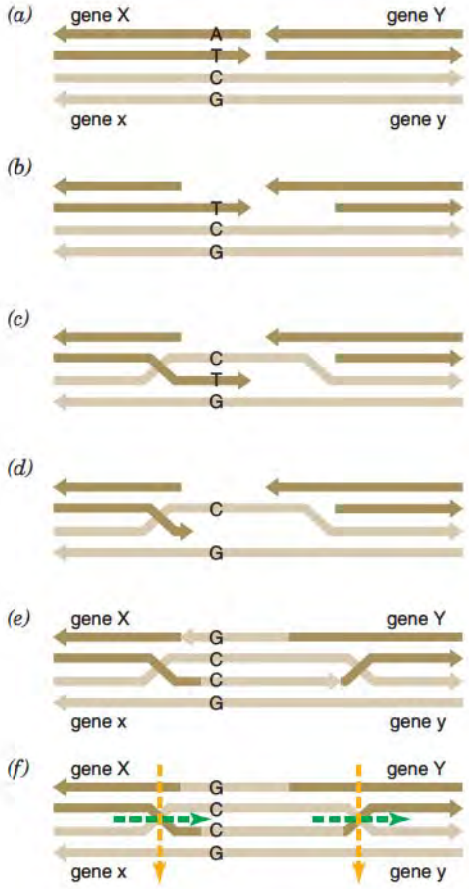

Figure 4.22 Double-strand break model of homologous recombination. This model is similar in many ways to the two models discussed previously, but initiation is by a double-strand break in one of the two DNAs. (*a*) Initiation is by a double-strand break in one DNA molecule. Two aligned duplexes are shown; flanking genes have different alleles (X,x;Y,y). Also shown is a position at which one duplex has an AT base pair and the other has a GC base pair. (*b*) DNA is resected from the break by an exonuclease that leaves 3′-OH-overhangs. This resection may remove one of the nucleotides at the site that differs between duplexes. (*c*) One or both of these overhangs can invade the intact homologous duplex. (*d*) Where there is a mismatch, the free end can be resected further by enzymes of mismatch repair. (*e*) The free end can be extended by a DNA polymerase, using the undegraded strand as a template and resulting in gene conversion. Remaining nicks are repaired, forming two Holliday junctions. (*f*) Both Holliday junctions are then resolved. Because there are two junctions and two ways to resolve each (as in Figure 4.20h), there are four possible results. Two of the four possible ways to resolve the Holliday junctions (vertical/vertical or horizontal/horizontal cuts) leave flanking genes as they were (XY/xy). The other two ways to resolve the Holliday junctions lead to exchange of flanking genes (Xy/xY). Resolution can also be carried out by topoisomerase.

strand and establishes a D-loop that allows copying of the intact duplex. This can result in a small replication bubble with synthesis on both strands for a short distance, and resolution when the bubble encounters the other side of the break. This would account for extensive gene conversion.

Resolution of the two Holliday junctions is by a pair of cuts (Figure 4.22*f*). Because there are two possible directions in which to resolve each junction, there are four possible outcomes. Two leave flanking genes together in their original configuration (X with Y and x with y), and two lead to the exchange of flanking genes (X with y and X with y). Resolution by a type II topoisomerase can also occur. Because one duplex has lost DNA in the region of the break, closure of the gap required the genetic information for both resulting chromosomes to come from the intact duplex; therefore if there were any sequence differences between the chromosomes in the gap, gene conversion will have occurred.

Key Proteins of Recombination in *E. Coli*

In *E. coli*, the key protein in the process of recombination is **RecA**, which binds in a cooperative manner to single-stranded DNA and forms a helical coil. This facilitates pairing of the single strand with a homologous duplex DNA to form a three-stranded D-loop structure. Strand switching can occur, leading to heteroduplex DNA. Eukaryotes have homologous proteins, the human version of which is called RAD51.

RecBCD is an *E. coli* complex with multiple activities; it binds at a double-strand break and processes it into a substrate for recombination by chewing back the DNA and, on encountering a special sequence called a χ site, leaving a protruding single strand with 3′-OH. RecA can bind to this single strand to initiate pairing with the homologous duplex. **RuvA** and **RuvB** form a complex with DNA helicase activity that catalyzes extensive branch migration, a key step in recombination. RuvC is an endonuclease that binds to this complex and catalyzes the resolution of Holliday junctions.

Nonhomologous Recombination

Site-Specific Recombination

In site-specific recombination, specialized enzymes catalyze the integration of a sequence into particular sites in the DNA. Integration of the bacteriophage λ into the *E. coli* chromosome is the best studied example. The **λ-integrase** catalyzes specific nicking of λ DNA and of a special sequence in the *E. coli* chromosome, and also catalyzes the resealing involved. This is a reversible process; the integrated λ-sequence can be excised from the chromosome. There are important examples of site-specific recombination that control processes such as mating type conversion in yeast, and phase change (alterations in major surface protein) in trypanosomes. Phase change in trypanosomes helps the parasite to evade the immune response.

Transposition

Transposition is the movement of specific pieces of DNA in the genome. There are two types of transposition events, simple transposition, in which a sequence is excised from one place in the genome and inserted elsewhere, and replicative transposition, in which a copy of the sequence is inserted elsewhere in the genome without the original being lost. **Transposases** are the enzymes that catalyze transposition. They recognize and act at **insertion sequences**. Some pieces of DNA, called **transposons**, encode transposases flanked by insertion sequences and can move nearly anywhere into a target chromosome. Transposons sometimes carry other genes with them when they transpose. Other pieces of DNA contain insertion sequences but do not encode their own transposase; these can move when a transposase encoded elsewhere is expressed.

Transposons can move to new places within a chromosome or integrate into other chromosomes. A significant fraction of the human genome has resulted from accumulation of transposons and insertion sequences. **Long interspersed elements (LINEs**, of which the L1 element is most common) are transposons present in about 50,000 copies in the human genome. Alu sequences are **short interspersed elements (SINE**s) present in about 500,000 copies per haploid human genome; they do not encode a reverse transcriptase. Some mutations that cause disease are due to insertion of a transposon into a gene, altering its coding or regulation.

Retrotransposons are sequences that were transcribed into RNA and then reverse-transcribed and integrated back into a random site in the genome. Retroviruses make DNA copies of their RNA genome (using **reverse transcriptase**, an enzyme that makes a DNA copy of an RNA) and insert them into the host chromosome by a transposition event catalyzed by a virus-encoded **integrase**.

Nonhomologous End Joining

In nonhomologous end joining (NHEJ; sometimes called illegitimate recombination) no homology is needed, nor are there special DNA sequences. Rather, broken ends of a DNA duplex can recombine with another duplex in the absence of homology. This can lead to the repair of a double-strand break in DNA, and therefore be of considerable survival value. It can also lead to chromosomal translocations or the insertion of a DNA fragment anywhere into the genome. In mammalian cells, a heterodimer called **Ku** binds avidly to DNA ends and can move along the DNA. Ku associates with a large catalytic subunit to form **DNA-PK**, a DNA-dependent serine/threonine protein kinase. This is thought to play a key role in nonhomologous end joining (NHEJ) by binding to and bringing together the two free ends of a double-strand break and protecting them from excessive nuclease action. It may unwind the ends until very short regions of "**microhomology**" (2–6 bp) can pair. The unpaired flaps could be removed by FEN1, the gaps filled by DNA polymerase, and the nicks ligated by DNA ligase. Defects in Ku lead to X-ray sensitivity, due to reduced ability to repair the double-strand breaks caused by X-rays. Defects in Ku can also lead to severe combined immunodeficiency disease (SCID) because another role of Ku is in V(D) J recombination, the site-specific cleavage and rejoining required to assemble functional immunoglobulin genes.

When genes are introduced into mammalian cells, they usually integrate randomly into the chromosome by nonhomologous end joining. This random integration of a fragment of DNA can disrupt genes and cause mutations or dysregulation. Therefore, it

CLINICAL CORRELATION 4.6

Recombination and Gene Therapy

Gene therapy is the introduction of new or altered genes into cells to correct a genetic defect or treat a disease. As we learn more about specific diseases, the possibilities for genetic intervention increase. The easiest type of disease to cure by gene therapy is one in which the supply of a circulating protein can be provided from cells engineered to produce it, with no requirement that those cells be in a specific location. Slightly more difficult would be the regulated production of a protein, for example insulin, that can be provided by cells located anywhere in the body. It will be much more difficult to replace a defective gene with a normal copy in particular cells in which it is expressed.

Several major limitations impede progress. One is the difficulty of introducing genes into the relevant cells; this is being addressed by more work on vectors for gene introduction and on stem cell biology. Another is the tendency of introduced genes to be incorporated randomly into the genome. DNA introduced into mammalian cells is most frequently integrated into the genome by nonhomologous end joining (NHEJ). This random insertion can result in the creation of a new mutation if the transgene inserts into either a coding or regulatory sequence of a gene. It can also create difficulties in sustaining gene expression over time, because the inserted gene will not be in its normal place within a chromosome and therefore may be inappropriately regulated by epigenetic mechanisms.

is possible that the attempt to correct one genetic problem by inserting a gene could cause another problem; this is a major limitation to gene therapy at present (Clin. Corr. 4.6).

Pseudogenes

The human genome contains many pseudogenes, nonfunctional copies of genes. These can result from retrotransposition of mRNAs, in which case they have no introns, or of partially processed transcripts, in which case they may contain some but not all of the introns. In other cases they appear to arise from recombination, such as unequal crossing over, and contain introns. Often these pseudogenes are nonfunctional because of missense or nonsense mutations (see p. 166) or because the sequences necessary for transcription initiation have been altered. In other cases, retrotransposition or unequal crossing over has provided the raw material for evolution, when accumulation of genetic changes leads to the gene copy taking on other functions.

4.5 • DNA DAMAGE AND MUTATIONS

DNA in cells is constantly being damaged by cellular constituents, including active oxygen species that are by-products of metabolism. Many environmental agents and chemicals in food attack and modify DNA. Damage to DNA can block essential processes including DNA replication and transcription and can lead to mutations.

In aqueous solution at 37°C, there is spontaneous **deamination** of C, A, and G bases in DNA. C deaminates to form U (Figure 4.23*a*), A to hypoxanthine, and G to xanthine. Spontaneous **depurination** due to cleavage of the glycosyl bond connecting purines to the backbone, leaving the backbone of the DNA intact (Figure 4.23*b*), occurs at a substantial rate. It has been estimated that between 2,000 and 10,000 purines are lost per mammalian cell in 24 hours. These depurinated sites are called abasic (lacking a base) or **AP sites** (originally meaning apurinic, lacking a purine, but since generalized to lacking any base).

Bases are oxidized at a substantial rate by reactive oxygen species that are by-products of oxidative metabolism; this creates altered bases, for example 8-hydroxyguanine (8-oxo G; Figure 4.23*c*). Oxidative damage tends to increase with age. Products of lipid peroxidation can form adducts with bases, particularly G residues.

Alkylating agents, including some used for chemotherapy, add methyl or other alkyl groups to the bases. S-adenosyl methionine, a carrier of methyl groups in normal metabolism, occasionally methylates a base in DNA.

Ultraviolet radiation (from sunlight or tanning lamps) covalently links adjacent pyrimidines along one strand of the DNA to form cis-syn cyclobutane **pyrimidine dimers** (Figure 4.23*d* and *e*) and other photoproducts, including pyrimidine 6–4 pyrimidones. Ionizing radiation, including X-rays and radioactive decay, creates strand breaks and produces reactive oxygen species that damage DNA.

Carcinogens and mutagens attack DNA. Some are direct acting and others are **pro-carcinogens**. Pro-carcinogens in their native form do not damage DNA, but they can be activated by metabolic processes (e.g. oxidized by cytochrome P450s) into carcinogens that damage DNA. This process is called **metabolic activation**. **Benzo(*a*)pyrene**, a constituent of coal tar, is an extremely potent pro-carcinogen that requires oxidation to the epoxide to attack DNA.

Many chemotherapeutic agents attack DNA; some cause bases to become alkylated, others, including cisplatin, cross-link the two strands (Clin. Corr. 4.7). The higher sensitivity of replicating cells to DNA damage means that rapidly dividing tumor cells are more sensitive to these damaging agents than are normal cells, but their damage to normal cells limits their dosing and use.

Mutations

Mutations are inheritable changes in the DNA sequence. They can result from replication errors, from damage to the DNA, or from errors introduced during repair of damage. Mutations that are changes of a single base pair are called **point mutations**.

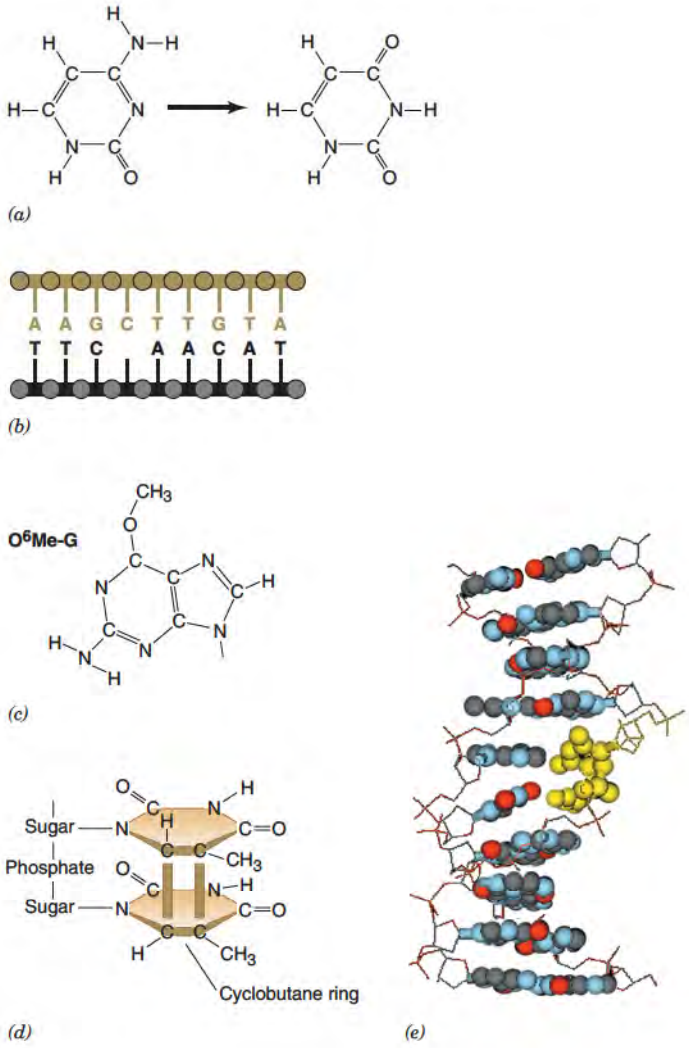

Figure 4.23 DNA damage. (*a*) Oxidative deamination converts C to U. (*b*) AP site. Depurination (or, less frequently, depyrimidination) is the cleavage of a glycosyl bond between the 1′ position of the sugar and the base. This leaves an abasic or AP site, but does not break the sugar–phosphate backbone. (*c*) O^6methyl guanosine is a highly mutagenic lesion. (*d*) Ultraviolet light leads to cross-linking of adjacent pyrimidines along one strand of DNA. A cis-syn cyclobutane thymine dimer is shown in schematic. (*e*) A cyclobutane dimer is shown within double-stranded DNA; the backbone is shown as a stick figure to reveal the distortion of the cross-linked bases (yellow) and complementary bases on the other strand.

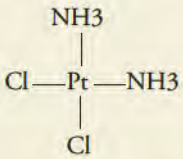
CLINICAL CORRELATION 4.7

Cisplatin and the Tour de France

Many widely used chemotherapeutic drugs are alkylating agents, often ones with two functional groups that can create both intrastrand and interstrand cross-links in DNA. Cyclophosphamide, busulfan, and nitrosoureas are alkylating agents. Alkylating agents are not only cytotoxic but also mutagenic, sometimes resulting in secondary cancers such as leukemias.

Cisplatin (cis-diamminedichloroplatinum),



used to treat metastatic testicular, ovarian, and a wide variety of other cancers, cross-links DNA. Among the serious side effects of cisplatin are bone marrow depletion, severe kidney impairment, and loss of hearing and balance. Disseminated testicular cancer used to be nearly always fatal (5% cure rate in 1973), until a combination chemotherapy, in which cisplatin was added to vinblastine and bleomycin, was developed by Drs. Larry Einhorn and John Donohue at the Indiana University School of Medicine; the new combination greatly increased survival. This regimen was later modified to a combination of cisplatin, etoposide, and bleomycin. Today, approximately 80% of patients survive. After treatment for advanced testicular cancer, world-leading cyclist Lance Armstrong went on to win the Tour de France a record seven consecutive times.

Einhorn, L. H. Curing metastatic testicular cancer. *Proc. Nat. Acad. Sci., USA* 99: 4592, 2002.

CLINICAL CORRELATION 4.8

Thiopurine Base Analogs as Drugs

6-Mercapto purine (6-MP) is an orally administered purine analog that is useful for chemotherapy of acute leukemias and for immunosuppression after organ transplantation. It acts through several mechanisms, including inhibiting purine biosynthesis and causing toxicity after incorporation into DNA. It is metabolized into the 6-MP riboside 5′-phosphate, which has a short half-life because it is degraded by xanthine oxidase. The rate of degradation is greatly reduced in patients being treated with allopurinol (an inhibitor of xanthine oxidase) for gout-related hyperuricemia, so the dose must be drastically reduced in such patients.

Another enzyme that metabolizes 6-MP (and the related antimetabolite 6-thioguanine) is thiopurine methyl transferase (TPMT). Some patients (about 10% of the population) are heterozygous for a polymorphism that inactivates the enzyme, and therefore have approximately 50% activity, and 1/300th of the people have no TPMT activity and are at extremely high risk for severe immunosuppression and death if treated with 6-MP. Conversely, people who metabolize the drugs more rapidly may not get a sufficient therapeutic dose. This pharmacogenetic difference, therefore, has serious implications for treatment with thiopurines.

Sanderson, J., Ansari, A., Marinaki, T., and Duley, J. Thiopurine methyltransferase: Should it be measured before commencing thiopurine drug therapy? *Annu. Clin. Biochem.* 41:294, 2004.

Point mutations can be categorized by the nature of the bases altered. **Transitions** are point mutations in which one purine is substituted for another (i.e., A for G or G for A) or one pyrimidine is substituted for another (i.e., T for C or C for T). Deamination of C to form U, if unrepaired, would lead to a transition. The frequency of transitions is increased by base analogs, including 2-amino purine and 6-mercapto purine (Clin. Corr. 4.8). **Transversions** are point mutations in which a purine is substituted for a pyrimidine or vice versa (e.g., A for C or C for A).

Point mutations can also be characterized by their effect on a coding sequence. **Missense mutations** are point mutations that change a single base pair in a codon such that the codon now encodes a different amino acid (Figure 4.24*a*). **Nonsense mutations** are point mutations that change a single base pair in a codon to a stop codon that terminates translation (Figure 4.24*b*). Nonsense mutations usually have more severe effects than missense mutations, because they lead to synthesis of truncated (and generally unstable) polypeptides. **Silent** or **synonymous** mutations do not alter the amino acid encoded; these include many changes in the third nucleotide of a codon. Some silent mutations may, however, have serious consequences if they alter the splicing pattern of the gene.

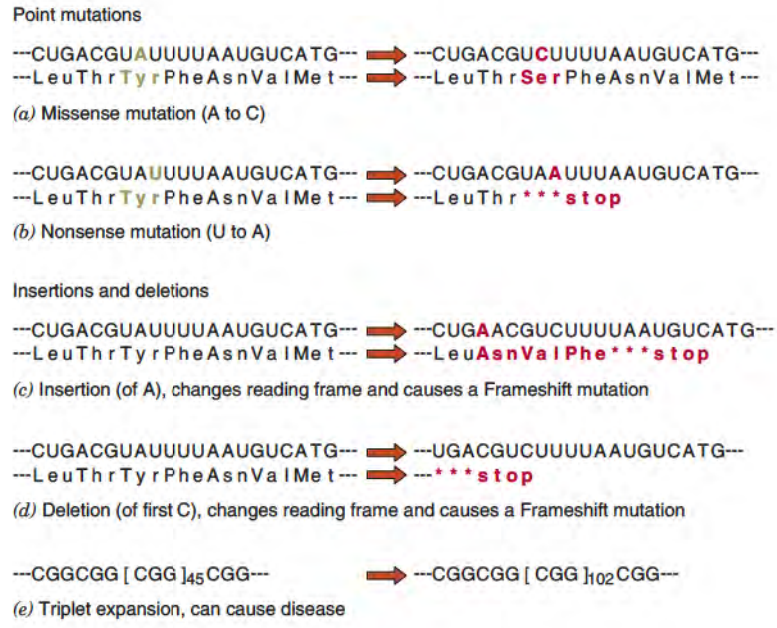


Figure 4.24 Mutations. Point mutations. (*a*) A missense mutation changes a single amino acid in the encoded polypeptide. (*b*) A nonsense mutation changes a codon for an amino acid into a stop codon, terminating synthesis of the encoded polypeptide. Insertion/deletion mutations. (*c*) Insertion of a single nucleotide changes the reading frame of all codons beyond the point of insertion; this usually leads to formation of a new stop codon that terminates synthesis. (*d*) Deletion of a single nucleotide changes the reading frame of all codons beyond the point of insertion; this usually leads to formation of a new stop codon that terminates synthesis. (*e*) Triplet expansion is a great increase in the number of triplet repeats. Triplet expansion causes many diseases, including Huntington disease and Fragile X disease, by adding long stretches of a single amino acid to the encoded polypeptide or by disrupting regulation of a gene.

Insertions or deletions of one or more base pairs (if the number of base pairs is not a multiple of 3) lead to **frameshifts** that disrupt the coding of a protein (Figure 4.24 *c* and *d*). Translation of an mRNA does not have punctuation; rather, once the initiation codon is determined, successive triplets are read as codons. Therefore, whereas addition (or deletion) of a multiple of three base pairs in a coding region would add (or subtract) amino acids to (or from) a protein, the addition of other numbers of base pairs shifts the reading frame from that point onward. Frameshifts usually lead to premature termination (or more rarely elongation) of the encoded polypeptide chain, when stop codons are generated or removed by the frameshift. Some chemicals, including **acridines** and **proflavin**, intercalate into the DNA; that is, they insert between adjacent base pairs. This usually leads to insertions or deletions of a single base pair, and thus a frameshift. Mutations may also result from large-scale changes including the insertion of transposons. Although rare in any one generation, mutations have accumulated in populations over millions of years, such that two people differ by about 1 bp per 1000 along their genomes. Many of these genetic differences are without effect, but others affect our physiology, susceptibility to disease, and response to treatment (Clin. Corr. 4.9).

The genome contains many stretches of repeating 2, 3, 4, and 5 nucleotide sequences. These simple repeats have a higher-than-average mutation rate because they can occasionally misalign during replication and recombination, leading to the insertion or deletion of a number of repeats. Thus over many generations, different lengths of these sequences have accumulated in the human population; these are called simple sequence-length polymorphisms (also called microsatellites or simple sequence-repeat polymorphisms). There is a special kind of mutation that results from a great increase in the number of repeating triplets (e.g., $CGGCGG[CGG]_nCGG$), called **Triplet expansion** (Figure 4.24*e*). When the length of a triplet repeat gets much longer than normal, it can cause disease by encoding a much longer than normal stretch of the same amino acid residue in the encoded polypeptide, as in **Huntington disease** (Clin. Corr. 2.6, p. 48). Triplet expansion can also affect regulation of a gene, as in **Fragile X syndrome** (Clin. Corr. 2.6), in which the greatly lengthened triplet sequence in the promoter alters gene expression. For these triplet expansion diseases, there is an unusual phenomenon: The disease often gets more severe in succeeding generations, as a result of even further increases in triplet length, because the longer the repeating sequence is, the more likely there can be misalignment during replication or unequal crossing over to lead to dramatically longer repeats.

CLINICAL CORRELATION 4.9

Personalized Medicine

Individuals differ in the sequence of DNA in their genome in subtle ways, as a result of the very gradual accumulation of mutations in the population over many generations. The most common difference involves a single base pair; this is called a single nucleotide polymorphism, (SNP) (although single-base-pair polymorphism would be more accurate). There are nearly 7 million validated SNPs in the human genome, and many more reported; this averages 1 per 500 bp. Most polymorphisms do not affect cell functions, but others contribute to the many differences that we see. Some affect the susceptibility to specific diseases, some affect the metabolism of drugs and other compounds (pharmacokinetics), and still others affect the response to these drugs (pharmacodynamics).

As part of the human genome project, there is a major effort to find and catalog polymorphisms. As more is learned about the effects of these sequence differences on disease and treatment, medicine will become more tailored to the individual. Technology already exists to determine rapidly which polymorphisms are present at specific sites in the genome of an individual. When these technologies are made cheaper and more routine, determining the alleles present in key genes will become a routine part of diagnosis and planning of treatment. For example, there are significant differences between individuals in the rate at which they metabolize drugs (compare Clin. Corr. 4.7). A standard dose based on body weight may be too low to be effective in those who metabolize the drug rapidly, but toxic to those who metabolize it very slowly. Determination of the relevant polymorphisms and routine testing could lead to more effective therapies with fewer side effects.

4.6 • DNA REPAIR

Maintenance of the genetic information requires constant repair of DNA damage. All free-living organisms have several mechanisms to repair damage to DNA. Some lesions are directly repaired, but most are removed from DNA as part of the repair process. A key feature in most repair processes is the double-stranded nature of DNA, which allows restoration of the correct sequence on a damaged strand using the complementary genetic information on the other strand.

Excision Repair

Excision repair is a general mechanism that can very accurately repair many different kinds of damage. The defining characteristic of excision repair is removal of the damaged nucleotide(s), leaving a gap in the DNA, followed by resynthesis using the genetic information on the opposite strand, and then ligation to restore continuity of the DNA. There are two major modes of excision repair: **base excision repair (BER)** and **nucleotide excision repair (NER)** (Table 4.4).

Base Excision Repair

Base excision repair is an essential process that repairs many different types of damaged bases, including methylated bases, deaminated bases (e.g., U resulting from deamination of C), oxidized bases, and abasic (AP) sites. The initial step is removal of a single

TABLE 4.4 • Excision Repair

Basic steps	
• Recognize damage	
• Remove damage by excising part of one strand to leave a gap	
• Resynthesize to fill gap; uses genetic information from other strand	
• Ligate to restore continuity of DNA backbone	
Base excision repair	*Nucleotide excision repair*
• Glycosylase removes base, leaves backbone intact • AP endonuclease cuts backbone, AP lyase removes sugar	• Double excision removes damage as part of an oligonucleotide (12–13 nt in *E. coli*, 27–29 nt in humans)
• DNA polymerase fills gap	• DNA polymerase fills gap
• DNA ligase seals nick	• DNA ligase seals nick

damaged base from the DNA backbone by a DNA **glycosylase**, an enzyme that cuts the N-glycosyl bond between the sugar and the base (Figure 4.25). This step does not break the sugar–phosphate backbone of the DNA; rather it leaves an abasic deoxyribose in the backbone, an AP site that must be removed. Two different activities are required to remove the remaining sugar: an **AP endonuclease** that cleaves the phosphodiester bond at the 5′-side but leaves the sugar still attached to the next nucleotide, and an **AP lyase** that cuts 3′ to the AP site to remove the sugar. The resulting single nucleotide gap has a free 3′-hydroxyl. The gap is filled by a DNA polymerase and ligated by DNA ligase (Figure 4.25).

There are at least eight different glycosylases in humans, each of which recognizes certain types of damaged bases. One of these, **uracil DNA glycosylase (UNG)**, is specialized to remove U from DNA. U is not a normal constituent of DNA but is formed when C is deaminated, and can occasionally be incorporated into DNA during replication. The frequent deamination of C to U noted in the preceding (Figure 4.23*a*, p. 165) would lead to a high rate of mutation; therefore, it is not surprising that a special repair mechanism evolved to remove U. But many C residues in mammalian DNA, in the sequence CG, are methylated at the 5 position ; this is important in the regulation of gene expression. Deamination of a 5-methyl C leaves a T, rather than a U, in the DNA. These T residues are not recognized by uracil DNA glycosylase, but there are other glycosylases that recognize the T:G mismatch and preferentially remove the T, leaving an AP site (Figure 4.23*b*, p. 165). Sometimes, however, the mismatch repair system removes the G instead of the T, creating a mutation. Over millions of years, this has led to a much lower than expected frequency of CG dinucleotides in mammalian DNA.

Another common lesion is 8-oxo-G (Figure 4.23*c*, p. 165), formed by oxidative damage, which leads to a transversion. There is a special repair pathway designed to repair 8-oxo-G; OGG1 removes the lesion from DNA. If replication has already occurred, MUTYH removes the A that might have inappropriately been incorporated opposite the 8-oxo-G and allows the repair polymerase to put in the correct C.

The most important **AP endonuclease** in humans is APE1. After cleaving the backbone at the 5′-side of an AP site to leave a free 3′-OH, APE1 recruits DNA polymerase β (pol β) to the site. Pol β has **AP lyase** activity that removes the abasic sugar phosphate remaining at the site of the strand break, leaving a single-nucleotide gap with a free 3′-OH. Pol β also has DNA polymerase activity that can fill the gap. For many types of damage, the gap is filled with only one or two nucleotides; this is called **short patch repair**. In cases where AP lyase cannot readily remove the sugar phosphate, strand displacement can create a flap of several nucleotides and the endonuclease FEN1 (which also serves to help remove the RNA from Okazaki fragments as noted in the preceding) can cleave it. The somewhat larger gap is filled by a polymerase such as pol β, or possibly pol δ (or pol ϵ) stimulated by PCNA. In either case, the remaining nick is sealed by a DNA ligase. Protein–protein interactions coordinate this process, keeping the nick and the intermediates protected until the next enzyme has been recruited to the site.

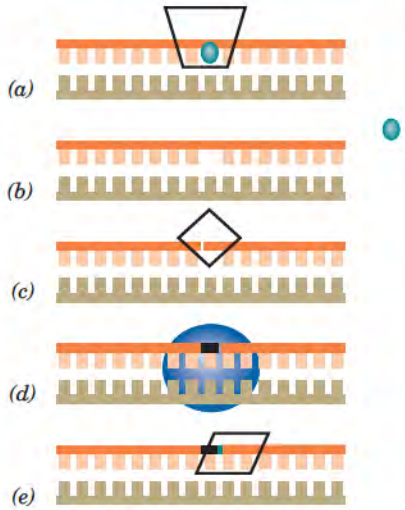

Figure 4.25 Base excision repair. (*a*) The damaged site (blue dot) is recognized by a DNA glycosylase. (*b*) The base is removed by cleavage of the glycosyl bond that connects it to the deoxyribose sugar; the sugar–phosphate backbone is not broken. This leaves an AP site. (*c*) The sugar–phosphate backbone is cleaved 5′ to the abasic site by an AP endonuclease. There is also a cleavage at the 3′-side of this site to remove the sugar residue; this can be done by some AP endonucleases or an AP lyase activity. (*d*) The single nucleotide gap is filled by a DNA polymerase. (*e*) The remaining nick is sealed by a DNA ligase.

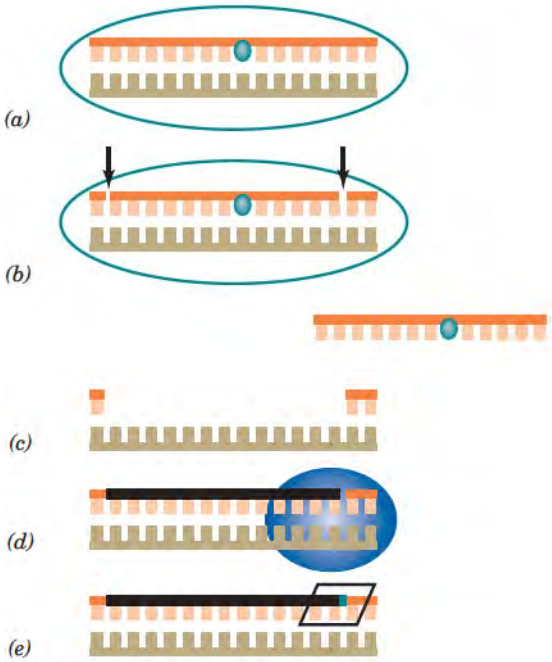

Figure 4.26 Nucleotide excision repair. (*a*) The damaged base (blue dot) is recognized by a DNA repair complex. (*b*) The segment around the damaged base is excised by an enzyme complex that makes two nicks in the damaged strand, one on either side of the damage. (*c*) An oligonucleotide (27–29 nt in humans, 12-13 nt in *E. coli*) is released. (*d*) Resynthesis: A DNA polymerase fills the gap, using the opposite strand as template. (*e*) DNA ligase seals the remaining nick.

Nucleotide Excision Repair

Nucleotide excision repair acts on a wide variety of damage, typically involving large adducts or distortion of the double helical structure of DNA. The best studied are pyrimidine dimers, the major products of ultraviolet damage (Figure 4.23*d* and *e*, p. 165). Chemical adducts with carcinogens such as **benzo(a)pyrene** and **aflatoxin**, and with chemotherapeutic agents such as **cisplatin**, are removed by this pathway, as are some mismatched bases and small loops in DNA. The damage is removed by an enzyme complex that cuts several nucleotides away on both sides of the damaged base(s), so the damage is released as part of an oligonucleotide (Figure 4.26).

In *E. coli*, a damage excision complex containing UvrA, UvrB, and UvrC recognizes the damage and makes two endonucleolytic cuts, one 3 to 5 nucleotides 3′ to the lesion and the other 8 nucleotides 5′ to the lesion. This excises the lesion as part of an oligonucleotide 12–13 nucleotides long. Damage recognition by UvrA appears to start the process, and opening of the strands by UvrB (a helicase) requires energy in the form of ATP hydrolysis. UvrC binds and catalyzes the dual cleavage, with one cut on either side of the damage. A DNA polymerase fills in the gap, followed by ligation of the nick.

In humans, several large enzyme complexes are involved in damage recognition, opening of DNA, and the two cleavages. The rare, autosomal recessive disease **Xeroderma pigmentosum (XP)**, which renders patients photosensitive and susceptible to skin cancers, results from mutation in any of seven genes involved in excision repair or in one gene involved in translesion DNA synthesis (Clin. Corr. 4.10). XPC is part of a complex that binds tightly to lesions that distort DNA structure. XPA is a key factor involved in damage recognition and assembly of the excision complex; mutations in the XPA gene render individuals essentially unable to remove UV-induced pyrimidine dimers. XPA recruits a large complex called **TFII-H**, a general transcription factor involved in initiation of transcription. TFII-H contains XPB and XPD subunits, both of which are ATPases with limited helicase activity. The DNA is partially unwound by the helicase activity of TFII-H, creating a bubble of about 25 base pairs. Then an excision repair cross-complementing 1 (XPF/ERCC1) heterodimer makes an endonucleolytic cut on the damaged strand approximately 22–24 nucleotides 5′ to the lesion, and XPG makes an endonucleolytic cleavage approximately 5 nucleotides 3′ to the lesion. These two cuts liberate a lesion-containing oligonucleotide approximately 27 to 29 nucleotides long. The single-stranded DNA-binding protein RPA is required for excision repair. The gap in DNA is bound by RPA and filled by pol δ (or pol ϵ) stimulated by PCNA. The remaining nick is sealed by a DNA ligase, probably LIG1. These latter steps resemble completion of an Okazaki fragment.

CLINICAL CORRELATION 4.10

Xeroderma Pigmentosum

Xeroderma pigmentosum (XP) (OMIM 194400) was the first disease demonstrated to be caused by defective DNA repair. Patients are photosensitive and highly susceptible to skin cancers in sun-exposed areas of the body; rates of skin cancer are 2000–5000-fold higher than average. Many patients also have neurological problems.

XP is a rare, autosomal recessive disease that can be caused by defects in any of eight different genes, reflecting the complexity of DNA repair of pyrimidine dimers, the most common damage introduced by exposure to ultraviolet light. Mutations in seven of the XP genes lead to defects in the initial incision step in nucleotide-excision repair of pyrimidine dimers. This explains the extreme photosensitivity that is characteristic of this disease. An additional class, called XP-V (for variant) is not detectably deficient in excision repair, but has a defect in translesion synthesis after UV damage. Cells from XP patients may also be hypersensitive to carcinogens in cigarette smoke.

XP-C is involved in initial binding to the damage in regions not being transcribed and recruits TFII-H, a general transcription factor. In transcribed regions, the stalled RNA polymerase recognizes the damage and recruits TFII-H. XPB and XPD encode proteins that function as subunits of TFII-H. TFII-H can function as a helicase, opening a region around the dimer. XPA is critical for the recognition of pyrimidine dimers and interacts with other repair proteins. ERCC1-XPF is a complex that binds to TFII-H and incises at the 5'-side of the dimer. XPG incises at the 3'-side.

It is notable that defects in XP-B, XP-D, or XP-G can also lead to Cockayne syndrome, with photosensitivity, growth defects, and mental deficiency among its symptoms. Defects in XP-B or XP-D can also lead to trichothiodystrophy, with symptoms including photosensitivity, short stature, and intellectual impairment. Thus different alterations in the same genes can lead to different syndromes, perhaps by differentially affecting the repair and transcription functions of these proteins.

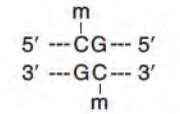
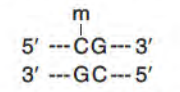
(*b*) Hemi-methylated DNA in *E. coli*



(*c*) Methylated DNA in human cells



(*d*) Hemi-methylated DNA in human cells

Figure 4.27 Methylated DNA (*a*) DNA methylation in *E. coli* is on the A within a GATC sequence. (*b*) Hemimethylated E. coli DNA. Parental strand methylated, daughter strand not yet methylated. (*c*) Methylation in human cells is on the C within a CG sequence. (*d*) Hemimethylated human DNA, daughter strand not yet methylated. Note that in both cases the sequence is a palindrome that reads the same (5′ to 3′) along both strands, and the residues in both strands are eventually methylated.

Transcription-Coupled Repair

Many lesions block transcription in the same manner that they block replication. Thus cells face an immediate problem even if they are not synthesizing DNA: They must be able to make key proteins in order to survive. **Transcription-coupled repair** directs the immediate repair response to the template strand of transcribed regions, so that lesions there are repaired faster than lesions elsewhere and transcription can resume; the survival value of this is obvious. Transcription-coupled repair is a form of excision repair triggered by an RNA polymerase complex halted at a lesion. In eukaryotic cells, a complex containing CSA and CSB (mutations in which cause Cockayne syndrome, another DNA repair deficiency disease) recognizes the stalled RNA polymerase, causing it to back up away from the lesion, and recruits repair proteins including the TFII-H complex. Then, many kinds of damage that block transcription are repaired by the nucleotide excision repair pathway involving XPA, TFII-H, and other excision repair factors. Recent evidence suggests that transcription-coupled repair also acts on oxidative lesions, which are repaired by base excision repair after the transcription complex is backed away from the lesion. Once repair is complete, transcription can resume.

Mismatch Repair

Mismatch repair is a specialized form of nucleotide excision repair that removes replication errors. Mismatches are not like DNA damage: There is no damaged or modified base present, just the wrong one of the four bases. Thus, recognition of mismatches relies on the distortion of the double-helical structure. A major difference between repair of DNA damage and repair of mismatches is in the choice of which base to excise. Enzymes can recognize damaged bases specifically and remove them, either individually in base excision repair or as part of an oligonucleotide in nucleotide excision repair. But when a mismatch is recognized, both bases are normal; which one should be excised? In newly replicated DNA, removing the newly synthesized base would preserve the genetic information, whereas excising the base on the parental strand would permanently alter the DNA, producing a mutation. Randomly choosing one would lead to mutations half of the time, a rate that is unacceptably high. Therefore, the challenge is to recognize the newly synthesized strand and remove the mismatched base on that strand.

The mismatch repair system is best understood in *E. coli*. DNA in most organisms (but not all) is methylated at specific positions. In *E. coli*, the most frequent methylation is of A in a GATC sequence (Figure 4.27*a*), a palindromic sequence (meaning that the

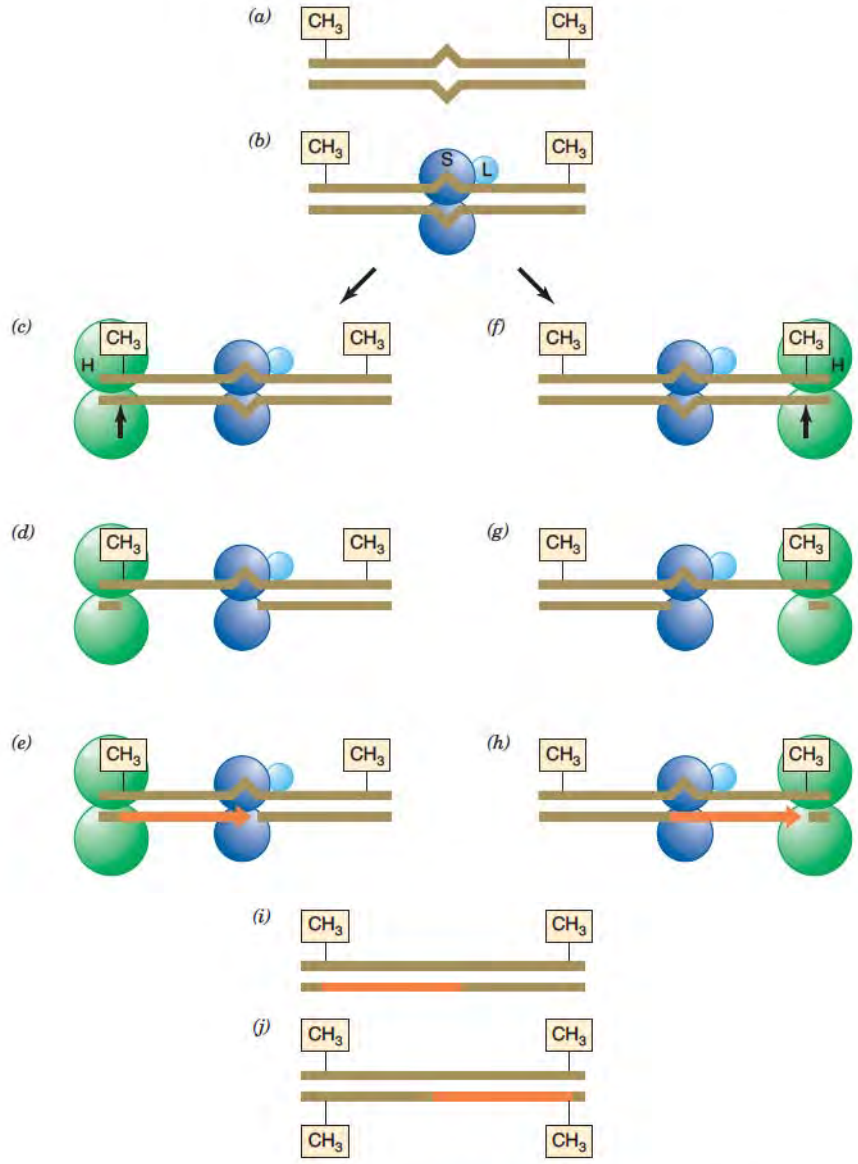


Figure 4.28 Mismatch repair in *E. coli*. (*a*) A mismatch in newly replicated DNA. The parental strand is methylated, but for the first few minutes after it is synthesized, the new strand is not yet methylated; such a site, with only one of the strands methylated, is called hemimethylated. (*b*) MutS and MutL bind to the mismatch. ATP is hydrolyzed as they extrude a short loop of DNA. (*c* and *f*) MutH binds at a hemimethylated site (which could be to either the left or right side of the mismatch). (*d* and *g*) The unmethylated strand is nicked and then excised, extending back past the site of the mismatch. This can be in either direction (*d* or *g*). (*e* and *h*) The resulting long gap is filled by a DNA polymerase, adding nucleotides to the 3′-end of the strand (red). (*i*) The remaining nick is sealed by a DNA ligase. (*j*) Hemimethylated sites are methylated.

opposite strand has the same sequence when read from 5′ to 3′); both strands are methylated. This specific methylation does not affect base pairing. The A residues are incorporated into the DNA in unmodified form, and later methylated by a **maintenance methylase** which recognizes **hemimethylated** sequences in DNA (sequences methylated on only one strand, the parental strand; Figure 4.27*b*) and methylates the appropriate base. During the very brief period in which the daughter strand is not yet methylated, the *E. coli* mismatch repair system can recognize the newly synthesized strand in the region of a mismatch and remove the mismatched nucleotide from the new strand. Mismatches are recognized by a MutS homodimer, which creates a loop that contains the mismatch (Figure 4.28). A MutL homodimer binds and coordinates the subsequent cleavage and excision. MutH nicks the unmethylated, newly synthesized strand on either side of the mismatch. A helicase (UvrD) unwinds the strand from the site of the nick through the site of the mismatch, and the nicked single strand is degraded by either a 5′ to 3′ exonuclease or a 3′ to 5′ exonuclease, depending on the free end. The long (hundreds-of-nucleotides) gap that is created is filled by the action of DNA polymerase, adding nucleotides to the 3′-end of the nicked strand. When the gap has been filled, the remaining nick is sealed by DNA ligase.

Humans have a similar mismatch repair system with homologous proteins, although the system is more complex and the mechanism by which it recognizes the new strand is not clear. Human DNA is methylated on the 5 position of C in CG sequences (Figure 4.27*c*), but it is not clear whether the hemimethylated CG sequences, transient single-strand breaks from

CLINICAL CORRELATION 4.11

Mismatch Repair and Cancer

Defects in mismatch repair cause hereditary nonpolyposis colon cancer (HNPCC) and are important in several other cancers. This was initially suggested by the finding that some colon tumors showed frequent mutations in microsatellites (simple sequence-length polymorphisms, short repeating sequences, particularly mono- and dinucleotides), a phenotype called microsatellite instability.

HNPCC is an autosomal dominant disease. A gene contributing to the risk for HNPCC was mapped to a region that contains a mismatch repair gene. This led to studies that demonstrated the primary defect to be a mutation in one of the mismatch repair genes. Defects in other mismatch repair genes have been found to cause HNPCC; the most common are MLH1 and MSH2.

Why does the inheritance of a single defective allele in a mismatch repair gene lead to HNPCC? Cells lining the intestinal tract actively divide throughout a person's life. There is a high probability that at some time in one's life, a somatic mutation will occur in one allele of a mismatch repair gene in at least one colon cell. Cells in which one of the alleles at any of these loci is inactive can still carry out mismatch repair, so this does not generally lead to a tumor. However, in an individual who inherits one inactive allele, a somatic mutation that inactivates the single active copy leads to defective mismatch repair. Mutation rates can be elevated 100- to 1000-fold in cells with inactivated mismatch repair. The result is the accumulation of mutations that eventually lead to tumor formation through mutations in growth-regulating genes.

unligated Okazaki fragments, or binding to PCNA aid in the recognition of the newly synthesized strand. There are several MutS homologs (MSH proteins) and MutL homologs (MLH proteins and PMS proteins), which work as heterodimers. MutSα, a heterodimer of MSH2 and MSH6, recognizes base–base mismatches and short insertion/deletions; MutSβ, a heterodimer of MSH2 and MSH3, recognizes short insertions/deletions. MutLα, dimers containing MLH1 and PMS2, are the main complexes required for the incision step. The enzymes responsible for excision of the nicked strand to a point beyond the mismatch have not been identified. As in *E. coli*, the excised region is hundreds of nucleotides long. PCNA, the sliding clamp, is required for mismatch repair. In addition to its role as a processivity factor for the DNA polymerase, it appears to function during the excision step. The resynthesis of the large gap requires DNA pol δ (or pol ϵ) and PCNA. The nick that remains is sealed by DNA ligase.

Mismatch repair can lead to gene conversion during recombination by removing one strand of a heteroduplex and resynthesizing it using the other strand as a template; it can also act to reduce the frequency of recombination.

Defects in mismatch repair cause **hereditary nonpolyposis colon cancer (HNPCC)** (Clin. Corr. 4.11). Between 60% and 70% of the cases of HNPCC are due to mutations in MLH1 or MSH2, with other cases due to mutations in other mismatch repair genes. Some sporadic cancers, particularly some colorectal, gastric, and endometrial carcinomas, also appear to be related to suppression or functional inactivation of the mismatch repair system.

Mismatch repair plays a paradoxical role in response of cells to cytotoxic agents such as methylating agents (*N*-nitrosourea) and cisplatin, which are used in cancer chemotherapy. The recognition of alkylation damage by mismatch repair proteins can trigger cell death by apoptosis; cells that are deficient in mismatch repair may escape this process, and thereby be resistant to chemotherapeutic agents. Mismatch repair-deficient cells have higher rates of mutation, and can thus evolve to tumors that are more aggressive.

Direct Demethylation

In addition to the normally methylated bases in DNA, some bases become alkylated inappropriately, by carcinogens or by interaction with the normal methyl carriers in cells (e.g., *S*-adenosyl methionine). Alkylation on positions that affect base pairing is highly mutagenic. For example, O^6methyl-guanine pairs with T rather than with C (Figure 4.29*a*), so its replication would lead to a mutation. Cells have glycosylases that recognize inappropriately methylated bases and trigger base excision repair, but they also have special proteins that recognize O^6-methyl guanine in DNA and directly remove the methyl group, leaving the DNA intact. **O^6-methyl guanine methyl transferase (MGMT)** recognizes O^6-methyl

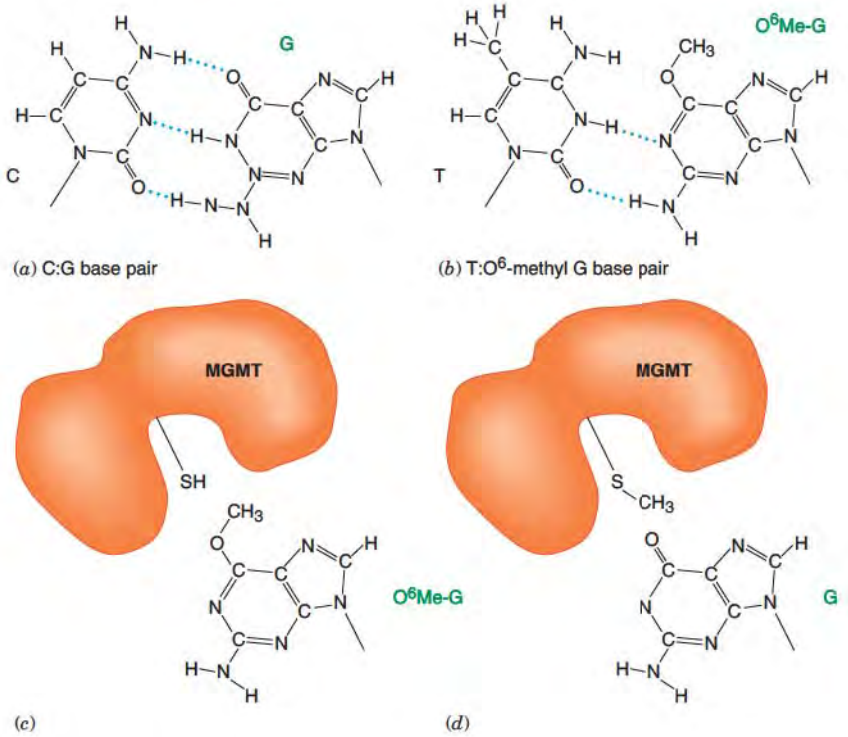

Figure 4.29 Direct demethylation. (*a*) Normal C:G base pair. (*b*) T:O^6-methyl G base pair. This base pairing would allow incorporation of a T opposite O^6-methyl G during DNA replication and lead to a mutation in next generation. (*c*) Methyl guanine methyl transferase (MGMT) can bind to O^6-methyl G. (*d*) MGMT transfers the methyl group from the O^6 of guanine to a sulfhydryl group on the MGMT protein itself, leaving an intact G in DNA. The methylated MGMT protein is inactive, becomes ubiquitinated, and is then degraded.

guanine and transfers the methyl group from the guanine to a cysteine on the protein itself (Figure 4.29*b*). A single molecule of MGMT can remove only one methyl group, because methylation of the cysteine inactivates the protein and targets it for degradation through the ubiquitin proteolytic pathway. The cost to the cell of removing a single methyl group through this pathway is high, because cells must replicate and transcribe the gene for this enzyme, then process and translate the mRNA, and all of these steps require considerable energy and material. This reemphasizes how important it is to maintain the integrity of the genome, even at great metabolic cost.

Photoreactivation

Photoreactivation is a specific mechanism for repair of cyclobutane pyrimidine dimers (Figure 23*d* and *e*, p. 165), the major lesions produced by ultraviolet irradiation. It is a direct reversal of the damage. A specialized enzyme called **photolyase** binds to the damage (Figure 4.30). On absorbing light, photolyase catalyzes the reversal of the bonds between the adjacent pyrimidines, leaving the DNA exactly as it was before the dimer formed. This

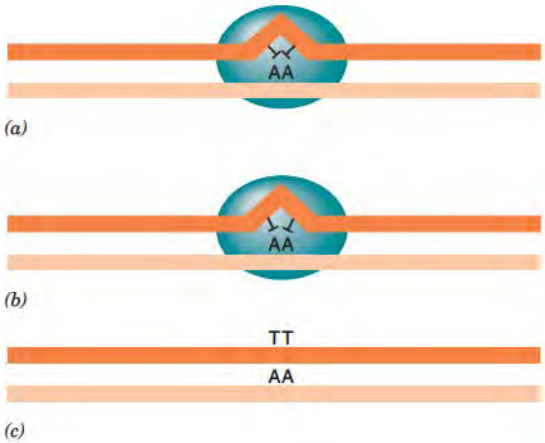

Figure 4.30 Photoreactivation. (*a*) Photolyase binds to a cyclobutane pyrimidine dimer; light is not needed for this step. (*b*) The complex absorbs light; this results in cleavage of the bonds linking adjacent pyrimidines. (*c*) The enzyme then dissociates from the DNA.

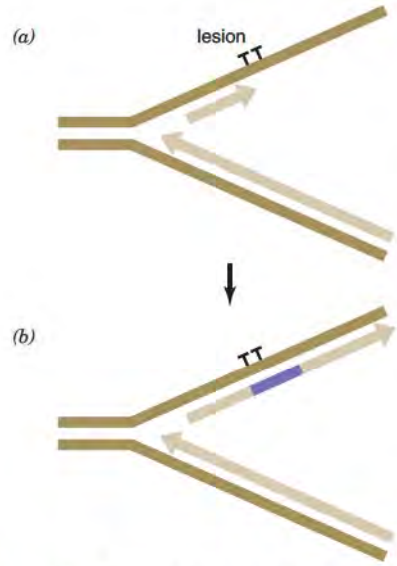

Figure 4.31 Bypass (translesion) synthesis. (*a*) Damage to the template generally halts replicative DNA polymerases, since they cannot add a nucleotide opposite a noncoding or strand-distorting lesion. (*b*) Specialized DNA polymerases with relaxed specificity (see Table 4.2) can insert nucleotides opposite lesions in the template, and thereby allow bypass of damage and synthesis of nongapped daughter strands. The relaxed specificity and lack of proofreading in these polymerases means that errors (potential mutations) are often introduced. These polymerases readily dissociate from the DNA, so the length of DNA they synthesize is usually short.

is a direct reversal of the damage. Photo-reactivation, while of great importance in most organisms, is not significant in mammals.

Lesions Can Block Replication

The accuracy and proofreading abilities of DNA polymerases generally prevent them from inserting nucleotides opposite damaged bases; they require very accurate base pairing before they insert a nucleotide and move on. Thus when a replication complex reaches a lesion in the template strand, it halts. There are three general ways for replication to proceed: the complex can either (a) disassemble or backup to allow repair of the lesion and then resume synthesis, (b) directly bypass the lesion, or (c) skip past the lesion and resume synthesis beyond it (leaving a gap in the daughter strand). All three mechanisms are used, and all present some advantages and some problems.

Bypass (Translesion) Synthesis

A very accurate, proofreading polymerase cannot insert nucleotides opposite damaged bases, and therefore would arrest synthesis (or leave a gap, as described in the following). A process called **bypass synthesis** or **translesion synthesis** can, however, allow replication to proceed past the lesion (Figure 4.31). There is a family of "error-prone" or "relaxed stringency" DNA polymerases that lack proofreading ability (Table 4.2). Due to their relaxed stringency, these polymerases can insert nucleotides opposite the damaged bases and thereby allow replication to continue. Their reduced accuracy increases the probability that the wrong nucleotide will be incorporated opposite the lesion, and in any other DNA made by these polymerases. The harmful consequences of this are evidently less than those of a long (or permanent) block to replication.

In *E. coli,* DNA polymerases IV (DinB) and V ($UmuD'_2C$ complex) are much less accurate than the normal replicative DNA polymerases III and I. They have low processivity, generally synthesizing fewer than 10 nucleotides before dissociating from the DNA; this serves to limit the extent of mutations introduced. They are induced as part of the SOS response described in the following. This ensures that the error-prone bypass (translesion) synthesis mechanism functions only when there is sufficient damage to the DNA to trigger the SOS response, limiting the risk of mutations to situations in which the cell's viability is seriously threatened.

Eukaryotes also have error-prone polymerases that can carry out bypass (translesion) synthesis (Table 4.2). DNA polymerase η predominantly incorporates A opposite the thymine dimers introduced by UV irradiation; because A is the appropriate nucleotide to incorporate opposite the T of the dimer, the probability of mutagenesis at those lesions is reduced (but not eliminated). Polymerase η lacks intrinsic proofreading capability and incorporates one mismatch per 20 to 400 nucleotides synthesized, suggesting that its activity must be tightly controlled. DNA polymerase i incorporates nucleotides opposite other highly distorting lesions or lesions such as abasic sites that cannot normally serve as templates. These polymerases appear to function along with DNA polymerase ζ, which doesn't itself add nucleotides opposite lesions but can extend the structures formed by the other bypass polymerases until the normal replicative polymerase can take over. These bypass polymerases are distributive enzymes, so the region in which mismatches are likely to be introduced is typically small, limiting the introduction of mutations.

Daughter-Strand-Gap Repair

If DNA synthesis is blocked by a lesion but restarts beyond the lesion, a gap is left in the DNA (Figure 4.32). This situation is easiest to picture on the discontinuous strand where it can occur simply by dissociation of the polymerase from the blocked site and initiation of the next Okazaki fragment by the normal replication mechanism. Gaps in DNA are potentially lethal. A lesion opposite a gap is not a substrate for excision repair, because there is no intact strand opposite the lesion to provide coding information necessary for repair. **Daughter-strand gap repair** (previously called postreplication recombination) does not remove the lesion that caused the gap, but does repair the gap. This protects the cell from the potential damage that gaps can cause, and also provides a substrate for excision repair to act on the lesion itself.

Daughter-strand gap repair is by recombination. Single-stranded DNA, such as that opposite a gap, is recombinogenic; that is, it stimulates recombination. Recombination between the two newly formed duplexes allows transfer of a piece of the normal parental strand into the gap (Figure 4.32*a*; the parental strand on one side of the fork has the same polarity as the daughter strand on the other side). This leaves a gap in the parental strand that donated the patch (Figure 4.32*b*), but because that strand has a normal strand of DNA opposite, that gap can readily be filled by DNA polymerase and sealed by a DNA ligase (Figure 4.32*c*). The result is that the gap is repaired, although the lesion remains. As noted previously, in this configuration the lesion is a substrate for excision repair.

Rewinding and Repair of Replication Forks

It is easy for a replication complex that has stopped synthesis of the discontinuous strand at a lesion to resume synthesis to form the next Okazaki fragment, using the normal mechanisms of DNA replication (see p. 145). Reinitiating the continuous strand beyond a block is more difficult, because initiations are normally tightly controlled at replication origins. It appears that in this case, replication forks can regress by the annealing of the daughter strands, which allows repair of the lesion and restarting of replication. In *E. coli,* RecA binds to the single-stranded regions at blocked replication forks and maintains the integrity of the DNA. The replication fork can regress by branch migration while it is protected by the RecA, allowing NER or BER repair mechanisms to remove the lesion. Then, a reversal of the branch migration or degradation of the displaced strand could allow synthesis to resume. Details are still unclear, including whether the replication apparatus could remain with the displaced strand or whether the replication complex would need to be reassembled in an origin-independent manner.

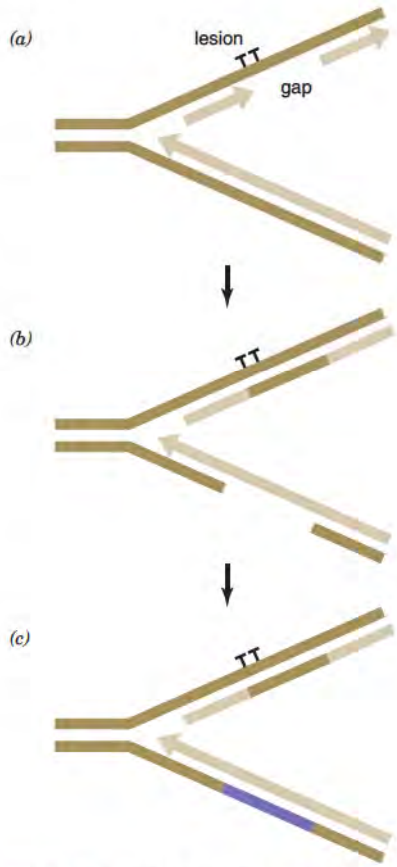

Figure 4.32 Daughter-strand gap repair. (*a*) Gaps are left in newly replicated DNA where replication forks are halted by lesions. Because the lesion does not have intact DNA opposite, it is not a substrate for excision repair. (*b*) Recombination allows the isopolar parental strand (dark tan) to fill the gap in the daughter strand (light tan). This leaves a gap in that parental strand. (*c*) The gap in the parental strand can be filled (purple) by a DNA polymerase, because there is an intact template opposite it. The result is repair of gap in daughter strand, but the lesion remains. Note that the lesion can now be repaired by excision repair, because it is now opposite an intact strand.

Double-Strand Break Repair

Double-strand breaks (DSBs) in DNA are potentially lethal events. They stimulate genetic recombination that can lead to chromosomal translocations, and unrepaired DSBs lead to broken chromosomes and cell death. Double-strand breaks are caused by many agents, particularly ionizing radiation, reactive oxygens species, and chemotherapeutic agents that generate oxidative free radicals (e.g., bleomycin) or are topoisomerase poisons. When a replication fork encounters a single-strand break, that break is converted into a double-strand break. Cells have mechanisms, including checkpoint controls that slow or arrest replication in the presence of damage to allow time for repair and to minimize the likelihood that a single-strand break would be encountered. Nevertheless, it has been estimated that about 10 double-strand breaks are formed during a single cycle of replication in mammalian cells.

The major pathway for cell survival involves double-strand-break repair by homologous recombination (described previously; Figure 4.24, p. 166) or by nonhomologous end joining. In yeast, homologous recombination predominates; in mammalian cells, nonhomologous end joining predominates.

Regulation of DNA Repair: The SOS Regulon

In *E. coli,* damage to DNA triggers the **SOS response**, a coordinated change in gene expression that aids in recovery from damage. The SOS response is a coordinated induction of many genes whose transcription is at least partly regulated by a common repressor, LexA. A group of operons that are controlled by a common repressor is called a **regulon**. Among the genes in the SOS regulon are uvrA, uvrB, uvrC, recA and LexA itself. There is a low, constitutive level of many of the genes in the SOS regulon, because repression by LexA is not complete and some of these genes have alternative promoters not repressed by LexA.

The **SOS response** is triggered by long stretches of single-stranded DNA such as those in gaps left by blocked replication (Figure 4.33). When such a stretch is formed, the low, constitutive level of RecA protein can cooperatively polymerize along single-stranded DNA to form a nucleoprotein filament. In this state, it is activated and it binds LexA, increasing the rate at which LexA is cleaved into inactive fragments. This relieves the repression and allows rapid synthesis of the genes normally repressed by LexA. RecA participates in

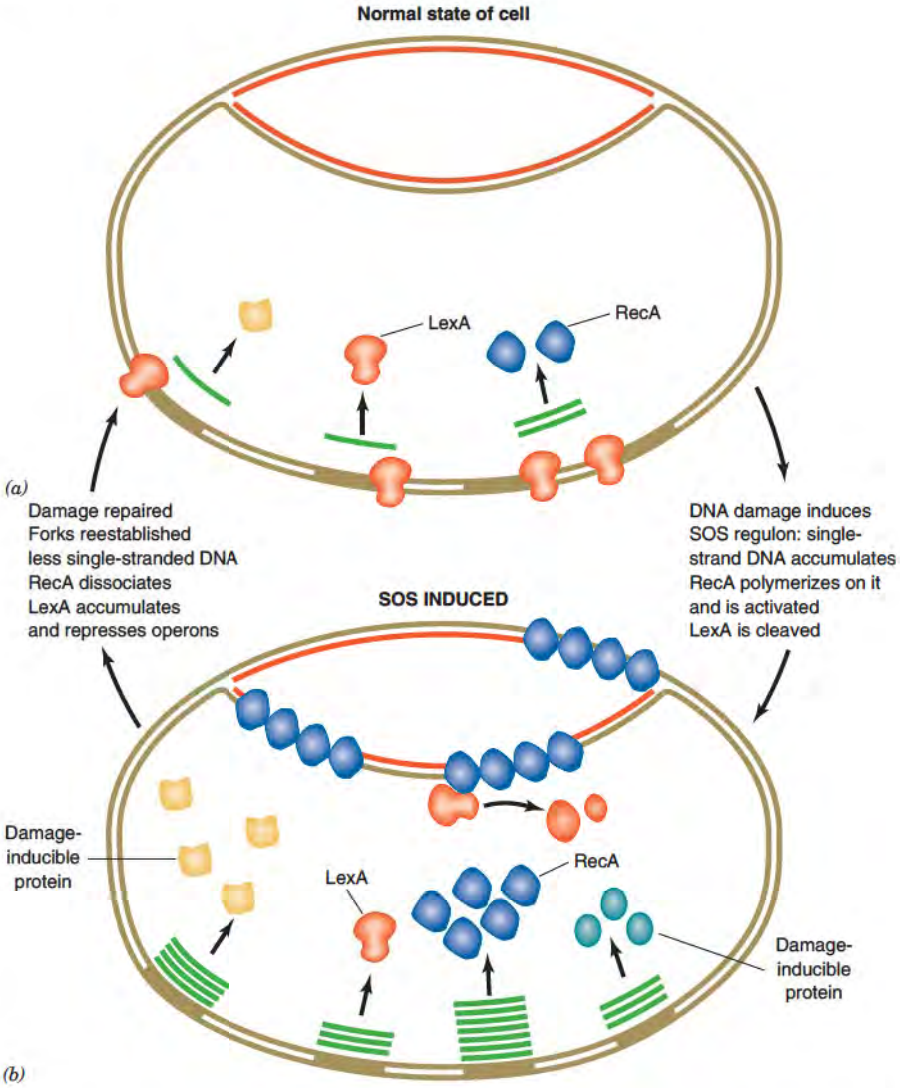

Figure 4.33 Regulation of DNA repair and recovery in *E. coli*: The SOS response. (*a*) In undamaged cells, a group of operons that constitute the SOS regulon is regulated by a common repressor, LexA. This regulon includes the lexA gene itself (autoregulation) and the recA gene, along with many genes encoding enzymes that act to repair damage. There is a low, constitutive transcription of many of these genes, including lexA and recA, even when LexA protein is present. (*b*) Damage blocks replication forks, and thereby leaves single-stranded DNA. RecA binds to single-stranded DNA and is activated. In that form, it aids in cleavage of LexA. The cleaved fragments of LexA cannot bind to operators, so the entire set of operons is induced. Much more RecA is made, along with other proteins including LexA. As long as the damage remains and RecA remains activated, LexA continues to be cleaved so the operons remain on. When damage is repaired, RecA is deactivated and no longer aids the cleavage of LexA, so active LexA builds up and shuts off the genes in this regulon.

daughter-strand gap repair and protection of the replication fork, as noted previously. The other damage-inducible genes (din genes) produce proteins that aid in DNA repair and cell recovery and inhibit initiation of new replication forks and cell division until repair is completed (Figure 4.33).

Autoregulation of LexA is based on a simple feedback loop that effectively allows a rapid but transient response to DNA damage. When LexA protein is cleaved, among the many genes of the SOS regulon that are induced is LexA itself, so the amount of LexA produced increases significantly. However, while DNA damage is still present and RecA protein is still activated, this LexA protein is cleaved and it cannot repress the many genes of the SOS regulon. As the damage is repaired, the amount of activated RecA drops and therefore cleavage of LexA decreases. The increasing levels of LexA bind to the operators of the din genes and gradually shut down the SOS response.

Key Terms

antiparallel strands
template
DNA polymerases
primase
proofreading
RNA polymerase
semiconservative replication
transesterification
exonucleolytic activity
helicase
replication fork
semi-discontinuous synthesis
Okazaki fragment
RNA hybridase (RNase H)
DNA ligase
Double-strand break
supercoiling
topoisomerase
processive reaction
continuous strand
discontinuous strand
DNA gyrase
origin of replication
bidirectional replication
origin recognition complex (ORC)
telomerase
homologous recombination
non-homologous recombination
Holliday junction
branch migration
heteroduplex
gene conversion
insertion sequence
transposition
missense mutation
nonsense mutation
point mutation
frameshift mutation
DNA repair
excision repair
nucleotide excision repair
base excision repair
short patch repair
transcription-coupled repair
mismatch repair
photoreactivation
bypass synthesis
daughter-strand gap repair
SOS response
reverse transcriptase

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. Replication
   - **A.** requires that a phosphodiester bond of the incoming dNTP be hydrolyzed in order to be added to the growing chain.
   - **B.** uses 5′ to 3′ polymerase activity to synthesize one strand and 3′ to 5′ polymerase activity to synthesize the complementary strand.
   - **C.** owes its accuracy, in part, to 3′ to 5′ exonucleolytic activity of DNA polymerases or associated proteins.
   - **D.** begins with two dNTPs joining together.
   - **E.** requires only proteins with DNA polymerase activity.

2. In eukaryotic DNA replication,
   - **A.** only one replisome forms because there is a single origin of replication.
   - **B.** separating the parental DNA strands to form the replication fork is an energy neutral process.
   - **C.** Okazaki fragments form on the leading strand within a replication fork (bubble).
   - **D.** topoisomerases catalyze changes in the linking number, facilitating untwisting of the parental DNA strands.
   - **E.** the role of ligase is to replace the nucleotides in the gap left by the removal of the RNA primer.

3. All of the following statements about telomerase are correct except
   A. the RNA component acts as a template for the synthesis of a segment of DNA.
   B. it adds telomeric repeats to the 5′-ends of the DNA strands.
   C. it provides a mechanism for replicating the ends of linear chromosomes.
   D. it recognizes a G-rich single strand of DNA.
   E. it is a reverse transcriptase.

4. A transition mutation
   A. occurs when a purine is substituted for a pyrimidine or vice versa.
   B. results from the insertion of one or two bases into the DNA chain.
   C. is most frequently caused by chemicals (like acridine) that intercalate into DNA.
   D. results from substitution of one purine for another or of one pyrimidine for another.
   E. always is a missense mutation.

5. Homologous recombination
   A. occurs only between two segments from the same DNA molecule.
   B. requires that a specific DNA sequence be present.
   C. requires one of the duplexes undergoing recombination be nicked in both strands.
   D. involves a four-stranded intermediate (Holliday junction) which can be cut in either of two ways.
   E. is catalyzed by transposases.

6. All of the following are true about transposons except
   A. transposons move from one location to a different one within a chromosome.
   B. they contain but do not code for transposases.
   C. transposons have insertion sequences that are recognized by transposases.
   D. the transposon may either be excised and then moved or be replicated with the replicated piece moving.
   E. they may either activate or inactivate a gene.

Questions 7 and 8: Retroviruses, like HIV which causes AIDS, have their genetic information in the form of RNA. Reverse transcriptase synthesizes a DNA copy of the viral genome. One drug used in treating AIDS is AZT, an analog of deoxythymidine, which has an azido group at the 3′ position of the sugar. It can be phosphorylated and competes with dTTP for incorporation into the reverse transcript. Once incorporated, its presence terminates chain elongation.

7. The growing chain is terminated because
   A. the analog can not hydrogen bond to RNA.
   B. the presence of the AZT analog inhibits the proofreading ability of reverse transcriptase.
   C. AZT does not have a free 3′-OH.
   D. the analog causes distortion of the growing chain, inhibiting reverse transcriptase.
   E. dTTP can no longer be added to the growing chain.

8. There is a window in which the effect is primarily on viral replication since AZT is much less effective at competing with dTTP for incorporation by cellular DNA polymerases because of the proofreading ability of DNA polymerases. Proofreading activity to maintain the fidelity of DNA synthesis
   A. occurs after the synthesis has been completed.
   B. is a function of 3′ to 5′ exonuclease activity intrinsic to or associated with DNA polymerases.
   C. requires the presence of an enzyme separate from the DNA polymerases.
   D. removes mismatched bases in the interior of the chain.
   E. does not occur in prokaryotes.

Questions 9 and 10: Patients with the rare genetic disease xeroderma pigmentosum (XP) are very sensitive to light and are highly susceptible to skin cancers. The study of such patients has enhanced our knowledge of DNA repair because XP is caused by defective DNA repair–nucleotide excision repair. (A variant, XP-V, is deficient in postreplication repair.)

9. In nucleotide excision repair
   A. removal of the damaged bases occurs on only one strand of the DNA.
   B. only thymine dimers generated by UV light can be removed.
   C. the excision nuclease is an exonuclease.
   D. a single multifunctional enzyme carries out the repair process.
   E. only the damaged nucleotides are removed.

10. Another type of DNA repair is base excision repair. Base excision repair
    A. is used only for bases that have been deaminated.
    B. uses enzymes called DNA glycosylases to generate an abasic sugar site.
    C. removes about 10 to 15 nucleotides.
    D. does not require an endonuclease.
    E. recognizes a bulky lesion.

Questions 11 and 12: Interfering with topoisomerases is one way of inhibiting DNA replication. Certain antibiotics target DNA gyrase (type II topoisomerase) of *E. coli* inhibiting catalytic activity. Topoisomerase poisons prevent resealing of the phosphodiester bond, leaving covalent protein–DNA junctions. These compounds are used in treating infections and as chemotherapeutic agents.

11. DNA gyrase
    A. ATP subunits hydrolyze ATP to form new phosphodiester bonds.
    B. removes negative supercoils.
    C. swivelase subunits create and reseal transient nicks on both strands.
    D. increases the linking number.
    E. occurs in eukaryotes as well as prokaryotes.

12. All of the following are correct about double-strand breaks in DNA *except* they
    A. can lead to loss of genetic information.
    B. are always involved in homologous recombination.
    C. are involved in nonhomologous recombination.
    D. are associated with a heterodimer (Ku) in mammals.
    E. can lead to mutations or improper regulation of gene expression.

Problems

13. Mismatch repair removes replication errors by excising incorrect bases. There is no DNA damage or modified bases present. How does the cell distinguish the newly synthesized strand and preserve the correct parental DNA strand?

14. In the coding strand of DNA for the alpha gene of normal hemoglobin (HbA), the three bases that correspond to codon 142 of the mRNA are TAA and the alpha chain has 141 amino acids. In the coding strand of the gene for the alpha chain of Hemoglobin Constant Spring, the three bases are CAA and the chain contains 172 amino acids. Explain the mutation that has occurred.

Answers

1. **C** This can remove a mismatched terminal nucleotide, that is, proofreading. A: The reaction is a nucleophilic attack of the 3′-OH of the DNA chain on the $\alpha-\beta$ phosphate bond of the incoming dNTP—a transesterification. B: Replication involves Okazaki fragments because synthesis occurs only in the 5′ to 3′ direction. D: Replication begins with the formation of an RNA primer. E: Replication requires proteins like primase, ligase, helicase, and others.
2. **D** Since changing the linking number is a transesterification, it protects the integrity of the DNA and occurs without the need of additional energy. A: There are multiple initiation sites. B: Helicases opening the replication fork require the hydrolysis of ATP. C: The continuous strand has the correct orientation; it is the lagging strand that requires formation of Okazaki fragments because it has the 5′-end oriented toward the fork. E: Ligase simply forms the phosphodiester bond between adjacent nucleotides after the gap has been filled.
3. **B** Telomeres are at the 3′-end of each strand so that the 5′-ends can be replicated. A and C: Telomerase positions itself at the 3′-end of the DNA and provides the template for extending that end. D: This is a characteristic of the 3′-end. E: It is using an RNA template to synthesize DNA.
4. **D** This is the definition. A: This is a transversion. B: This is frame shift; transitions are point mutations. C: This would cause a frameshift mutation. E: It could be a missense mutation if the change coded for a different amino acid or a nonsense mutation if the code was changed to a stop signal.
5. **D** One of these cuts accounts for formation of a new chromosome in which part comes from one parent and part from the other. A and B: It may occur between two distinct DNA molecules if the two sequences are homologous. C: Nicks can be on a single strand. E: These are the enzymes of transpositional site-specific recombination.
6. **B** Transposons are DNA, not protein: They can code for a transposase. A: This is the definition. C: This is one of the key features. D: Both types of event are catalyzed by transposases. E: Insertion into the middle of a gene would inactivate it; insertion of a promoter next to a gene may activate it.
7. **C** The chemistry of nucleotide formation requires a free 3′-OH at the end of the chain for attachment of the next nucleotide. A: The presence of the azido group does not affect hydrogen bonding. B: Reverse transcriptase does not have proofreading properties. D: This does not happen. E: The AZT analog competes with dTTP; it does not eliminate it.
8. **B** This activity removes a newly added base if there is a mismatch with the template. A: This is called repair. C: Most polymerases are multifunctional and have proofreading ability. D: Only the terminal mismatched base is removed. E: pol I of *E. coli* has the intrinsic 3′ to 5′ exonuclease activity.
9. **A** The uncut strand serves as the template for repair. B: This repairs a variety of damage typically involving large adducts or disturbances to the DNA structure. C and E: Cuts are made several nucleotides on either side of the damaged bases so this is an endonuclease. D: Several enzyme complexes are involved including a polymerase, ligase, and helicase.
10. **B** These catalyze the first step of the process. A: Methylated and other chemically modified bases can also be removed. C and E: These are characteristics of a different repair system. D: The abasic sugar phosphate must be removed.
11. **C** This enables unwinding of the DNA. A: ATP hydrolysis triggers conformational changes. B: It removes positive supercoils and introduces negative ones. D: The linking number is reduced. E: DNA gyrase is specifically prokaryotic; eukaryotes have different topoisomerases that carry out the same activity.
12. **B** This can also occur with single-strand nicks. A: This can be repaired but covalent protein–DNA junctions caused by topoisomerase poisons can be lethal. C: Broken ends of a DNA duplex can recombine with another duplex. D: This plays a role in nonhomologous end joining. E: Random integration of a fragment of DNA by nonhomologous end joining can disrupt genes or disrupt promoters.
13. In *E. coli*. DNA is methylated on the A of a GATC sequence. Both strands are methylated. Methylation occurs after the unmethylated bases are incorporated into DNA. During synthesis, the DNA will be hemimethylated for a short period. The mismatch repair system recognizes the hemimethylated state and can remove the mismatch on the unmethylated (new) strand. Eukaryotes have a similar repair system although the details of recognizing the new strand are not yet known.
14. The coding strand of the gene has the same sequence as the mRNA (except U replaces T in the RNA). In HbA, the codon at position 142 of mRNA is a stop codon so the last amino acid added is 141. In Hb Constant Spring, a point mutation has mutated the DNA so that the mRNA codon at 142 now codes for an amino acid instead of stop. Translation continues until a stop codon appears at position 173 (so 172 amino acids).

Key Concepts

- Transcription is the synthesis of RNA whose sequence is complementary to that of a DNA template. Transcription begins at a promoter sequence and proceeds in the 5′ to 3′ direction.
- RNA polymerases, which initiate transcription, of all types are related by common ancestry.
- Bacterial RNA polymerase contains a special subunit (sigma); different sigma subunits recognize different promoter classes.
- Eukaryotic initiation operates by recruitment of RNA polymerase and accessory protein factors to promoters located in accessible regions of chromatin.
- RNA transcripts are modified by cleavage, additions, and base modification. Most eukaryotic mRNA transcripts are processed to synthesize a 5′ cap and 3′ poly(A) sequence, and to remove introns. Ribonucleoprotein particles participate in processing.
- Short RNAs can inhibit gene expression, allowing post-transcriptional gene regulation.
- There are no repair mechanisms for RNA so all classes of RNA molecules turnover. Exo- and endonucleases hydrolyse RNA to nucleotides for reutilization.
- The different RNAs turnover at different rates and by different mechanisms.

5.1 • INTRODUCTION

Synthesis of an RNA molecule involves copying one strand of a template sequence using Watson–Crick base pairing between nucleotides of the template (usually DNA) and the nucleotides that are being incorporated into the **transcript**. The initiation of transcription by RNA polymerase is perhaps the most important event in the control of gene expression. Transcription initiation requires specialized DNA sequences, called **promoters**, which signal where RNA synthesis should begin. The recognition of promoter sequences involves molecular contacts between DNA and protein **factors**. Factors bind both to RNA polymerase enzyme and to DNA nucleotides through hydrogen bonds and other contacts. During or after transcript elongation, **RNA processing** reactions remove, add, or modify nucleotides in the primary transcript. These processing reactions can occur co-transcriptionally. In other words, they occur on parts of the transcript while downstream sequences are still being transcribed.

5.2 • MECHANISMS OF TRANSCRIPTION

Initial Process of RNA Synthesis Is Transcription

Transcription is the process by which RNA chains are made from DNA templates. Transcription reactions take the following form:

$$\text{DNA template} + n\,(\text{NTP}) \rightarrow \text{pppN(pN)}_{n-1} + (n-1)\text{PP}_i + \text{DNA template}$$

Enzymes that catalyze this reaction are the RNA polymerases; it is important to recognize that, like DNA polymerases, they are absolutely template dependent. Unlike DNA polymerases, however, RNA polymerases do not require a primer molecule. The RNA polymerase reaction is driven forward by two factors: First, the 5′ α-nucleotide phosphate of the ribonucleoside triphosphate is converted from a phosphate anhydride to a phosphodiester bond with a change in free energy ($\Delta G'$) of approximately 12.5 kJ/mol (3 kcal/mol) under standard conditions. Second, the released pyrophosphate, PP_i, is cleaved to two phosphates by pyrophosphatase so that its concentration is low and phosphodiester bond formation is more favored relative to standard conditions (see p. 632).

Since a DNA template is required for RNA synthesis, eukaryotic transcription takes place in the nucleus or in the matrix of mitochondria and chloroplasts. Structural changes occur in DNA during its transcription. In polytene chromosomes of *Drosophila,* transcriptionally active genes are visualized in the light microscope as puffs distinct from the condensed, inactive chromatin. In fact, active genes exist in modified chromatin structures that are less compacted, as revealed by the accessibility of these genes to chemical reagents or enzymes. In both prokaryotes and eukaryotes, the DNA double helix is transiently opened (unwound) as the transcription complex proceeds along the DNA.

These openings and unwindings are necessary because DNA is a double helix and the two strands of DNA must be separated from one another to permit Watson–Crick base pairing between the template strand of DNA and nucleotides in the newly synthesized RNA. Local opening and unwinding of the DNA allows transcription to proceed without wrapping the RNA product around the DNA template. Type I and type II topoisomerases (p. 152) are involved in these changes in DNA helicity.

The process of transcription is generally divided into three parts: **Initiation** refers to the recognition of a specific DNA sequence by RNA polymerase and the beginning of the bond formation process. **Elongation** is the actual synthesis of the RNA chain, which is followed by chain **termination** and release.

DNA Sequence Information Signals RNA Synthesis

Much of the human genome is not transcribed into RNA. Even in bacteria, where almost all the DNA specifies gene products, not all genes are expressed at any one time. RNA polymerase molecules must, therefore, distinguish between genes and nongenes in the DNA, as well as between genes that need to be expressed and those that do not.

Initiation of transcription starts with recognition of a **promoter sequence** in the DNA template. Typically, promoters are located a short distance upstream of the nucleotide where transcription starts. Different promoters often contain similar sequences, permitting identification of a "consensus" promoter sequence (Figure 5.1), from which actual promoters vary to differing extents. Although prokaryotic and eukaryotic promoters differ from one another, conserved sequences are found within both categories of promoters. Some DNA sequences stimulate transcription but are located further away from the initiation site, and some of these can stimulate transcription independently of distance, location, or orientation relative to the transcriptional start site. Such regulatory sequences are called **enhancers.** Enhancers stimulate the synthesis of some prokaryotic RNAs and of most, if not all, eukaryotic mRNAs. Enhancers work by binding specific protein factors, called activators. When an activator binds to an enhancer, a structural change (often a looping or bending) in the DNA template allows interaction of the activator with other factors or with RNA polymerase. This interaction facilitates transcription by recruiting RNA polymerase and other factors to form an initiation complex.

RNA Polymerase Catalyzes the Transcription Process

RNA polymerases synthesize RNA in the 5′ → 3′ direction using a DNA template. In this regard, they are similar to the template-dependent DNA polymerases discussed in Chapter 4. Unlike DNA polymerases, however, RNA polymerases initiate polymerization at promoter sequences without the need for a DNA or RNA primer.

Prokaryotic and eukaryotic RNA polymerases are large multisubunit enzymes. RNA polymerase from *Escherichia coli* consists of five subunits with an aggregate molecular weight of over 500,000 (Table 5.1). Two α-subunits, one β-subunit and one β'-subunit constitute the core enzyme, which is capable of faithful transcription but not of specific (i.e., promoter-initiated) RNA synthesis. Addition of a fifth protein subunit, designated σ, forms the

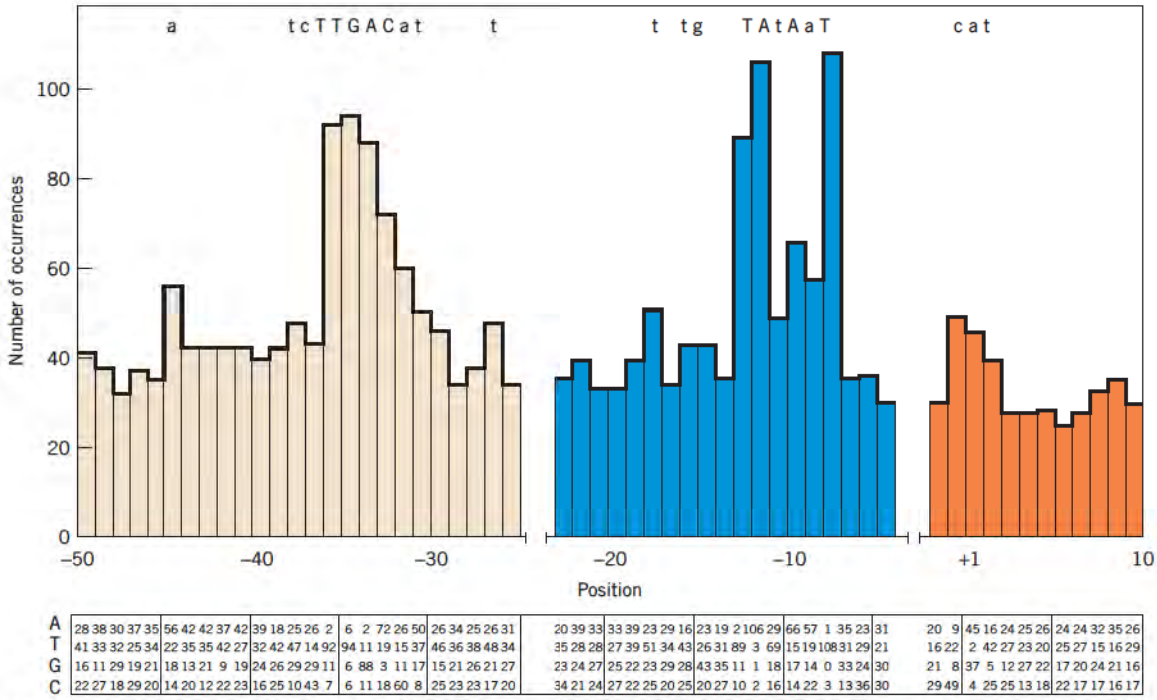

Figure 5.1 A consensus sequence for prokaryotic promoters. The sequences of a large number of promoters from *E. coli* were compiled and the number of times each base occurs at individual positions in the promoter was tabulated. The histogram displays the number of occurrences of the most frequent base at each position. This analysis permits the definition of a consensus sequence for *E. coli* promoters recognized by the form of RNA polymerase holoenzyme containing σ^{70}. This consensus sequence is shown at the top, with the most highly conserved bases in capital letters and the more weakly conserved bases in lowercase letters.

[a]Homologous subunits are shown in the same row. Note that five subunits are shared between RNA polymerases I, II, and III from yeast, and that two additional subunits are shared between RNA polymerases I and III. In addition, RNA polymerase III contains three subunits that have no obvious homologs in the other polymerases. It is likely that A49/C37 and A34.5/C53 are homologous to the subunits of TFIIF, an initiation and elongation factor that associates with RNA polymerase II during transcription but which is not considered a part of the polymerase itself. Four subunits of each of the eukaryotic polymerases are homologous to the four different subunits of *E. coli* core RNA polymerase. The letters A, B, and C in the subunit names refer to the occurrence of that subunit in RNA polymerase I, II, or III, respectively, and the number in the subunit name refers to the subunit's molecular weight in kilodaltons. For RNA polymerase II, the gene encoding each of the subunits is given in parentheses.

holoenzyme that is capable of specific RNA synthesis *in vitro* and *in vivo*. Although one major σ factor is involved in most transcription, specific σ factors are made in response to large-scale environmental or developmental events. These σ factors recognize different classes of genes. Thus, a specific σ factor recognizes promoters for genes that are induced as a result of heat shock. In sporulating bacteria, specific σ factors recognize genes induced during sporulation. Some bacteriophages (viruses that infect bacteria) synthesize σ factors that allow the appropriation of the cell's RNA polymerase for transcription of the viral DNA.

The common prokaryotic RNA polymerases are inhibited by the antibiotic **rifampicin** (used in treating tuberculosis), which binds to the β subunit (Clin. Corr. 5.1). Eukaryotic nuclear RNA polymerases can be distinguished because they are inhibited differentially by **α-amanitin**, which is synthesized by the poisonous mushroom *Amanita phalloides*. Three nuclear RNA polymerase classes can be distinguished since very low concentrations of α-amanitin inhibit the synthesis of mRNA and some small nuclear RNAs (snRNAs); higher concentrations inhibit the synthesis of tRNA, 5S rRNA, and other snRNAs. rRNA synthesis (other than 5S rRNA synthesis) is not inhibited much even by very high concentrations of the toxin. The purified enzymes are differentially inhibited by α-amanitin, so it is possible to conclude that mRNA synthesis is the function of RNA polymerase II, the most sensitive of the purified RNA polymerase forms. Synthesis of tRNA, 5S rRNA, U6 snRNA, and other small cellular and viral RNAs is carried out by RNA polymerase III. rRNA genes are transcribed by RNA polymerase I, which is concentrated in the nucleolus. (The numbers refer to the order of elution of the enzymes from a chromatography column.) Each enzyme has a highly complex structure (Table 5.1).

An RNA polymerase in mitochondria is responsible for synthesis of mitochondrial mRNA, tRNA, and rRNA species. This enzyme, like bacterial RNA polymerase, is inhibited by rifampicin (Clin. Corr. 5.1).

CLINICAL CORRELATION 5.1

Antibiotics and Toxins That Target RNA Polymerase

RNA polymerase is an essential enzyme for life since transcription is the first step of gene expression. Lack of RNA polymerase activity means no other proteins are made. Two natural products illustrate this principle; in both cases inhibition of RNA polymerase leads to death of the organism.

The *death cap* or *destroying angel* mushroom, *Amanita phalloides,* is highly poisonous and still causes several deaths each year despite widespread warnings to amateur mushroom hunters (it is reputed to taste delicious, incidentally). The most lethal toxin, α-amanitin, inhibits eukaryotic RNA polymerase II, thereby inhibiting mRNA synthesis. The poisoning starts with relatively mild gastrointestinal symptoms, followed about 48 h later by massive liver failure as essential mRNAs and their proteins are degraded but not replaced by newly synthesized molecules. The only therapy is supportive, including liver transplantation.

More benign (at least from the point of view of our own species) is the action of the antibiotic rifampicin to inhibit the RNA polymerases of a variety of bacteria, most notably in the treatment of tuberculosis. *Mycobacterium tuberculosis*, the causative agent, is insensitive to many commonly used antibiotics, but it is sensitive to rifampicin, the product of a soil streptomycete. Since mammalian RNA polymerase differs from the prokaryotic variety, inhibition of the latter enzyme is possible without great toxicity to the host. This implies a good therapeutic index for the drug, that is, the ability to treat a disease without causing undue harm to the patient. Together with improved public health measures, antibiotic therapy with rifampicin and isoniazid (an antimetabolite) has greatly reduced the morbidity due to tuberculosis in industrialized countries. Unfortunately the disease is still endemic in impoverished populations in the United States and in other countries. In increasing numbers, immunocompromised individuals, especially AIDS patients, have active tuberculosis.

Steps of Transcription in Prokaryotes

Chromosomal DNA is usually transcribed in only one direction. The DNA strand that serves as the template for RNA synthesis is complementary to the RNA transcript. Conventionally, the template strand is usually the "bottom" strand of a double-stranded DNA as written. The other strand, the nontemplate, or *top,* strand, has the same direction as the transcript when read in the 5′ to 3′ direction; this strand is sometimes called the coding strand. When only a single DNA sequence is given in this book, the coding strand is represented. Its sequence can be converted to the RNA transcript of a gene by simply substituting U (uracil) for T (thymine) bases.

Promoter Recognition

Prokaryotic transcription begins with binding of RNA polymerase to a gene's **promoter** (Figure 5.2). RNA polymerase holoenzyme binds to one face of the DNA extending 45 or so bp upstream and 10 bp downstream from the RNA initiation site. Two short sequences in this region are highly conserved (see Figure 5.1, p. 183). One sequence that is located about 10 bp upstream from the transcription start is the consensus sequence (sometimes called a -10 or *Pribnow* box):

T*A*TAAT*

The positions marked with an asterisk are the most conserved.

A second consensus sequence is located upstream from the –10 or Pribnow box. This –35 sequence

T*T*G*ACA

is centered about 35 bp upstream from the transcription start; the nucleotides with asterisks are most conserved. The spacing between the –35 and –10 sequences is crucial with 17 bp being highly conserved. The TTGACA and TATAAT sequences are asymmetrical; that is, they do not have the same sequence if the complementary sequence is read. Thus, the promoter sequence itself determines that transcription will proceed in only one direction.

What difference do these consensus sequences make to a gene? Measurements of RNA polymerase binding affinity and initiation efficiency on various promoter sequences show that the most active promoters fit the consensus sequences most closely. The degree of similarity of a particular promoter sequence to the consensus correlates well with the measured "strength" of a promoter, that is, its ability to initiate transcription with purified RNA polymerase.

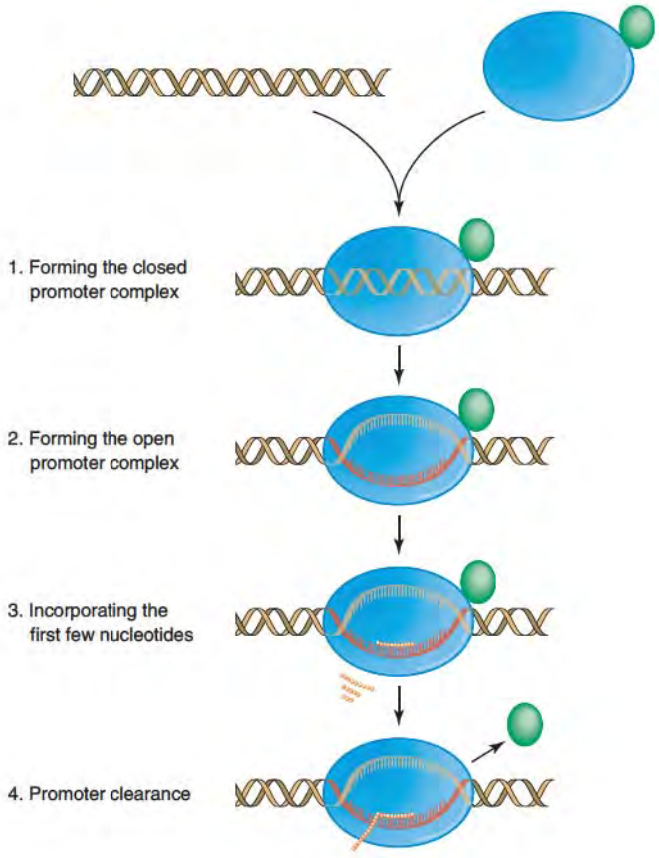

Figure 5.2 Early events in prokaryotic transcription. Promoter-containing DNA is shown in double-helical form, and *E. coli* RNA polymerase holoenzyme is shown as two ovals, the smaller of which represents the sigma factor and the larger of which represents the core. The nascent RNA is shown within the transcription bubble annealed to the DNA template strand, and abortive initiation products are shown as products released from the initiation complex. Although this figure depicts release of the sigma subunit as RNA polymerase enters productive elongation mode, the fate of the sigma factor at this stage of the transcription process remains somewhat controversial.

Bases flanking the –35 and –10 sequences, bases near the transcription start, and bases located near the –16 position are weakly conserved. In some of these weakly conserved regions, RNA polymerase may require that a particular nucleotide not be present or that local variations in DNA helical structure be present. Promoters for *E. coli* heat shock genes have different consensus sequences at the –35 and –10 regions. This is consistent with their being recognized by a different σ factor.

An RNA transcript usually starts with a purine riboside triphosphate; that is, pppG . . . or pppA . . . , but pyrimidine starts are also known (see Figure 5.1, p. 183). The position of transcription initiation differs slightly among various promoters, but usually is five to eight base pairs downstream from the final T of the Pribnow box.

Start of Synthesis

Two kinetically distinct steps are required for RNA polymerase to initiate synthesis of an RNA transcript (see Figure 5.2). In the first step, described above, RNA polymerase holoenzyme binds relatively weakly to the promoter DNA to form a *closed complex*. In the second step, the holoenzyme forms a more tightly bound *open complex*, characterized by a local opening of about 10 bp of the DNA double helix. Since the consensus Pribnow box is A-T rich, it can facilitate this local unwinding; its base pairs are more easily disrupted during opening. Opening 10 bp of DNA is topologically equivalent to the relaxation of a single negative supercoil. As might be predicted from this observation, the activity of some promoters depends on the superhelical state of the DNA template. Some promoters are more active on highly supercoiled DNA whereas others are more active when the superhelical density of the template is lower. The template strand of the unwound DNA base pairs with the initiating nucleoside triphosphate as well as with the second nucleotide of the RNA chain; RNA polymerase then catalyzes formation of the first phosphodiester bond. The enzyme translocates to the next position (this is the rifampicin-inhibited step) and continues synthesis. After several nucleotides have been added to the growing RNA chain, the enzyme enters an elongation mode characterized by a very stable association with the DNA template and does not disengage until specific sequence signals for transcription termination are encountered. Alteration of the association of the sigma subunit with the

core polymerase may be associated with entry into this highly processive elongation state. Once the RNA polymerase has cleared the promoter region, other RNA polymerase molecules can bind and initiate at the promoter so that the gene can be transcribed by many polymerases at the same time (Figure 5.3).

Elongation

RNA polymerase continues the nucleotide binding-bond formation-translocation cycle at an average rate of about 40 nucleotides per second. However, many examples are known where RNA polymerase pauses or slows down at particular sequences. As discussed in the following, these pauses can be linked to transcription termination.

As RNA polymerase moves along the double helix, it continues to separate the two strands of the DNA template. This process allows the template strand of the DNA to base-pair with the growing RNA chain. Thus a single mechanism of information transfer (Watson–Crick base pairing) serves several processes: DNA replication, DNA repair, and transcription of genetic information into RNA. Base pairing is also essential for translation (p. 21). The process of unwinding and restoring the DNA double helix leads to changes in superhelical density in the DNA, and the superhelical state of the DNA is controlled by the activity of DNA topoisomerases I and II.

Changes in the transcription complex during the elongation phase can affect subsequent termination events. These changes depend on the binding of other cellular proteins (NusA protein, for example) to core RNA polymerase. Failure to bind these protein factors can result in an increased frequency of termination and, consequently, a reduced level of gene expression.

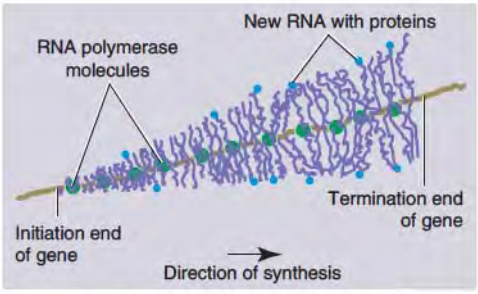

Figure 5.3 Simultaneous transcription of a gene by many RNA polymerases, depicting increasing length of nascent RNA molecules. Courtesy of Dr. O. L. Miller, University of Virginia. Reproduced with permission from O. L. Miller and B. R. Beatty, *J. Cell Physiol.* 74:225, 1969.

Termination

The RNA polymerase complex also recognizes the ends of genes (Figure 5.4). Transcription termination can occur in either of two modes, depending on whether or not it is dependent on the protein factor **ρ (rho)**. Terminators are thus classified as **ρ-independent** or **ρ-dependent**; ρ-independent terminators are well characterized (Figure 5.4). A consensus-type sequence is involved: a G-C-rich palindrome (inverted repeat) which precedes a sequence of 6–7 U residues in the RNA chain. As a result the RNA chain forms a stem-and-loop structure just upstream of the oligoU residues. This secondary structure of the stem and loop is crucial for termination, as demonstrated by experiments showing that base change mutations that disrupt pairing in the RNA also reduce termination. The stem and loop left after termination stabilizes prokaryotic mRNA against nucleolytic degradation.

The ρ-dependent terminators are less well defined. The ρ factor is a hexameric protein that has an essential RNA-dependent ATPase activity. The sequences of ρ-dependent termination sites feature C-rich sequences located some distance upstream of the termination site, which is often a rather broad region within which termination occurs, rather than a specific site. The ρ factor is thought to translocate along the nascent RNA chain in an ATP-dependent fashion until it catches up with the elongating RNA polymerase. When that occurs, ρ in some way destabilizes the elongation complex, leading to release of both the template DNA and the completed RNA chain from each other and from the polymerase.

Prokaryotic ribosomes usually attach to nascent mRNA while it is being transcribed. This coupling between transcription and translation is important in gene control by attenuation (p. 313).

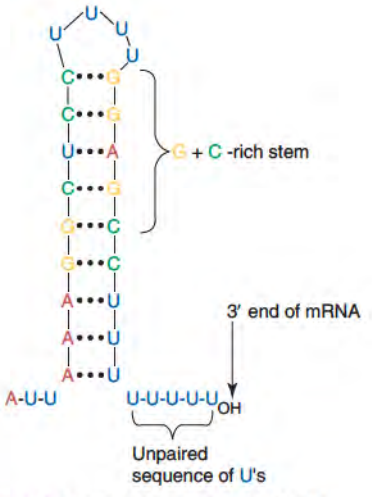

Figure 5.4 Stem-loop structure of RNA transcript that determines rho-independent transcriptional termination. Note the two components of the structure: the G + C-rich stem and loop, followed by a sequence of U residues.

5.3 • TRANSCRIPTION IN EUKARYOTES

Initiation of eukaryotic transcription differs substantially from its prokaryotic counterpart. Whereas the definition of a promoter is the same—DNA sequence information that specifies the start of transcription—the molecular events required for transcription initiation are more complex. First, chromatin containing the promoter sequence must be made accessible to the transcription machinery. Second, transcription factors distinct from RNA polymerase must bind to DNA sequences in the promoter region for a gene to be active. Third, enhancers and other cis-acting transcriptional control elements bind other protein factors (activators) to stimulate transcription.

Eukaryotic transcription factors bind to DNA and recruit RNA polymerase to the promoter. This contrasts with the action of bacterial σ factors, which do not bind DNA without

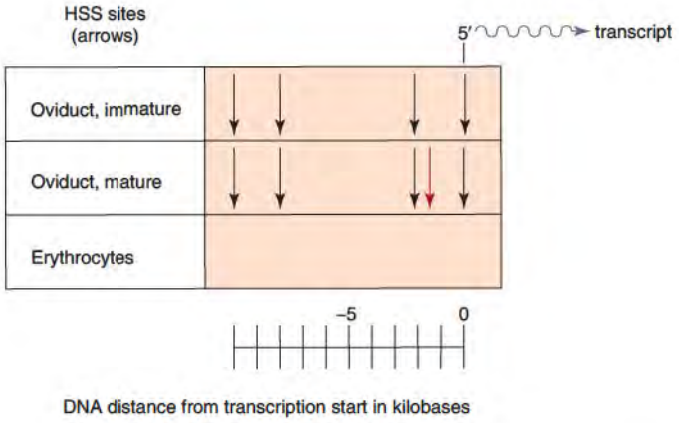

Figure 5.5 DNase-hypersensitive sites (HSS) upstream of the promoter for the chick lysozyme gene, a typical eukaryotic transcriptional unit. Hypersensitive sites, that is, sequences around the lysozyme gene where nucleosomes are not bound to DNA, are indicated by arrows. Note that some hypersensitive sites are found in the lysozyme promoter whether the oviduct is synthesizing or not synthesizing lysozyme; the synthesis of lysozyme is accompanied by the opening up of a new hypersensitive site in mature oviduct. In contrast, no hypersensitive sites are present in nucleated erythrocytes that never synthesize lysozyme.
Adapted from Elgin, S. C. R. *J. Biol. Chem.* 263:1925, 1988.

first binding to the RNA polymerase core enzyme. Eukaryotic RNA polymerase consists of three distinct enzyme forms, each specific form capable of transcribing different classes of cellular RNA. By contrast, all prokaryotic genes are transcribed by a single form of core RNA polymerase, although different σ factors may be involved in initiation on different genes.

Nature of Active Chromatin

The structural organization of eukaryotic chromosomes is discussed in Chapters 4 and 8. Although chromatin is organized into nucleosomes whether or not it is capable of being transcribed, an active gene has a generally "looser" conformation than transcriptionally inactive chromatin. This difference is most striking in the promoter sequences, parts of which are not organized into nucleosomes at all (Figure 5.5). The lack of nucleosomes is manifested experimentally by the enhanced sensitivity of promoter sequences to external reagents that cleave DNA, such as the enzyme DNase I. This enhanced accessibility of promoter sequences (termed DNase I hypersensitivity) ensures that transcription factors can bind to appropriate regulatory sequences. Although the transcribed sequences of a gene may be organized into nucleosomes, the nucleosomes are less tightly bound than those in an inactive gene. Various covalent modifications of the histones are associated with changes in the transcriptional state of genes organized into nucleosomes. One such modification that is usually associated with transcriptional activation is the acetylation of histones by histone acetyltransferases, a reaction that transfers acetyl groups from Acetyl CoA to histones, especially to the N-terminal regions of histones H4 and H3. Other histone modifications that influence gene activity include methylation, phosphorylation, and ubiquitination. Histone methylation is often associated with inactive chromatin, whereas the histones of actively transcribed genes are subject to the other modifications. Combinations of these modifications occurring at different specific positions in histones may constitute a "histone code" that couples histone modification, chromatin compaction, DNA modification, and gene activity (Clin. Corr. 5.2). An overall theme is that partially unfolded chromatin is necessary but not sufficient for transcription.

Transcription Activation Operates by Recruitment of RNA Polymerase

Eukaryotic protein factors, regardless of the sequence to which they bind, operate in a fundamentally different way than *E. coli* σ factor. Rather than first forming part of a protein complex and then seeking out the relevant DNA sequence, the factors bind to a specific site (sequence) on DNA and then bind to RNA polymerase (with or without involvement of intermediary factors). This mechanism is termed "recruitment", which is a minor means of gene activation in prokaryotes and the major mechanism in eukaryotes.

Enhancers

Enhancers increase expression of a gene manyfold. Enhancer-binding transcription factors are called activators. Activator proteins have at least two domains, one of which binds to the enhancer sequence, whereas the other binds to other protein factors or to RNA polymerase.

CLINICAL CORRELATION 5.2

Fragile X Syndrome: A Chromatin Disease?

Fragile X syndrome (OMIM 300624) is the single most common form of inherited mental retardation, affecting 1 out of 1250 males and 1 out of 2000 females. A variety of anatomical and neurological symptoms result from inactivation of the FMR1 gene, located on the X chromosome, which encodes the protein FMRP. The genetics of the syndrome are complex due to the molecular mechanism of the Fragile X mutation.

The Fragile X condition results from the expansion of a trinucleotide repeat sequence, CGG, found in the 5′ untranslated region of the FRM1 gene. Normally, this repeat is present in 30 copies, although normal individuals can have up to 200 copies of the repeat. In individuals with Fragile X syndrome, the FMR1 gene contains many more copies, from 200 to thousands, of the CGG repeat. The complex genetics of the disease result from the potential of the CGG repeat sequence to expand from generation to generation.

The presence of an abnormally high number of CGG repeats induces extensive DNA methylation of the entire promoter region of FMR1. The production of methylated DNA may be mechanistically linked to histone modifications that are associated with transcriptionally inactive chromatin. Certainly, heavily methylated DNA is transcriptionally inactive, and FMRP mRNA is not synthesized when large numbers of CGG repeats lead to FMR1 promoter methylation. The absence of FMRP leads to the pathology of the disease.

FMRP protein is an RNA-binding protein that can bind to cellular polyribosomal mRNAs. Association with FMRP negatively regulates translation of the target mRNAs, thus controlling gene expression in the dendrite. The action of FMRP is one of many recent examples that show how posttranslational mechanisms control gene expression and molecular phenotype.

Penagarikano, O., Mulle, J. G., and Warren, S. T. The pathophysiology of Fragile X syndrome. *Annu. Rev. Gen. Hum. Genet.* 8:109, 2007.

The most accepted model for these effects is that chromatin forms a loop that allows the enhancer and the promoter to be close together in space, even though they are separated by a relatively long sequence of DNA.

Transcription by RNA Polymerase II

RNA polymerase II is responsible for synthesis of mRNA in the nucleus. Several common themes have emerged from research on a large number of genes (Figure 5.6). (1) The DNA sequences that control transcription are complex; a single gene may be controlled by dozens of DNA sequence elements in addition to the promoter, which includes the site at which a multiprotein complex containing RNA polymerase assembles. This preinitiation complex is made up of a number of basal-level, or general, transcription factors (p. 320) whose function is to place RNA polymerase II at the correct site for initiating transcription, to assist

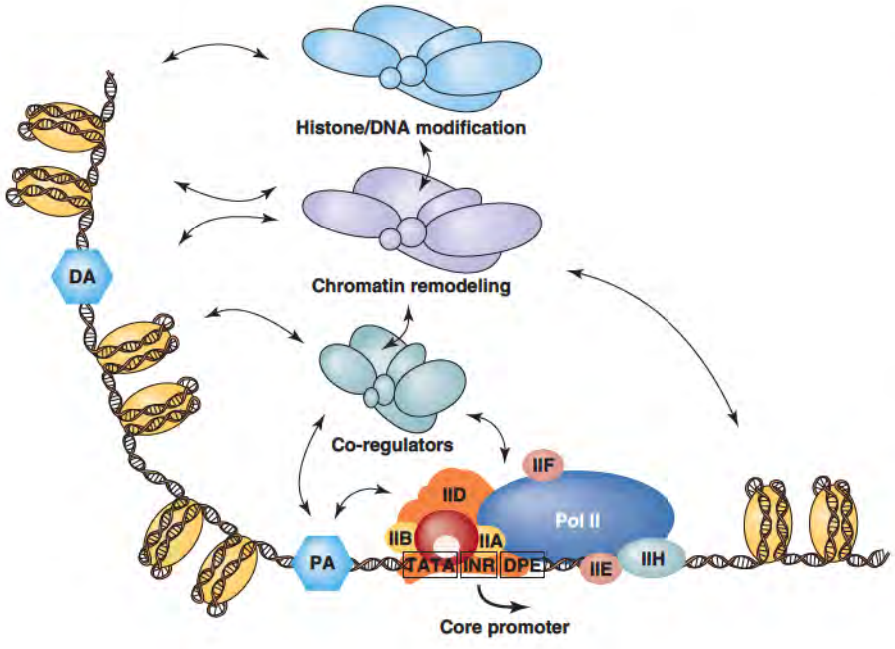

Figure 5.6 Interaction of transcription factors and chromatin-modifying factors with eukaryotic promoters. Cis-acting transcriptional control elements located near the transcription start site may include a TATA box, initiator element (INR), or a downstream promoter element (DPE) and are shown here interacting with the core factors required for specific transcription by RNA polymerase II. Promoters typically contain only a subset of these elements, not all three. The core factors include TFIIA, TFIIB, TFIID, TFIIE, TFIIF, and TFIIH, in addition to RNA polymerase II. Transcriptional activator proteins can bind to promoter-proximal (PA) or promoter-distal (DA) sequences and activate transcription through interactions with the core factors, coregulators, or chromatin-modifying complexes, as shown. Binding of either the core factors or transcriptional activators may require or be accompanied by modifications of chromatin structure, including loss of nucleosomes. Reproduced with permission from Hochheimer, A. and Tjian, R. *Genes and Dev.* 17:1309, 2003.

in separation of DNA strands at the start site, and to control the transition of polymerase from initiation to elongation mode. Without additional transcription control proteins interacting with enhancers and other cis-acting sequence elements, this process is generally quite inefficient, however. Controlling sequence elements function in combination to give a finely tuned pattern of control. (2) The effect of controlling sequences on transcription is mediated by binding of proteins to each sequence element. These transcription factors recognize the nucleotide sequence of the appropriate controlling sequence element. (3) Bound transcription factors interact with each other and ultimately act to recruit RNA polymerase, often acting through factors in the preinitiation complex or other intermediates. The DNA-binding and activation activities of the factors reside in separate domains of the proteins. (4) RNA polymerase II is modified during the transcription reaction. The modified polymerase recruits other nuclear components, including RNA processing enzymes, during the elongation phase of transcription.

Promoters for mRNA Synthesis

In contrast to prokaryotic RNA polymerase which recognizes only a single promoter sequence, transcription factors acting in conjunction with RNA polymerase II can recognize several classes of consensus sequences upstream from the mRNA start site. The first and most prominent of these, sometimes called the **TATA box**, has the sequence

TATA(A/T)(A/T) A

where the nucleotides in parentheses can be either an A or a T.

The TATA box is centered about 25 bp upstream from the transcription unit. Experiments in which it was deleted suggest that it is required for efficient transcription of many genes, but may only specify the correct transcriptional start site in others. Some promoters lack it entirely.

Other promoter-proximal control elements are often found in genes transcribed by RNA polymerase II, but are not universal. One such sequence is the **CAAT box**, with the sequence

GG(T/C) CAATCT

Other sequences, illustrated in Figure 5.6, may also promote transcription.

CAAT and TATA boxes, as well as other sequences shown in Figure 5.6, do not contact RNA polymerase II directly. Rather, they require the binding of specific transcription factors to function. Note how protein factors bind not only to their recognition sequences but also to each other and to RNA polymerase, itself a very large and complex enzyme. Mutated forms of some of these transcription factors are products of oncogenes (Clin. Corr. 5.3).

Transcription by RNA Polymerase I

Ribosomal RNAs are synthesized in a specific nuclear body, the nucleolus, and the rRNA genes are located in a specific chromosomal region termed the nucleolar organizer. Each transcriptional unit contains sequences for 28S, 5.8S, and 18S rRNAs, in that order. Several hundred copies of each transcriptional unit occur tandemly (one after another) in the chromosome. Transcriptional units are separated by spacer sequences. Spacer sequences include sequences that specify binding of RNA polymerase I and of Class I transcription factors, which promote RNA polymerase I activity. Figure 5.7 is a diagram of this arrangement. Each repeat unit is transcribed as a unit, yielding a primary transcript that contains one copy each of the 28S, 5.8S, and 18S sequences, ensuring synthesis of equimolar amounts of these three RNAs. The primary transcript is then processed by ribonucleases and modifying enzymes to the three mature rRNA species. Termination of transcription occurs within the nontranscribed spacer region before **RNA polymerase I** reaches the promoter of the next repeat unit. The mechanism of termination differs from those discussed previously for *E. coli* RNA polymerase.

The promoter recognized by RNA polymerase I is located within the nontranscribed spacer, from about positions −40 to +10 and from −150 to −110. A transcription factor binds to the promoter and thereby directs recognition of the promoter sequence by RNA polymerase I. In addition, an enhancer element is located about 250 bp upstream from the

CLINICAL CORRELATION 5.3

Involvement of Transcriptional Factors in Carcinogenesis

Conversion of a normally well-regulated cell into a cancerous one requires a number of independent steps whose end result is a transformed cell capable of uncontrolled growth and metastasis. Insights into this process have come from recombinant DNA studies of the genes, termed oncogenes, whose mutated or overexpressed products contribute to carcinogenesis. Oncogenes were first identified as constituents of the genomes of DNA or RNA tumor viruses, but those found in RNA tumor viruses have been derived from genes present in normal cells. The normal, nonmutated cellular analogs of oncogenes are termed protooncogenes. Their products are components of the many pathways that regulate growth and differentiation of a normal cell; mutation into an oncogenic form involves a change that makes the regulatory product less responsive to normal control.

Some protooncogene products are involved in transduction of hormonal signals or recognition of cellular growth factors and act cytoplasmically. Other protooncogenes have a nuclear site of action; their gene products are often associated with the transcriptional apparatus, and they are synthesized in response to growth stimuli. It is easy to visualize how overproduction or permanent activation of such a positive transcription factor could aid the transformation of a cell to malignancy: Genes normally transcribed at a low or controlled level would be overexpressed by such a deranged control mechanism.

A more subtle genetic effect predisposing to cancer is exemplified by the human tumor suppressor protein p53. This protein is the product of a member of another class of genes implicated in tumorigenesis, the tumor suppressor genes. In contrast to oncogenes, whose products positively regulate cell growth and division, the product of a tumor suppressor gene like p53 negatively regulates cell division. A single copy of the mutant p53 gene causes Li–Fraumeni syndrome, an inherited condition predisposing to carcinomas of the breast and adrenal cortex, sarcomas, leukemia and brain tumors.

Somatic mutations in p53 can be identified in about half of all human cancers. Mutations represent a loss of function, affecting either the stability or the DNA-binding ability of p53. The wild-type protein helps to control the checkpoint between the G1- and S-phases of the cell cycle, activates DNA repair, and in other circumstances, leads to programmed cell death (apoptosis). Thus the biochemical actions of p53 serve to keep cell growth regulated, maintain the information content of the genome, and finally, eliminate damaged cells. All of these functions would counteract the neoplastic transformation of a cell.

These varied roles are a function of the action of p53 as a transcription factor, inhibiting some genes and activating others. For example, p53 is a site-specific DNA-binding protein and promotes transcription of some genes, including those involved in DNA repair.

The three-dimensional structure of p53 has been determined. Mutations found in p53 from tumors affect the DNA-binding domain of the protein. For example, nearly 20% of all mutated residues involve mutations at two positions in p53. The crystal structure of the protein–DNA complex shows that these two amino acids, both arginines, form hydrogen bonds with DNA. Arginine 248 forms hydrogen bonds in the minor groove of the DNA helix with a thymine oxygen and with a ring nitrogen of adenine. Mutation disrupts this H-bonded network and therefore the ability of p53 to regulate transcription.

Weinberg, R. A. *The Biology of Cancer*. New York: Garland Science, 2007.

promoter in human ribosomal DNA. The size of nontranscribed spacer varies considerably among organisms, as does the position of the enhancer element.

Transcription of rRNA can be very rapid; this reflects the fact that synthesis of ribosomes is rate limiting for cell growth and the demand for rRNA can therefore be very high. In other situations, when growth is not so rapid, only some of the rDNA repeats are transcriptionally active.

Transcription by RNA Polymerase III

Many of the themes elaborated above for transcription of Class I and Class II promoters hold for the synthesis of 5S RNA, tRNA, and other small cellular and viral RNAs by **RNA polymerase III.** Transcription factors bind to DNA and direct the action of RNA polymerase. One unusual feature of RNA polymerase III action is the location of transcription factor-binding sequences; these can be located within the DNA sequence encoding the RNA

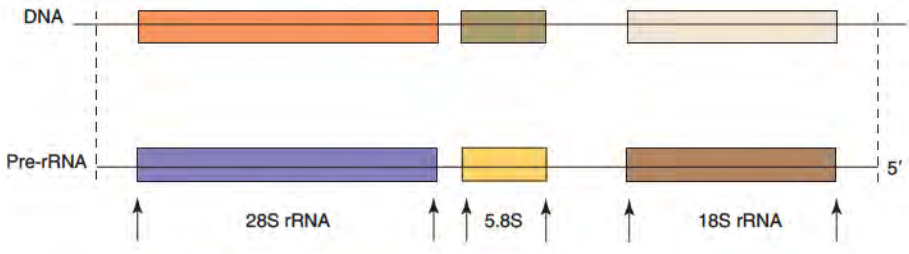

Figure 5.7 Structure of an rRNA transcription unit. Ribosomal RNA genes are arranged with many copies one after another. Each copy is transcribed separately, and each transcript is processed into three separate RNA species. Promoter and enhancer sequences are located in the nontranscribed regions of the tandemly repeated sequences.

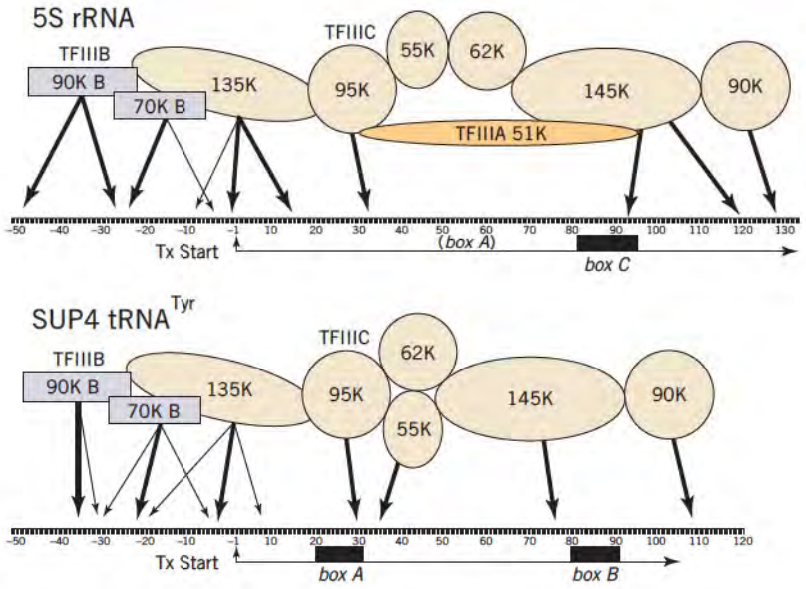

Figure 5.8 The sequences of the nontemplate strands of yeast genes encoding 5S rRNA and a tRNA are shown, along with schematic representations of the various subunits of TFIIIA, TFIIIB, and TFIIIC. The approximate locations of these subunits relative to the DNA sequences of the two genes are indicated by arrows. Note that TFIIIA is required to form a transcription complex on 5S rRNA genes but not on tRNA genes. TFIIIA is responsible for much of the sequence-specific recognition of the internal control region of the 5S rRNA gene, whereas TFIIIC performs this function for the tRNA gene. Nonetheless, both TFIIIC and TFIIIB are required for transcription of both 5S rRNA and tRNA genes. Redrawn from Braun, B. R., Bartholomew, B., Kassevetis, G. A., and Geiduschek, E. P. *J. Mol. Biol.* 228:1063, 1992.

and are often referred to as the internal control region. In some cases, the DNA in the region immediately 5′ to the transcribed region of the gene can be substituted by other sequences with relatively minor effects on transcription. In other cases, however, sequences upstream of the transcription start site can play a major role in establishing efficient transcription. The differences appear to result from the relative importance of various DNA–protein contacts in stabilizing the entire transcription complex made up of multiple proteins in addition to RNA polymerase III. The relationships of these various proteins to the underlying DNA sequence are shown for a 5S rRNA gene and for a tRNA gene in Figure 5.8.

The Common Enzymatic Basis for RNA Polymerase Action

Our understanding of the molecular basis of RNA polymerase action has grown recently, as the three-dimensional structures of a σ factor, a bacterial core RNA polymerase, the RNA polymerase holoenzyme, a eukaryotic RNA polymerase II, and even an RNA polymerase II engaged in transcription elongation have been determined by X-ray crystallography. Despite all the differences in subunit composition, size, and mechanism, RNA polymerases seem to interact with their DNA templates, nucleotide substrates, and nascent RNA chains in a similar fashion.

Remarkably, the shapes of the prokaryotic and eukaryotic enzymes are strikingly similar, particularly within the enzymes' catalytic core. Both bacterial core RNA polymerase and RNA polymerase II from yeast are shaped rather like the claw of a crab (Figure 5.9). DNA comes in at one end of the molecule, and moves through a deep cleft in the polymerase before making a 90-degree bend and exiting from the polymerase. The catalytic site, that is, the site at which a new nucleotide is added to the 3′-end of the growing RNA chain, is located at the end of the channel. The two strands of the double-helical DNA molecule are separated by the enzyme to form a "transcription bubble," and a transient nine-base pair RNA–DNA hybrid forms within the bubble. Nucleotides come in and RNA exits through two other, separate channels in the molecule. Despite the differences in sequence and subunit composition, the prokaryotic and eukaryotic RNA polymerases have retained similar structures to accomplish the same goals leading to synthesis of a new RNA chain. These include (1) threading the DNA template through a channel in the enzyme, (2) separating the DNA strands to form a bubble within which an RNA-DNA hybrid exists with the 3′-end of the RNA chain positioned in the active site, (3) bringing nucleotides into the active site through a pore in the enzyme, (4) using a metal ion to assist in catalyzing the formation of a new phosphate ester bond between the alpha phosphate of the incoming nucleoside triphosphate and the 3′-end of the nascent RNA chain, (5) extruding the RNA product through another pore, and (6) directing reannealing of the two DNA strands as they exit from the enzyme.

Recall that the σ-subunit of the prokaryotic holoenzyme is responsible for binding to the -10 and -35 boxes of promoters. Structural studies have shown that sigma is an

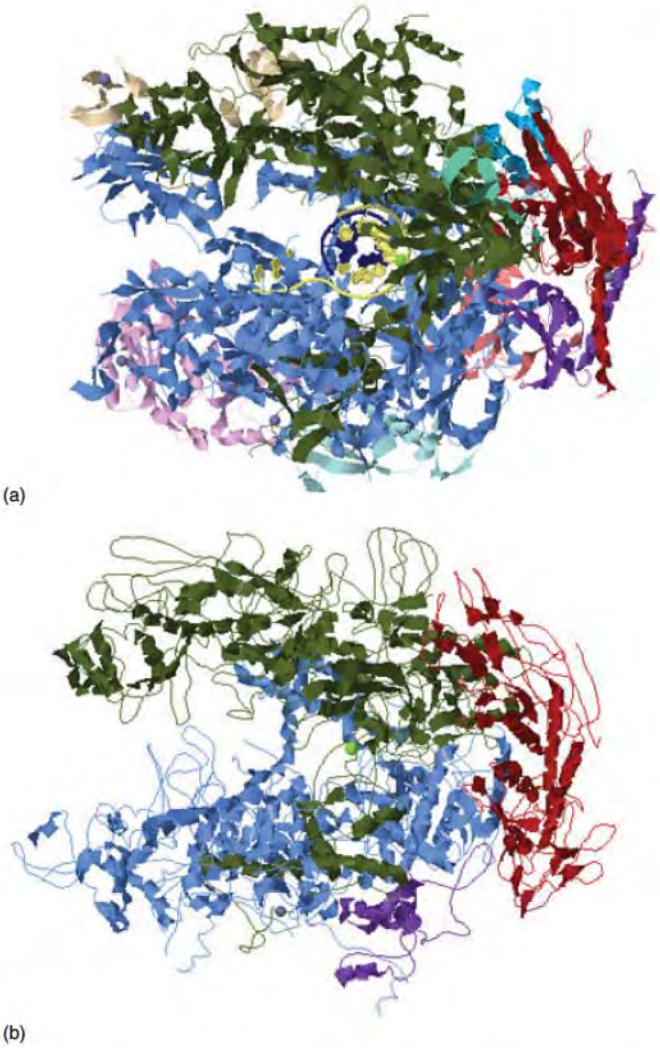

Figure 5.9 Comparison of the structures of eukaryotic and prokaryotic RNA polymerases. The same colors are used to represent homologous subunits in the two enzymes. Note the similarity in the overall shapes. (*a*) The three-dimensional structure of yeast RNA polymerase II engaged in transcription elongation. The various subunits are shown in different colors, with the largest subunit shown in blue and the second largest subunit in green. The DNA template strand is yellow and the nascent RNA is dark blue. This structure is missing two subunits of the RNA polymerase (products of the Rpb4 and Rpb7 genes), and the nontemplate strand of DNA was not resolved in the structural determination. (*b*) The structure of the RNA polymerase core from *Thermus aquaticus* is shown at the bottom. The β' subunit is shown in green, the β subunit in blue, the two α subunits in red, and the ω subunit in violet.

USA* 98:892, 2001.

oblong molecule, composed of a bundle of α-helical residues, packed into an open V shape. One arm of the "V" contains critical residues for promoter recognition and core polymerase binding. One side of this arm contains an α-helix that binds to the -10 sequence and the other face binds to core polymerase through hydrophobic interactions.

5.4 • RNA PROCESSING

RNA copies of DNA sequences must be modified to mature, functional, molecules in prokaryotes and eukaryotes. The reactions of RNA processing can include: removal of extra nucleotides, base modification, addition of nucleotides, and separation of different RNA sequences by the action of specific nucleases. Processing reactions can occur either cotranscriptionally (while the RNA is still being synthesized by RNA polymerase) or posttranscriptionally (after the transcript is released by RNA polymerase). Finally, in eukaryotes, RNAs are exported from the nucleus.

Transfer RNA Is Modified by Cleavage, Addition, and Base Modification

Cleavage

The primary transcript of a tRNA gene contains extra nucleotide sequences both 5′ and 3′ to the tRNA sequence. These primary transcripts may also contain **introns** in the anticodon region. Posttranscriptional processing reactions occur in a closely defined but not necessarily rigid temporal order. First, the primary transcript is trimmed in a relatively nonspecific manner to

yield a precursor molecule with shorter 5′- and 3′-extensions. Then ribonuclease P, a ribozyme (p. 68), removes the 5′-extension by endonucleolytic cleavage. The 3′-end is trimmed exonucleolytically, followed by synthesis of the CCA terminus. Synthesis of the modified nucleotides occurs in any order relative to the nucleolytic trimming. Intron removal is dictated by the secondary structure of the precursor (Figure 5.10) and is carried out by a soluble, two-component enzyme system; one enzyme removes the intron and the other reseals the nucleotide chain.

3′-End Addition

Each functional tRNA has the sequence CCA at its 3′-terminus. This sequence is essential for tRNA to accept amino acids. In most instances it is added sequentially by the enzyme tRNA nucleotidyltransferase. Nucleotidyltransferase uses ATP and CTP as substrates and

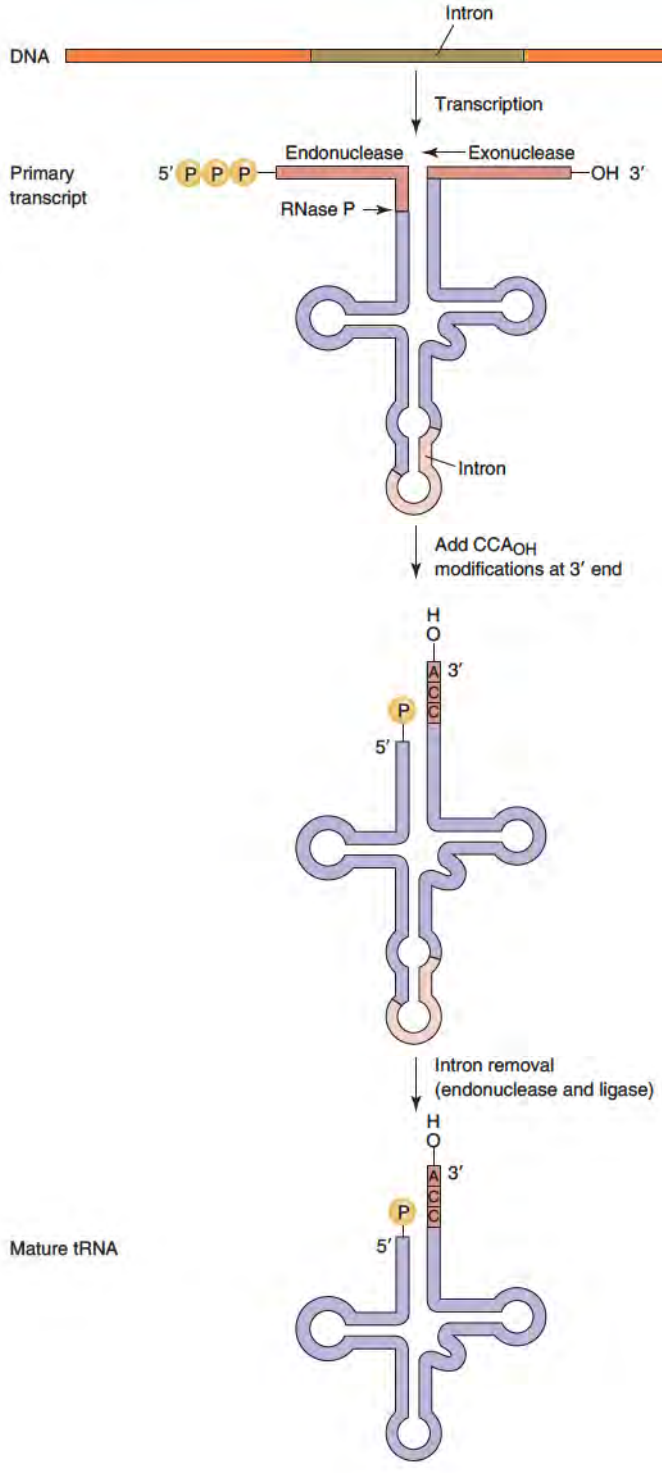

Figure 5.10 Scheme for processing a eukaryotic tRNA. Primary transcript is cleaved by RNase P and a 3′ exonuclease and the terminal CCA is synthesized by tRNA nucleotidyltransferase before the intron is removed, if necessary.

always incorporates them into tRNA at a ratio of 2C/1A. The CCA ends are found on both cytosolic and mitochondrial tRNAs.

Modified Nucleosides

Transfer RNA nucleotides are the most highly modified of all nucleic acids. More than 60 different modifications to the bases and ribose, requiring well over 100 different enzymatic reactions, have been found in tRNA. Many are simple, one-step methylations, but others involve multistep synthesis. Formation of some modified bases actually requires severing of the β-glycosidic bond between ribose and the base. Modifying enzymes produce the same specific modification in more than one species of tRNA; however, the modifying enzymes are location specific. Most modifications are completed before the tRNA precursors have been cleaved to the size of mature tRNA.

Ribosomal RNA Processing Releases Several RNAs from a Longer Precursor

The primary product of rRNA gene transcription is a long RNA, termed 45S RNA, which contains the sequences of 28S, 5.8S, and 18S rRNAs. Processing of 45S RNA occurs in the nucleolus and is carried out by large multisubunit ribonucleoprotein assemblies. Processing of the rRNAs follows a sequential order (Figure 5.11). Processing of pre-rRNA in prokaryotes also involves cleavage of high-molecular-weight precursors to smaller molecules. At an early stage of processing in eukaryotes, some bases in 35S rRNA are modified by methylation on the ring nitrogens of the bases and by the formation of pseudouridine. These reactions are specified by small nucleolar ribonuclear protein particles (snoRNPs) in the nucleolus. Each snoRNP contains a **guide RNA** which base-pairs to the rRNA transcript at the site of modification, specifying where a methylation or formation of pseudouridine should occur. A similar mechanism operates for modification of some other small RNAs.

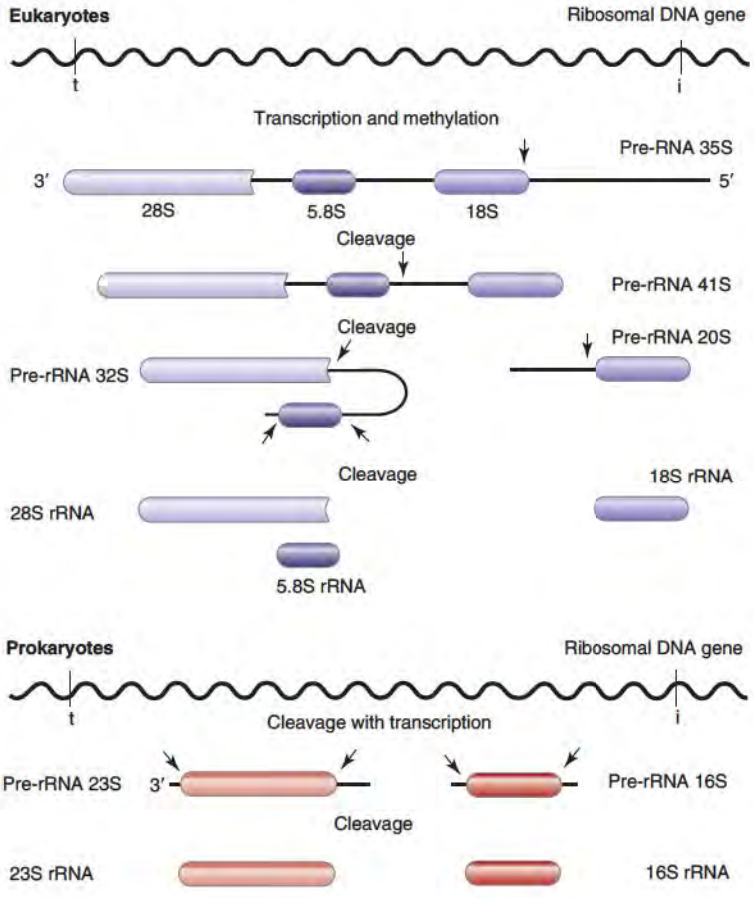

Figure 5.11 Schemes for transcription and processing of rRNAs.
Redrawn from Perry, R. *Annu. Rev. Biochem.* 45:611, 1976.

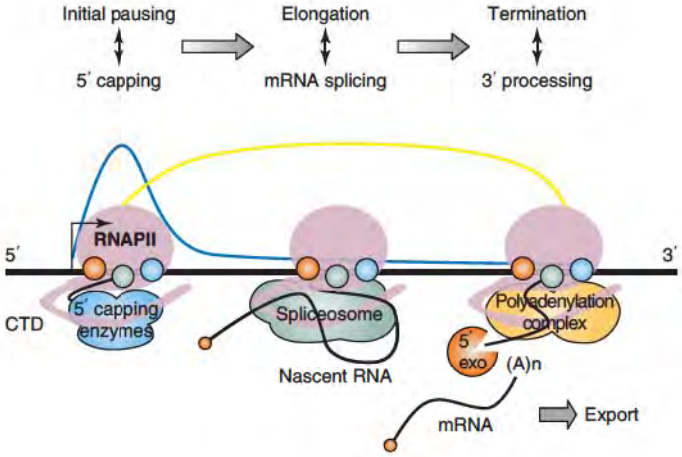

Figure 5.12 RNA processing occurs during transcriptional elongation. Phosphorylation of the C-terminal domain of RNA polymerase II (RNAPII) moves transcription into the elongation phase and results in the recruitment of processing factors. As the partially completed (nascent) mRNA precursor emerges from the transcription complex, the spliceosome removes introns. When the polyadenylation signal is reached, the polyadenylation complex cleaves the nascent mRNA and adds the poly(A) tail, $(A)_n$. The remaining nascent RNA is degraded by 5′ exonucleases, while the processed mRNA is exported for translation.

Messenger RNA Processing Ensures the Correct Coding Sequence

Most eukaryotic mRNAs have distinctive structural features added in the nucleus by enzyme systems other than RNA polymerase. These include the 3′-terminal poly(A) tail, methylated internal nucleotides, and the cap 5′-terminus. Mature mRNAs are shorter than their primary transcripts. Noncoding sequences present within pre-mRNA, but not present in mature mRNAs, are called intervening sequences or introns. The retained sequences are called **exons**. The general pattern for mRNA processing is depicted in Figure 5.12. Incompletely processed mRNAs make up a large part of the heterogeneous nuclear RNA (HnRNAs).

Processing of eukaryotic pre-mRNA involves a number of molecular reactions all of which must be carried out with exact fidelity. This is most clear in the removal of introns from an mRNA transcript. An extra nucleotide in the coding sequence of mature mRNA would cause the reading frame of that message to be shifted, and the resulting protein will almost certainly be nonfunctional. Indeed, mutations that interfere with intron removal are a major cause of human genetic diseases, for example, in some cases of β-thalassemia (Clin. Corr. 5.4). The task for cells becomes even more daunting since some important human genes consist of over 90% intron sequences. The complex reactions to remove introns are accomplished by multicomponent ribonucleoprotein enzyme systems in the nucleus; after these reactions are completed, the mRNA is exported to the cytoplasm where it interacts with ribosomes to initiate translation. Most processing is cotranscriptional.

RNA Polymerase II Recruits Processing Enzymes during Transcription in Eukaryotes

The largest subunit of RNA polymerase II contains a C-terminal domain (CTD) that functions to couple transcription and processing. When RNA polymerase II is in an initiation mode, the CTD is not modified. When the transcript is about 25 nucleotides long, the CTD is extensively phosphorylated. Phosphorylated CTD successively recruits the capping enzyme, splicing and polyadenylation complexes.

Capping

As the transcription complex moves along the DNA, the capping enzyme complex modifies the 5′-end of the nascent mRNA. Capping involves the synthesis of a 5′– 5′ triphosphate bond with the addition of a G residue. This structure is further modified by methylation.

Removal of Introns from mRNA Precursors

As pre-mRNA is extruded from the RNA polymerase complex, it is rapidly bound by **small nuclear ribonucleoproteins, snRNPs** ("snurps") which carry out the dual steps of RNA splicing: breaking the intron at the 5′ donor site and joining the upstream and downstream exon sequences together. Almost all introns begin with a GU sequence and end with AG; these are termed the donor and acceptor intron–exon junctions, respectively. Not all GU

CLINICAL CORRELATION 5.4

Thalassemia due to Defects in Messenger RNA Synthesis

Thalassemias are genetic defects in the coordinated synthesis of α- and β-globin peptide chains; a deficiency of β globin chains is termed β-thalassemia whereas a deficiency of α globin chains is termed α-thalassemia. Patients suffering from β-thalassemia present with anemia at about 6 months of age, at the time when HbF synthesis ceases and HbA synthesis becomes predominant. The severity of symptoms leads to the classification of the disease into either thalassemia major, where a severe deficiency of globin synthesis occurs, or thalassemia minor, where a less severe imbalance occurs. Occasionally an intermediate form is seen. Therapy for thalassemia major involves frequent blood transfusions, leading to a risk of complications from iron overload. Unless chelation therapy is successful, the deposition of iron in peripheral tissues, termed hemosiderosis, can lead to death before adulthood. Carriers of the disease are typically asymptomatic or nearly so. Ethnographically, the disease is common in persons of Mediterranean, Arabian, and East Asian descent. As in sickle-cell anemia (HbS) and glucose 6-phosphate dehydrogenase deficiency, the abnormality of the carriers' erythrocytes affords some protection from malaria. Maps of the regions where one or another of these diseases is frequent in the native population superimpose over the areas of the world where malaria is endemic.

The most common form of α-thalassemia is due to a genetic deletion which presumably results from unequal crossing over between adjacent, duplicated α-globin alleles. In contrast, β-thalassemia can result from a wide variety of mutations. Known events include mutations leading to frame shifts in the β-globin coding sequence, as well as mutations leading to premature termination of peptide synthesis. Many β-thalassemias result from mutations affecting the biosynthesis of β-globin mRNA. Genetic defects are known that affect the promoter of the gene, leading to inefficient transcription. Other mutations result in aberrant processing of the nascent transcript, either during splicing out of its two introns from the pre-mRNA or during polyadenylation of the mRNA precursor. Examples where the molecular defect illustrates a general principle of mRNA synthesis are discussed in the text.

Orkin, S. H. Disorders of hemoglobin synthesis: The thalassemias. In Stamatoyannopoulis, G., Nienhuis, A. W., Leder, P., and Majerus, P. W. (Eds.), *The Molecular Basis of Blood Diseases.* Philadelphia; Saunders, 1987; and Weatherall, D. J., Clegg, J. B., Higgs, D. R., and Wood, W. G., The hemoglobinopathies. In Scriver, C. R., Beaudet, A. L., Sly, W. S., and Valle, D. (Eds.), *The Metabolic Bases of Inherited Disease,* 7th ed. New York: McGraw Hill, 1995.

or AG sequences are spliced out of RNA, however. How does the cell know which GU sequences are in introns (and therefore must be removed) and which are destined to remain in mature mRNA? This discrimination is accomplished by formation of base pairs between U1 RNA and the sequence of the mRNA precursor surrounding the donor GU sequence (Figure 5.13; Clin. Corr. 5.5). Another snRNP, containing U2 RNA, recognizes important sequences at the 3′-acceptor end of the intron. Still other snRNP species, among them U5 and U6, then bind to the RNA precursor, forming a large complex termed a **spliceosome** (by analogy with the large ribonucleoprotein assembly involved in protein synthesis, the ribosome). The spliceosome uses ATP to carry out accurate removal of the intron. First, the phosphodiester bond between the exon and the donor GU sequence is broken, leaving a free 3′-OH group at the end of the first exon and a 5′-phosphate on the donor G of the intron. This pG is then used to form an unusual linkage with the 2′-OH group of an adenosine within the intron to form a branched, or **lariat**, RNA structure, as shown in Figure 5.14. After the lariat is formed, the second step of splicing occurs. The phosphodiester bond immediately following the AG is cleaved, and the two exon sequences are ligated together.

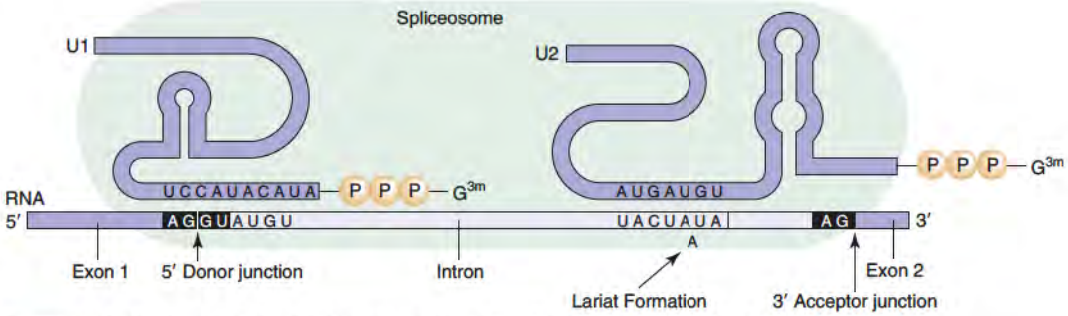

Figure 5.13 Mechanism of splice junction recognition. Recognition of the 5′ splice junction involves base pairing between the intron–exon junction and the U1 RNA snRNP. This base pairing targets the intron for removal.

CLINICAL CORRELATION 5.5

Autoimmunity in Connective Tissue Disease

Humoral antibodies in sera of patients with various connective tissue diseases recognize a variety of ribonucleoprotein complexes. Patients with systemic lupus erythematosus exhibit a serum antibody activity designated Sm, and those with mixed connective tissue disease exhibit an antibody designated RNP. Each antibody recognizes a distinct site on the same RNA–protein (U1–RNP) complex that is involved in mRNA processing in mammalian cells. The U1–RNP complex contains U1 RNA, a 165 nucleotide sequence highly conserved among eukaryotes, that at its 5′-terminus includes a sequence complementary to intron–exon splice junctions. Addition of this antibody to *in vitro* splicing assays inhibits splicing, presumably by removal of the U1 RNP from the reaction. Sera from patients with other connective tissue diseases recognize different nuclear antigens, nucleolar proteins, and/or chromosomal centromere. Sera of patients with myositis have been shown to recognize cytoplasmic antigens such as aminoacyl-tRNA synthetases. Although humoral antibodies have been reported to enter cells that have Fc receptors, there is no evidence that this is part of the mechanism of autoimmune disease.

Polyadenylation

RNA polymerase continues transcribing the gene until a polyadenylation signal sequence is reached (Figure 5.15). This sequence, which has the consensus AAUAAA, appears in the mature mRNA but does not form part of its coding region. Rather, it signals cleavage of the nascent mRNA precursor about 20 or so nucleotides downstream. The poly(A) sequence is then added by a specialized polymerase to the free 3′-end produced by this cleavage. The C-terminal domain of RNA polymerase II recruits the cleavage and polyadenylation complex to the transcript. Termination of transcription by the elongating RNA polymerase occurs further downstream and is coupled to the cleavage and polyadenylation reaction, although the detailed mechanism is not clear. The end result of processing is a fully functional coding mRNA, all introns removed, and ready to direct protein synthesis.

Mutations in Splicing Signals Cause Human Diseases

Messenger RNA splicing is an intricate process dependent on many molecular events. If these events are not performed with precision, functional mRNA is not produced. This is illustrated in the human thalassemias, which affect the balanced synthesis of α- and β-globin chains (see Clin. Corr. 5.4, p. 197). Some mutations that lead to β-thalassemia interfere with splicing of β-globin mRNA precursors. For example, we know that all intron sequences begin with the dinucleotide GU. Mutation of the G in this sequence to an A means that the splicing machinery will no longer recognize this dinucleotide as a donor site. Splicing will skip over the correct exon–intron junction. This could lead to extra sequences appearing in the β-globin mRNA that would normally be spliced out, or alternatively, sequences could be deleted from the mRNA product (Figure 5.16). In either event, functional β-globin will be synthesized in reduced amounts and the anemia characteristic of the disease will result.

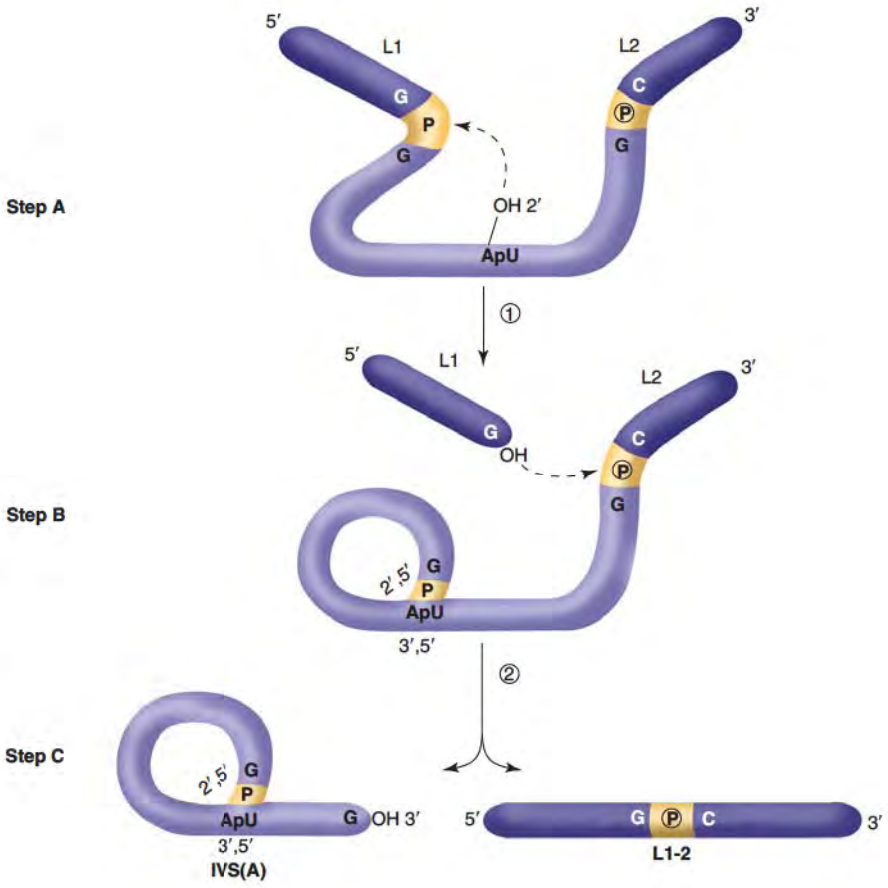

Figure 5.14 Proposed scheme for mRNA splicing to include the lariat structure. A messenger RNA is depicted with two exons (in blue) and an intervening intron (in orange). A 2′-OH group of the intron sequence reacts with 5′-phosphate of the intron's 5′-terminal nucleotide producing a 2′–5′ linkage and the lariat structure. Simultaneously, the exon 1–intron phosphodiester bond is broken leaving a 3′-OH terminus on this exon free to react with 5′-phosphate of the exon 2, displacing the intron and creating the spliced mRNA. The released intron lariat is subsequently digested by cellular nucleases.

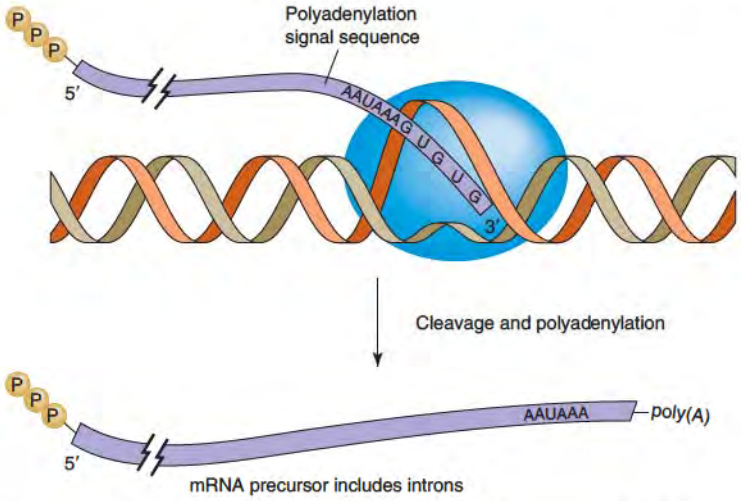

Figure 5.15 Cleavage and polyadenylation of eukaryotic mRNA precursors. The 3′-termini of eukaryotic mRNA species are derived by processing. The sequence AAUAAA in mRNA specifies cleavage of mRNA precursor. The free 3′-OH end of the mRNA is a primer for poly(A) synthesis. Adapted from Proudfoot, N. J. *Trends Biochem. Science* 14:105, 1989.

Alternate Pre-mRNA Splicing Can Lead to the Synthesis of Multiple Protein Isoforms from a Single DNA Coding Sequence

The existence of intron sequences is paradoxical. Introns must be removed precisely so that the mRNA can accurately encode a protein. As described in Clin. Corr. 5.4, a single base mutation can drastically interfere with splicing and cause a serious disease. Further, the presence of intron sequences in a gene means that its overall sequence is much larger than is required to encode its protein product. A large gene is a target for more mutagenic events than is a small one. Indeed, common human genetic diseases like Duchenne muscular dystrophy occur in genes that encompass millions of base pairs of DNA information. Why has nature not removed introns completely over the long time scale of eukaryotic evolution? The answer seems to lie in the ability of differential processing to generate multiple proteins from a single transcript.

Tropomyosin proteins are essential components of the contractile apparatus in the three types of muscle (p. 970) and each contains a specific tropomyosin. This diversity arises from a single gene that is transcribed into a primary transcript. The transcript is then processed as diagramed in Figure 5.17. Each cell type processes the primary tropomyosin transcript in a characteristic fashion. The resulting mRNA species are translated to yield the tropomyosins characteristic of each cell type. This is a general theme in eukaryotic gene expression. There are only 20,000–25,000 protein-coding genes in the human genome; however, approximately two-thirds of these give rise to differentially spliced transcripts. Differentially spliced transcripts are translated into protein products that have different locations, molecular interactions, or enzymatic properties. Thus the existence of introns supplies the organism with a powerful method of generating protein diversity. The choice of a specific splicing pattern is often regulated by protein factors that bind to sequences within an exon. These proteins can either enhance or repress splicing at adjacent intron–exon junctions.

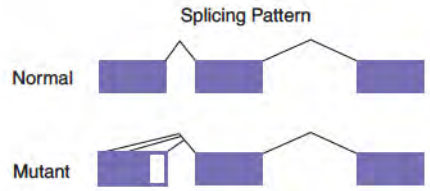

Figure 5.16 Nucleotide change at an intron–exon junction of a human β-globin gene, which leads to aberrant splicing and β-thalassemia. This figure shows the splicing pattern of a mutated transcript containing a change of G-U to A-U at the first two nucleotides of the first intron. Loss of this invariant sequence means that the correct splice junction cannot be used; therefore transcript sequences that base-pair with the U1 snRNA less well than the correct sequence junction are used as splice donors. The diagonal lines indicate the portions spliced together in mutant transcripts. Note that some of the mutant mRNA precursor molecules are spliced so that portions of the first intron (denoted as white boxes) appear in the processed product. In other instances the donor junction lies within the first exon and portions of the first exon are deleted. In no case is wild-type globin mRNA produced. Adapted from Orkin, S. H. In Stamatoyannopoulis, G., et al. (Eds.), *The Molecular Basis of Blood Diseases.* Philadelphia: Saunders, 1987.

5.5 • RNA EXPORT AND QUALITY CONTROL

Messenger, transfer, and ribosomal RNAs function in the cytoplasm. Movement out of the nucleus is through the nuclear pore. The nuclear pore assembly is a cylinder that spans the membrane. Within the cylinder lie two stacked rings and a central "plug." Small ions can move through the pore between the plug and the rings, but RNAs are too big to pass through that space. RNA export occurs through a channel in the plug; this is a process that requires

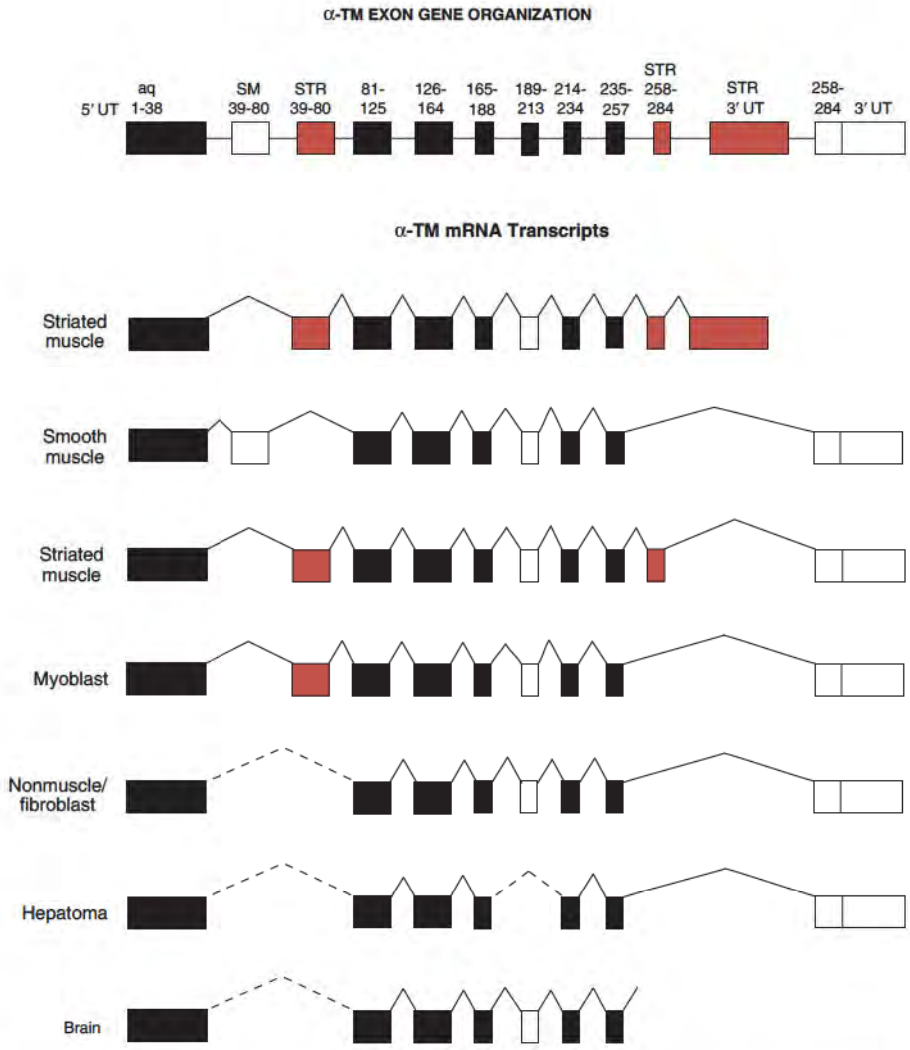

Figure 5.17 Alternate splicing of tropomyosin gene transcripts results in a family of tissue-specific tropomyosin proteins. Redrawn from Breitbart, R. E., Andreadis, A., and Nadal-Ginard, B. *Annu. Rev. Biochem.* 56:467, 1986.

that the RNAs be bound to proteins to form ribonucleoprotein particles. The movement of ribosomal RNAs occurs after they are assembled into ribosomes in the nucleolus. Transfer RNAs may be bound to aminoacyl-tRNA synthetases, since they can be aminoacylated in the nucleus prior to export. Messenger RNAs are exported in complexes that contain a cap-binding protein at the 5′-end and RNA-binding proteins along the rest of the sequence. The process requires metabolic energy in the form of GTP, specific signal sequences in the protein, and a G-protein GTPase.

RNA splicing and export ensure quality control of mRNA integrity. The chain termination codon (one of the three nonsense codons, UAA, UAG, or UGA) of an mRNA is usually located in the last exon. If mRNA were to contain an upstream nonsense codon, the protein coded would be shorter than the normal protein (Clin. Corr. 5.6). This shorter protein would likely be nonfunctional and could interfere with cellular function. The nonsense-mediated decay pathway prevents the export and translation of mRNAs whose **chain termination codon** is upstream of the last exon. A few spliceosomal proteins remain on the spliced mRNA at the junction of two exons. A nonsense codon in an upstream exon is followed by these junction proteins; these mRNAs are targeted for nonsense-mediated decay. Recognition of the upstream nonsense codon must involve translation. Apparently, the first translating ribosome removes the exon junction proteins. If the ribosome stops at a chain termination codon before all the exon junction proteins are removed, a specific set of nucleases degrades the mRNA, preventing its translation. Similarly, mRNA that lacks a normal chain-terminating nonsense codon is targeted for degradation because the mRNA most likely has been synthesized inaccurately or has been cleaved by mistake. Translation of this mRNA would likewise result in synthesis of a shortened protein.

CLINICAL CORRELATION 5.6

Nucleic Acid Editing Enzymes: An Antiviral Defense as well as a Way of Altering Gene Expression

Apolipoprotein B, a key player in cholesterol metabolism, exists in two forms: one of M_r = 48,000 which is produced in the intestine and a second one with M_r = 100,000 which is made in the liver. The two RNAs are transcribed from a single gene, and the intestine-specific isoform results from an editing event. An intestinal cytidine deaminase enzyme, termed Apolipoprotein B mRNA editing enzyme, catalytic polypeptide 1 (APOBEC1) converts a specific C in ApoB mRNA to U, transforming a CAA (Gln) codon to a UAA (stop) codon. APOBEC enzymes form a family and different isoforms are expressed in different cell types.

Why such an unusual mechanism, when a similar result could be obtained by differential splicing of a single transcript or a duplicated gene? An answer may lie in the properties of the APOBEC family of enzymes. Primary T cells and macrophages are relatively resistant to HIV infection. Recall that HIV has an RNA genome, which must be reverse transcribed into cDNA (p. 257). One host-encoded isoform of the APOBEC family, APOBEC3G, is carried along in the viral particle as it buds off from an infected cell. APOBEC3G converts multiple C residues in the initial cDNA product to deoxy-U. The dUs then specify dAs during synthesis of the second-strand cDNA, which has the same sense as the viral RNA. The hypermutated viruses are defective in later phases of the life cycle.

APOBEC3G does not confer absolute resistance, however. In another example of how disease organisms evolve to evade host defenses, HIV encodes a protein termed Vif, which specifically targets APOBEC3G for degradation by the proteasome. Vif is related to ubiquitin–E3 ligase enzymes, although the exact mechanism by which it targets APOBEC3G is not yet clear.

Immunol.* 4:868, 2004; and Wahl, S. M., Greenwill-Wild, T., and Vazquez, N. HIV accomplices and adversaries in macrophage infection. *J. Leukocyte Biol.* 80:973, 2006.

5.6 • RNA INTERFERENCE

Double-stranded regions in cellular mRNA are usually fairly short, less than 10 base pairs. Longer double-stranded sequences can result from replication of RNA viruses, from transcription of repetitive sequences, or from longer regions of some natural mRNAs. These double-stranded RNAs are processed into single-stranded, **inhibitory RNAs** (**RNAi**) which then act to silence expression from their target mRNAs.

The processing pathway for these RNAs is shown in Figure 5.18. A double-stranded RNA-specific RNase (a member of the RNase III family) first processes the double-stranded RNA to a smaller double-stranded species that is exported from the nucleus. Once it is in the cytoplasm, the double-stranded RNA is further processed by another RNase III termed Dicer to form a small double-stranded RNA about 21 base pairs long. Then the double-stranded RNA is unwound by a protein complex called RNA-induced silencing complex (RISC) or micro-RNA–protein (miRNP). In either case, one strand of the RNA duplex is selected, almost always the one that is complementary to the mRNA target. Then the protein-bound small RNA base pairs bind to the mRNA, causing one of two events. If there is perfect complementarity (the RNA is termed **small inhibitory RNA [siRNA]**), the enzymes of the RISC complex cleave the mRNA strand. If there is imperfect complementarity (the RNA is termed **micro-RNA** [**miRNA**]), the mi-RNP represses mRNA translation by base pairing of the miRNA with the mRNA. RNA interference is efficient because one RISC–siRNA complex can cleave many mRNA molecules, and translational repression may lead to mRNA degradation. Recent research suggests that miRNAs may regulate the expression of as many as one-third of all mammalian genes, and the involvement of noncoding RNAs in heterochromatin formation implies that they may regulate transcription as well as translation. Clin. Corr. 5.7 discusses the involvement of microRNAs in oncogenesis.

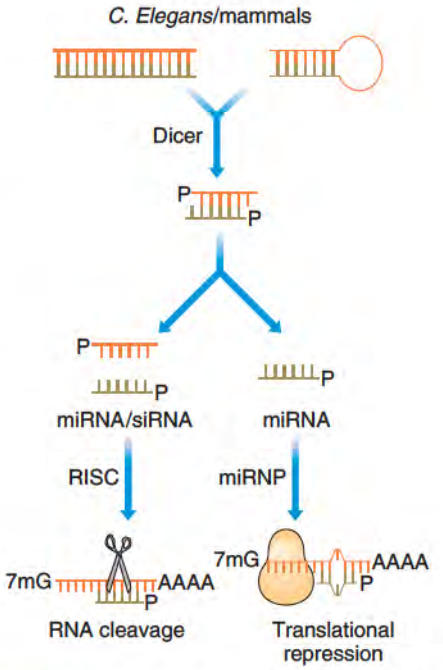

Figure 5.18 Effects of small inhibitory RNAs on eukaryotic mRNA metabolism. Double-stranded RNA, for example, from replication of RNA viruses (top left), or from hairpins in long RNA transcripts (top right) is processed by the Dicer enzyme into short double-stranded RNAs. One strand is complementary to mRNA and base-pairs with it, aided either by RISC (left pathway) or the miRNP complex (right pathway). RISC cleaves mRNA at the double-stranded region, whereas miRNP base pairing stops translation of the mRNA.

5.7 • TRANSCRIPTION-COUPLED DNA REPAIR

A chemical lesion in DNA affects gene expression only if the altered sequence is transcribed. Sequences that aren't expressed will not lead to an observed mutation. It makes sense, therefore, that the repair of DNA would be targeted to sequences that are actively being transcribed. This coupling of transcription and repair occurs because DNA lesions (such as

CLINICAL CORRELATION 5.7

Involvement of MicroRNAs in Oncogenesis

MicroRNAs (miRNAs) reduce expression of their target genes by binding mRNAs and thus either inhibiting their translation or triggering their destruction (Figure 5.18). Approximately 30% of all human mRNAs are potentially regulated by miRNAs. Since cancer is caused by deranged gene expression, it seems logical that the miRNA pathway would be involved in oncogenesis. This hypothesis has been supported by a number of observations. (1). Genes of miRNA families are often deleted in human cancer cell lines. (2) Conversely, some B-cell lymphomas are characterized by amplified DNA sequences that specify miRNAs. (3) The let-7 miRNA interacts with several oncogenes. Reduction of let-7 miRNA is correlated with poor prognosis of nonsmall cell lung cancer (NSCLC). Conversely, in a mouse model of NSCLC, functional let-7 transgenes reduce the oncogenic phenotype. (4) Several miRNAs inactivate the p53 pathway, which triggers apoptosis in response to genetic damage.

These and similar data have led to a working model of the roles of miRNAs in the development of cancers (see figure). Although the model is incomplete, it points to the possibility of therapies that would target this new regulatory mechanism.

cyclobutane dimers; p. 165) that occur on the template strand cause RNA polymerase II to stall. Stalled RNA polymerase provides a signal to the excision-repair systems to remove the altered sequences and resynthesize the correct one. Obviously, this cannot occur with the bulky RNA polymerase bound to the DNA, so the stalled transcript is sacrificed. A deficiency in transcription-coupled repair is a hallmark of Cockayne syndrome (Clin. Corr. 5.8).

5.8 • NUCLEASES AND RNA TURNOVER

The different roles of RNA and DNA in genetic expression are reflected in their metabolic fates. A cell's information store (DNA) must be preserved, thus the multiple DNA repair and editing systems in the nucleus. Although individual stretches of nucleotides in DNA may turn over, the molecule as a whole is metabolically inert when not replicating. RNA molecules, on the other hand, are individually dispensable and can be replaced by newly synthesized species of the same specificity. It is no surprise that RNA repair systems are not known. Instead, defective RNAs are removed from cells by degradation into nucleotides, which then are reused for new RNA species.

CLINICAL CORRELATION 5.8

Cockayne Syndrome

Cockayne syndrome (CS) (OMIM 216400) is a complex autosomal recessive disorder most commonly caused by a mutation in one of two genes. CS patients have developmental and neurological disorders, skeletal and retinal abnormalities, and a birdlike facial dysmorphia. Death usually results by the age of 20 years and is caused by neural degeneration. Most Cockayne syndrome patients also are photosensitive and predisposed to skin cancer. This photosensitivity points to a defect in DNA repair. For example, xeroderma pigmentosum (XP) results from mutations in a number of components of the DNA repair pathway. CS also is a DNA repair deficiency.

There are two genes whose mutation causes most cases of Cockayne syndrome; both are known to be involved in the repair of DNA damage. CSB encodes a DNA-dependent ATP helicase related to proteins involved in chromatin remodeling. CSA is an E3 ubiquitin ligase apparently involved in turnover of proteins. The CSA and CSB proteins cooperate with other DNA repair proteins to clear away the stalled RNA polymerase and transcripts and repair the damaged template. After repair, new transcription initiation can occur at the promoter, or other RNA polymerase II molecules that are stalled behind the lesion can proceed with accurate transcription.

Transcription-coupled repair occurs when RNA polymerase is stalled by encountering an altered base (for example, a thymine photodimer). Transcription is halted, the partial transcript is degraded, and the template DNA strand is repaired. Apparently, enhancement of transcription by the CSB protein also stimulates transcription-coupled DNA repair.

If this were all to the story, Cockayne syndrome would be a variant of xeroderma pigmentosum; however, XP patients are developmentally and neurologically normal while still being photosensitive. What causes the other features of CS? It is likely that these other symptoms are due to a primary deficiency in transcription elongation caused by the mutationally altered elongation factor CSB. This idea expands our understanding of the relationship between mutation and disease. Usually, genetic diseases are caused by a mutation in biochemical processes that are outside the central information pathways of cells. This makes sense because overall inhibition of DNA, RNA, or protein synthesis would be lethal at an early stage of development. The widespread defects of CS must be due to the mutation affecting the transcription of some genes more than of others.

Citterio, E., Vermeulen, W., and Hoeijmakers, J. H. J. Transcriptional healing. *Cell* 101:447, 2000; D'Errico, M., et al. The role of CSA in the response to oxidative DNA damage in human cells. *Oncogene* 26:4336, 2007; and Laine, J. P., and Egly, J. M. When transcription and repair meet: a complex system. *Trends Genet.* 22:430, 2006.

This is clearest for mRNA species, which are relatively unstable. However, even the so-called stable RNAs turn over; for example, the half-life of tRNA species in liver is about 5 days. A fairly long half-life for a mammalian mRNA is 30 h.

RNA degradation occurs both in the nucleus and in the cytoplasm. In the nucleus, degradation accomplishes two overlapping functions. First, it serves as quality control so that RNAs that result from incorrect transcription or processing are prevented from getting out of the nucleus. Secondly, RNAs in ribonucleoprotein particles turn over, especially during the cell cycle. RNAs are decapped by a nuclear enzyme and degraded in the 3′ to 5′ direction by the **exosome**, a multienzyme complex.

Cytoplasmic Messenger RNA Turnover Is Coupled to Translation

Removal of RNAs from the cytoplasm is accomplished by cellular ribonucleases. Messenger RNAs are initially degraded in the cytoplasm. The rates vary for different mRNA species, raising the possibility of control by differential degradation.

Two examples of the role of RNA stability in gene control illustrate how the stability of mRNA influences gene expression. Tubulin is the major component of the microtubules of the cytoskeleton of many cell types. When there is an excess of tubulin in the cell, the monomeric protein binds to and promotes degradation of tubulin mRNA, thereby reducing tubulin synthesis. A second example is provided by Herpes simplex viruses (HSVs), the agent causing cold sores and some genital infections. An early event in the establishment of HSV infection is the ability of the virus to destabilize all cellular mRNA molecules, thereby reducing the competition for free ribosomes. As a result, viral proteins are more efficiently translated.

Nucleases are of several types and specificities. The most useful distinction is between exonucleases, which degrade RNA from the 5′- or 3′-end, and endonucleases, which cleave phosphodiester bonds within a molecule. Products of RNase action contain either 3′- or 5′-terminal phosphates, and both endo- and exonucleases can be further characterized by the position (5′ or 3′) at which the monophosphate created by the cleavage is located.

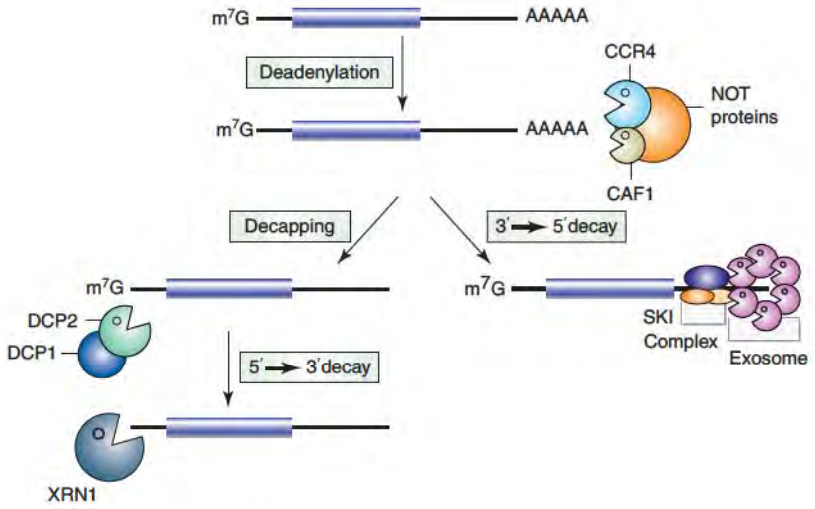

Figure 5.19 Two pathways for mRNA decay. Both pathways begin with the shortening of the poly(A) tail of the mRNA. The deadenylated mRNA is then degraded by either decapping followed by 5′–3′ decay (left) or the 3′–5′ pathway by the exosome and the SKI complex (right). Adapted from Eulalio, A., Behm-Ansmant, I., and Izaurralde, E. *Nature Rev. Mol. Cell Biol.* 8:9, 2007.

Another 3′–5′ exonuclease activity involved in RNA degradation is polynucleotide phosphorylase. Its mechanism for RNA degradation uses inorganic phosphate to displace the phosphodiester bond at the 3′-end of RNA, yielding a shorter RNA and a nucleotide diphosphate.

The structure of RNA can affect nuclease action. Most ribonucleases are less efficient on regions of highly ordered RNA structure. Thus, tRNAs are preferentially cleaved in unpaired regions of the sequence, and the exosome prefers unstructured or misfolded RNA substrates. On the other hand, many RNases involved in RNA processing require the substrate to have a defined three-dimensional structure for recognition.

Cytoplasmic mRNAs can be degraded by several overlapping pathways (Figure 5.19). The mRNA degradation machinery is commonly found in P-bodies, which are subcellular granules that contain a host of mRNA-metabolizing enzymes, including those for degradation. Most commonly, the 3′ poly(A) tail of mRNA is shortened primarily by exonuclease digestion. This deadenylation is inhibited by poly(A)-binding protein(s). Then the cap is removed by a specialized **decapping enzyme,** which is also inhibited by poly(A)-binding protein. Decapped RNA is the substrate for a 5′–3′ exonuclease that degrades the RNA to nucleotides. An alternative pathway involves deadenylation and 3′–5′ exonucleolytic degradation by cytoplasmic exosomes of mRNAs that still retain their cap (Figure 5.19).

Nonsense-mediated decay eliminates mRNAs that are incapable of making a complete protein. Nothing is perfect. Whereas transcription and processing use cellular energy to keep the frequency of mistakes low, they still occur. Since each mRNA is translated into multiple proteins, an incorrectly processed mRNA would both waste the energy required for translation and lead to misfolded proteins, which could trigger inflammation or more severe pathologies, as in the formation of amyloid plaques in Alzheimer disease.

A misprocessed or mistranscribed RNA would have a high probability of carrying chain-terminating (nonsense) codons. Premature nonsense codons trigger mRNA destruction, a process termed nonsense-mediated decay (NMD). During the first (pioneer) round of translation, any premature termination codon is recognized by termination factors. This complex recruits other factors which signal mRNA destruction and send the defective mRNA to the P body. The surveillance mechanism is able to distinguish between premature and correct nonsense codons because the former occur upstream of (5′ to) intron–exon junctions of the mRNA.

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. In eukaryotic transcription,
- **A.** RNA polymerase does not require a template.
- **B.** all RNA is synthesized in the nucleolus.
- **C.** consensus sequences are the only known promoter elements.
- **D.** phosphodiester bond formation is favored because there is pyrophosphate hydrolysis.
- **E.** RNA polymerase requires a primer.

2. The sigma (σ) subunit of prokaryotic RNA polymerase
- **A.** is part of the core enzyme.
- **B.** binds the antibiotic rifampicin.
- **C.** is inhibited by α-amanitin.
- **D.** must be present for transcription to occur.
- **E.** specifically recognizes promoter sites.

3. Termination of a prokaryotic transcript
   - **A.** is a random process.
   - **B.** requires the presence of the rho subunit of the holoenzyme.
   - **C.** does not require rho factor if the end of the gene contains a G-C-rich palindrome.
   - **D.** is most efficient if there is an A-T-rich segment at the end of the gene.
   - **E.** requires an ATPase in addition to rho factor.

4. Eukaryotic transcription
   - **A.** is independent of the presence of upstream consensus sequences.
   - **B.** may involve a promoter located within the region transcribed rather than upstream.
   - **C.** requires a separate promoter region for each of the three ribosomal RNAs transcribed.
   - **D.** requires that the entire gene be in the nucleosome form of chromatin.
   - **E.** is affected by enhancer sequences only if they are adjacent to the promoter.

5. Processing of transfer RNA (tRNA)
   - **A.** involves cleaving out several different tRNAs from one primary transcript.
   - **B.** involves only exonucleases.
   - **C.** cleaves excess bases from the 3′-end after the sequence CCA.
   - **D.** cleaves excess bases from either end of the primary transcript but not in the interior of the molecule.
   - **E.** necessitates modification of some of the bases by methylation.

6. In the cellular turnover of RNA,
   - **A.** repair is more active than degradation.
   - **B.** regions of extensive base pairing are more susceptible to cleavage.
   - **C.** a small double-stranded region of mRNA could lead to cleavage of the mRNA if one strand has perfect complementarity with a region of the mRNA.
   - **D.** the products are always nucleotides with a phosphate at the 5′-OH group.
   - **E.** all species except rRNA are cleaved.

Questions 7 and 8: Fragile X syndrome is a common form of inherited mental retardation. The mutation in the disease allows the increase of a CGG repeat in a particular gene from a normal of about 30 repeats to 200–1000 repeats. This repeat is normally found in the 5′ untranslated region of a gene for the protein FMR1. FMR1 might be involved in the translation of brain-specific mRNAs during brain development. The consequence of the very large number of CGG repeats in the DNA is extensive methylation of the entire promoter region of the FMR1 gene.

7. Methylation of bases in DNA usually
   - **A.** facilitates the binding of transcription factors to the DNA.
   - **B.** makes a difference in activity only if it occurs in an enhancer region.
   - **C.** prevents chromatin from unwinding.
   - **D.** inactivates DNA for transcription.
   - **E.** results in increased production of the product of whatever gene is methylated.

8. Transcription of eukaryotic genes requires the presence of a promoter and usually the presence of enhancers. An enhancer
   - **A.** is a consensus sequence in DNA located where RNA polymerase first binds.
   - **B.** may be located in various places in different genes.
   - **C.** may be on either strand of DNA in the region of the gene.
   - **D.** functions by binding RNA polymerase.
   - **E.** stimulates transcription in both prokaryotes and eukaryotes.

Questions 9 and 10: The synthesis of normal adult hemoglobin (HbA) requires the coordinated synthesis α-globin and β-globin. β-Thalassemia is a genetic disease leading to a deficiency of β-globin chains and an inability of the blood to deliver oxygen properly. β-Thalassemia can result from a wide variety of mutations.

9. All of the following could lead to lack of or nonfunctional β-globin except
   - **A.** a frameshift mutation leading to premature termination of protein synthesis.
   - **B.** mutation in the promoter region of the β-globin gene.
   - **C.** mutations toward the 3′-end of the β-globin gene that codes for the polyadenylation site.
   - **D.** mutations in the middle of an intron that is not at an A base.
   - **E.** all of the above could lead to this result.

10. One mutation leading to β-thalassemia occurs at a splice junction. Which of the following statements about removing introns is correct?
   - **A.** Small nuclear ribonucleoproteins (snRNP) are necessary for removing introns.
   - **B.** The consensus sequences at the 5′- and 3′-ends of introns are identical.
   - **C.** Removal of an intron does not require metabolic energy.
   - **D.** The exon at one end of an intron must always be joined to the exon at its other end.
   - **E.** The nucleoside at the end of the intron first released forms a bond with a 3′-OH group on one of the nucleotides within the intron.

Questions 11 and 12. Protooncogenes produce products that have specific roles in regulating growth and differentiation of normal cells. Mutations can turn these genes into oncogenes whose products are less responsive to normal control. Unmutated protein p53, a tumor suppressor, is a transcription factor, inhibiting some genes and activating others. P53 inhibits genes with TATA sequences and activates genes for DNA repair.

11. The TATA sequence
   - **A.** occurs about 25 bp downstream from the start of transcription.
   - **B.** binds directly to RNA polymerase.
   - **C.** binds transcription factors which bind RNA polymerase.
   - **D.** binds p53.
   - **E.** is an enhancer sequence.

12. Transcription-coupled DNA repair
   - **A.** occurs because a DNA lesion causes the RNA polymerase to stall during transcription.
   - **B.** occurs when a DNA lesion forms in a region of DNA which is highly compacted.
   - **C.** leads to a normal transcript because transcription continues after the repair is made.
   - **D.** occurs because both the template and coding strands of the DNA have lesions.
   - **E.** all of the above.

Problems

13. How does nonsense-mediated decay help prevent the export and translation of mRNA that would lead to a shorter, nonfunctional protein?

14. a. How could you experimentally determine whether a purified preparation of an RNA polymerase is from a prokaryotic or eukaryotic source?
b. A purified preparation of RNA polymerase is sensitive to inhibition by α-amanitin at a concentration of 10^{-8} M. The synthesis of what type or types of RNA is inhibited?

Answers

1. D This is an important mechanism for driving reactions. A and B: Transcription is directed by DNA, generating rRNA precursors in the nucleolus and mRNA and tRNA precursors in nucleoplasm. C: Eukaryotic transcription may have internal promoter regions as well as enhancers. E: This is a difference from DNA polymerase.

2. E A, D, and E: The sigma factor is required for correct initiation and dissociates from the core enzyme after the first bonds have been formed. The core enzyme can transcribe but cannot correctly initiate transcription. B and C: Rifampicin binds to the β-subunit, and α-amanitin is an inhibitor of eukaryotic polymerases.

3. C Rho-independent termination involves secondary structure, which is stabilized by high G-C content. A, B, and E: There is a rho-dependent as well as a rho-independent process. Rho is a separate protein from RNA polymerase and appears to possess ATPase activity. D: A G-C-rich region is required.

4. B RNA polymerase III uses an internal promoter. A: RNA polymerase II activity involves the TATA and CAAT boxes. C: RNA polymerase I produces one transcript, which is later processed to yield three rRNAs. D: Parts of the promoter are not in a nucleosome. E: Enhancers may be as much as 1000 or more bp away.

5. E Transfer RNAs are the most highly modified nucleic acids. A: This occurs with the precursor of rRNAs. B: Both endo- and exonucleases are required. C: CCA are added sequentially by nucleotidyltransferase and are not part of the primary transcript. D: There may be introns, for example, in the anticodon region, of the primary transcript.

6. C This strand is called siRNA. If the complementarity is imperfect (miRNA), translation is repressed. A: There are no RNA repair processes. B: Most degradative enzymes are less efficient on an ordered structure. D: It could be either 3′- or 5′ depending on which side the phosphodiester bond is cleaved. E: All RNAs turn over.

7. D Methylation-demethylation of DNA is one form of control, with the methylated DNA being inactive for transcription. A and E: These would indicate that methylation activates DNA. B: Altering the enhancer region could make a difference but alteration of the promoter region certainly would. C: Unfolding of chromatin in this region is necessary for transcription but methylation of DNA is not directly involved in the process.

8. B B and C: Enhancer sequences seem to work whether they are at the beginning or end of the gene, but they must be on the same DNA strand as the transcribed gene. A: RNA polymerase first binds at the promoter. D: They seem to function by binding proteins which themselves bind RNA polymerase.

9. D Mutation at either terminus of the intron would lead to a splicing error, but a mutation in the middle of the intron should not. The exception would be if the specific mutation site were at the adenosine that forms the branch point. A, B, and C: These are all correct.

10. A snRNPs are responsible both for cleaving the intron at the 5′-end and joining the exons together. B: The sequences at the two ends of an intron are different: GU at the 5′-end and AG at the 3′end. C: The spliceosome requires ATP to remove the intron. D: Nonconsecutive exons can be joined together, leading to multiple proteins from one gene. E: The lariat forms at a 2′-OH.

11. C B and C: RNA polymerase does not bind directly to TATA but to transcription factors that bind TATA. A and E: TATA is part of the promoter and so upstream from the transcription start. D: p53 probably binds to the complex formed between transcription factors and TATA, interfering with transcription.

12. A This signals the excision repair system to repair the lesion. B: Repair is targeted to actively transcribed genes where chromatin is more loosely organized. C: For repair to occur, RNA polymerase must dissociate and the transcript is sacrificed. D: A typical lesion is thymine dimers in the template strand. The coding strand is normal and acts as the template for repair.

13. A chain termination codon upstream of the last exon is abnormal. When translation stops at such a codon, some exon junction proteins still remain. This triggers a specific set of nucleases to degrade the mRNA, preventing its translation.

14. a. Test the preparation for inhibition by α-amanitin at a high concentration where eukaryotic RNA polymerases, except for I, are inhibited but prokaryotic enzyme is not. If the preparation is not inhibited by the amanitin, confirm that it is inhibited by rifampicin. It will not be possible to distinguish eukaryotic mitochondrial RNA polymerase from prokaryotic enzyme because they have the same sensitivity.
b. RNA polymerase II is sensitive to α-amanitin at a very low concentration so mRNA synthesis would be inhibited.

Key Concepts

- Protein biosynthesis involves translation of the polynucleotide language of genes into the language of proteins.
- Three nucleotide sequences (codons) in mRNA specify a single amino acid, the starting point of translation, and the termination of the peptide chain. There are 64 possible codons and most amino acids are specified by more than one codon. The genetic code is termed degenerate and is almost universal.
- Translation is centered on RNA: mRNA transmits the genetic information, tRNA carries amino acids, and ribosomal RNA helps shape the ribosome and catalyzes peptide bond formation. Many proteins, enzymes, and factors are involved in protein synthesis.

- Synthesis is from the amino to the carboxyl terminus. At each step, (1) the appropriate amino acid is activated by attachment to a tRNA, (2) the aa-tRNA is positioned at the acceptor site of the ribosome, (3) the nascent peptide chain is coupled to the new amino acid by peptidyl transferase, and (4) the elongated peptidyl-tRNA is moved to the donor site of the ribosome.
- Translation is highly regulated, at both individual protein and global levels. Posttranslational and cotranslational modification of proteins is common and can affect protein shape, function, localization in the cell, export from the cell, and lifetime.
- Folding of a protein into its final conformation is spontaneous or assisted by protein chaperones.
- Mechanisms exist for degradation of proteins no longer needed, misfolded, damaged, or incomplete. The proteasome is an important but not exclusive degradation center.

6.1 • INTRODUCTION

Protein biosynthesis is called **translation** because it involves the biochemical translation of genetic information, stored and transmitted in the 4-letter alphabet and structural language of DNA, into the 20-letter alphabet and structural language of proteins. Translation is centered on multiple functions of RNA: messenger RNA transmits the genetic information, transfer RNA carries amino acids and decodes the message, ribosomal RNA catalyzes peptide bond formation and makes up the core of the assembly bench, and very small RNAs are important regulators of the process.

Cells vary in their need and ability to synthesize proteins. Terminally differentiated red blood cells lack the apparatus for translation and have a life span of only 120 days. Other cells synthesize proteins they need to maintain concentrations of enzymes and other proteins. Growing and dividing cells must synthesize much larger amounts of protein, and some cells also produce proteins for export. For example, liver cells are protein factories that synthesize enzymes used in multiple metabolic pathways plus proteins for export including serum albumin, the major protein of blood plasma.

6.2 • COMPONENTS OF THE TRANSLATIONAL APPARATUS

Messenger RNA Transmits Information Encoded in DNA

Genetic information is inherited and stored as nucleotide sequences of DNA. Selective expression of this information requires its transcription into mRNA that carries a specific and precise message from the nuclear "data bank" to the cytoplasmic site of protein synthesis.

In eukaryotes mRNAs are usually synthesized as larger precursor molecules that are processed prior to their export from the nucleus (p. 196). Eukaryotic mRNA is almost always **monocistronic;** that is, it encodes a single polypeptide. The 5′-end is **capped** with **7-methylguanosine** linked through a 5′-triphosphate bridge to the 5′-end of the mRNA (p. 196). A 5′-nontranslated region precedes the translation **initiation signal.** Usually, but not always, this is the first AUG sequence encountered as the message is read 5′ → 3′. Uninterrupted 3-nucleotide-long **codon** sequences that specify a unique polypeptide sequence follow the **initiation codon** until a translation termination codon is reached. This is followed by a 3′-untranslated sequence (or UTR), usually about 100 nucleotides long, before the mRNA terminates in a 100–200 nucleotide long polyadenylate tail.

Prokaryotic mRNA differs significantly. The 5′-end of the mRNA is not capped but it retains a terminal triphosphate from its synthesis by RNA polymerase. Most mRNAs are **polycistronic;** they encode several polypeptides and include more than one initiation AUG codon. A ribosome-positioning sequence is located about 10 nucleotides upstream of the AUG initiation codon. A UTR follows the termination signal but there is no polyadenylate tail.

Transfer RNA Is a Bilingual Translator Molecule

All **tRNA** molecules have several common structural characteristics including the 3′-terminal –CCA sequence to which an amino acid is bound, a conserved "cloverleaf" secondary structure, and an L-shaped tertiary structure (p. 63). However, each of the many tRNA species

has a unique nucleotide sequence that allows great specificity in interactions with mRNA and with the aminoacyl tRNA synthetase that couples one specific amino acid to it.

The Genetic Code Uses a Four-Letter Alphabet of Nucleotides

Genetic information exists as linear sequences of nucleotides in DNA, analogous to the linear sequence of letters in these words. The DNA language uses a **four-letter alphabet** composed of two purines, A and G (adenine and guanine), and two pyrimidines, C and T (cytosine and thymine). Information in DNA is selectively transcribed into mRNA in a similar four-letter alphabet, but U (uracil) replaces T. The language of RNA is thus a dialect of the genetic language of DNA. Genetic information is **expressed** mostly in the form of proteins that derive their properties from their sequence of amino acids. In protein biosynthesis the 4-letter language of nucleic acids is **translated** into the 20-letter language of proteins. Implicit in the language analogy is the directionality of these sequences. By convention, nucleic acid sequences are written in a 5′ → 3′ direction and protein sequences from the amino terminus to the carboxy terminus. These directions correspond in their reading and biosynthetic senses.

Codons in mRNA Are Three-Letter Words

A 1:1 correspondence of bases to amino acids would permit mRNA to encode only four different amino acids, while a 2:1 correspondence would encode $4^2 = 16$ amino acids. Neither is sufficient since 20 different amino acids occur in most proteins. The three-letter genetic code has $4^3 = 64$ permutations or words; this is also sufficient to encode start and stop signals, equivalent to punctuation. The triplets are called **codons** and are customarily shown in the form of Table 6.1. Two amino acids are designated by single codons: methionine by AUG and tryptophan by UGG. The rest are designated by two, three, four, or six codons. Multiple codons for a single amino acid represent **degeneracy** in the code. The genetic code is nearly **universal,** since the same code words are used in all organisms. An exception to universality occurs in mitochondria, in which a few codons have a different meaning than in the cytosol of the same organism (Table 6.2).

Punctuation

Four codons act partially or fully as punctuation. The **start signal, AUG,** also specifies methionine. An AUG at an appropriate site in mRNA signifies methionine as the initial, amino-terminal residue. AUG codons later in the mRNA specify methionine residues

TABLE 6.1 • The Genetic Code[a]

5′ Base	U	C	A	G	3′ Base
U	UUU Phe	UCU Ser	UAU Tyr	UGU Cys	U
	UUC Phe	UCC Ser	UAC Tyr	UGC Cys	C

	GUG Val	GCG Ala	GAG Glu	GGG Gly	G

[a] The genetic code comprises 64 codons, which are permutations of four bases taken in threes. Note the importance of sequence: three bases, each used once per triplet codon, give six permutations: ACG, AGC, GAC, GCA, CAG, and CGA, for threonine, serine, aspartate, alanine, glutamine, and arginine, respectively.

TABLE 6.2 • Nonuniversal Codon Usage in Mammalian Mitochondria

Codon	*Usual Code*	*Mitochondrial Code*
UGA	Termination	Tryptophan
AUA	Isoleucine	Methionine
AGA	Arginine	Termination
AGG	Arginine	Termination

A CLOSER LOOK 6.1

Aminoacyl–tRNA Synthetases

Eukaryotes and some bacteria have the expected 20 aminoacyl-tRNA synthetases, but many prokaryotes and archae lack synthetases for glutaminyl-, asparaginyl-, and sometimes cysteinyl-tRNA formation. Instead, these tRNAs are formed indirectly. The tRNAs are first aminoacylated with glutamate, aspartate, or *O*-phosphoserine by aminoacyl-tRNA synthetases with relaxed specificity for recognition of their cognate tRNA species. The bound amino acids are then converted by aminoacyl-tRNA-dependent modifying enzymes that recognize only the appropriate aminoacyl-tRNA.

Selenocysteine is formed from seryl-tRNA^{Sec} in a two-step process; the serine is phosphorylated by a kinase and then converted to selenocysteine by a synthase that uses selenophosphate. Many proteins that include selenocysteine have an antioxidant role in eliminating reactive oxygen species, and elimination of the seryl-tRNA^{Sec} gene is lethal.

Sheppard, K., Yuan, J., Hohn, M. J., Jester, B., et al. From one amino acid to another: tRNA-dependent amino acid biosynthesis. *Nucl. Acids Res.* 36:1813, 2008.

within the protein. Three codons, UAG, UAA, and UGA, are **stop signals** that specify no amino acid and are **termination codons** or, less appropriately, **nonsense codons.**

The UGA codon has an additional function, coding for **selenocysteine** (sec) in at least 25 human proteins. **Selenocysteinyl-tRNA** is synthesized from a specific seryl-tRNA$^{(sec)\ ser}$ (A Closer Look 6.1) and selenocysteine is incorporated only if the UGA codon occurs in a sec-insertion sequence, a defined stem-loop structure in mRNA. A specific elongation factor (eEFSec) and a selenocysteine insertion binding protein (SBP2) are also required.

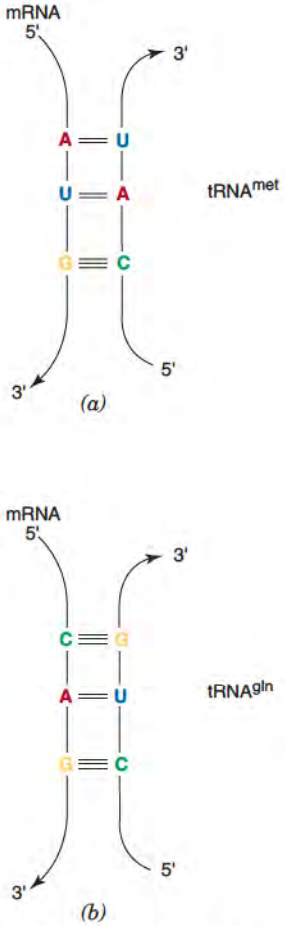

Figure 6.1 Codon–anticodon interactions. Interactions between (*a*) the AUG (methionine) codon and its CAU anticodon and (*b*) the CAG (glutamine) codon and a CUG anticodon show that base pairing of mRNA with tRNA is antiparallel.

Codon–Anticodon Interactions Permit Reading of mRNA

Translation of the codons of mRNA involves their interaction with complementary anticodon sequences in tRNA. Each tRNA species carries a unique amino acid, and each has a specific anticodon triplet. Like base pairing in DNA, codon-anticodon base pairing is **antiparallel,** as shown in Figure 6.1. Codons are read in a **sequential, non-overlapping reading frame.** Anticodon and amino acid-acceptor sites are at opposite ends of the L-shaped tRNA molecule (p. 63). The tRNA, conceptually and physically, bridges the gap between the nucleotide sequence of the ribosome-bound mRNA and the site of protein assembly on the ribosome.

Since 61 codons designate 20 amino acids, it might seem necessary to have exactly 61 different tRNA species. This is not the case. Many amino acids are carried by more than one tRNA species, but variation from standard base pairing is also common in codon–anticodon interactions. Many degenerate codons can be read by more than one tRNA (but always one carrying the correct amino acid). A frequent anticodon nucleotide is inosinic acid (I), the nucleotide of hypoxanthine, which base-pairs with U, C, or A. Modified nucleotides at or beside the first nucleotide of the anticodon in many tRNA species also modulate codon–anticodon interactions. The **wobble hypothesis** permits less stringent base pairing between the first position of the anticodon and the **degenerate** (third) position of the codon. Wobble base pairing rules are shown in Table 6.3. If the wobble rules are followed, the 61 nonpunctuation codons could be read by 31 tRNA molecules, but most cells have 50 or more tRNA species. Some codons are read more efficiently by one anticodon than another. Not all codons or codon pairs are used equally; some are used very rarely. Examination of many mRNA sequences shows that different organisms preferentially use different codons to generate similar polypeptide sequences.

"Breaking" the Genetic Code

The genetic code (see Table 6.1, p. 611) was determined before DNA or RNA sequencing was possible. Code-breaking experiments used simple synthetic mRNAs to provide insight into how proteins are encoded.

Polynucleotide phosphorylase catalyzes the template-independent reaction.

$$x\text{NDP} \leftrightarrow \text{polynucleotide (pN)}_x + x\text{P}_i$$

where NDP is any nucleoside 5′-diphosphate. With UDP a polymer of U, poly(U), is formed. *In vitro* protein synthesis with poly(U) as mRNA generates polyphenylalanine. Similarly, poly(A) encodes polylysine and poly(C) polyproline. An mRNA with a random sequence of only U and C produces polypeptides that contain not only proline and phenylalanine as predicted, but also serine (from UCU and UCC) and leucine (from CUU and CUC). Degeneracy in the code and the complexity of products made experiments with random sequence mRNAs difficult to interpret, but mRNAs of defined sequence can be transcribed from simple repeating synthetic DNAs. Thus poly(AU), transcribed from a repeating poly(dAT), produces only a repeating copolymer of Ile-Tyr-Ile-Tyr, read from successive triplets AUA UAU AUA UAU, and so on. Poly(CUG) contains possible codons CUG for Leu, UGC for Cys, and GCU for Ala, each repeating itself once the **reading frame** has been set. Initiation is random in these experiments, so three homopolypeptides are produced: polyleucine, polycysteine, and polyalanine. A perfect poly(CUCG) produces a polypeptide with the sequence (-Leu-Ala-Arg-Ser-) whatever the initiation point. These relationships, summarized in Table 6.4, show codons to be triplets read in exact sequence, without overlap or omission.

Other experiments used synthetic trinucleotide codons as minimal messages. No proteins were made, but ribosome binding of only one amino acid (as a tRNA conjugate) was stimulated by a given codon. The meaning of each possible codon was later verified by determination of mRNA sequences.

TABLE 6.3 • Wobble Base-Pairing Rules

3′ Codon Base	*5′ Anticodon Bases Possible*
A	U or I
C	G or I
G	C or U
U	A or G or I

Mutations

Understanding the genetic code and how it is read provides a basis for understanding the nature of mutations. A mutation is simply a heritable change in a gene. **Point mutations** involve a change in a single base pair in the DNA, and thus a single base in the corresponding mRNA. If this change occurs in the third position of a degenerate codon, there may be no change in the amino acid specified (e.g., UCC to UCA still codes for serine). Such **silent mutations** are commonly seen in comparison of genes for similar proteins, for example hemoglobins from different species, so they are usually without effect. (For an exception, see Clin. Corr. 6.1.)

Missense mutations arise from a base change that causes incorporation of a different amino acid in a protein (Clin. Corr. 6.2). Point mutations can also form or destroy a termination codon and thus change the length of a protein. Formation of a termination codon from one that encodes an amino acid is a **nonsense mutation;** it results in premature termination and a truncated protein (Clin. Corr. 6.3). Mutation of a termination codon to one for an amino acid allows the message to be read through until another stop codon is encountered. The result is a larger than normal protein. This phenomenon is the basis of several disorders (Table 6.5 and Corr. Clin. 6.4).

Insertion or deletion of a single nucleotide within the coding region of a gene results in a **frameshift mutation.** The reading frame is altered at that point and subsequent codons are read in the new context until a termination codon is reached. Table 6.6 illustrates this phenomenon. The significance of reading frame selection is underscored by a phenomenon in some very small viruses in which the size of the virus limits the amount of DNA it contains. As compensation, a single segment of DNA encodes different polypeptides that are translated using different reading frames. An example is the tumor-causing simian virus SV40 (Figure 6.2). HIV and some other viruses rely on frameshifting during translation to generate different proteins from a single message (Clin. Corr. 6.5).

CLINICAL CORRELATION 6.1

Silent Mutations May Not Be Silent: (1) Hutchinson–Gilford Progeria Syndrome and (2) Multidrug Resistance 1 Gene

Single nucleotide polymorphisms, in which one nucleotide is changed from that in the normal gene, can be detected by DNA analysis. When a polymorphism in a coding region of the gene does not alter the amino acid encoded by the affected codon, it is considered a silent mutation. Nevertheless, there may be significant consequences.

Hutchinson–Gilford progeria syndrome is a very rare disorder characterized by extreme premature aging; children remain small and suffer hair and hearing loss, osteoporosis, cardiovascular disease, and other maladies of old age. Most die of myocardial infarctions in their early teens. In 90% of cases a change from GGC to GGT in codon 608 of the lamin A gene would be expected to be silent, since glycine is specified in each case. However, a cryptic splice site is activated, resulting in a Lamin A protein with an internal deletion of 50 amino acids and which is not properly processed. Lamin A is a component of the nuclear membrane; the mutant protein disrupts the membrane and somehow results in the disease. Since the affected children do not reach reproductive age, each case represents a new mutation at this precise spot in one allele of the gene.

Combinations of two and three silent mutations in the multidrug resistance 1 (MDR1) gene result in proteins with the normal sequence but a different conformation and altered drug and inhibitor interactions. The change from frequently used codons to rarely used codons slows or pauses translation in the affected region and results in changed cotranslational folding of the protein. Codon use preference extends to the frequency of use of adjacent codons that specify the same sequence. Synthetic genes that used disfavored codon pairs to encode poliovirus capsid protein were translated at decreased rates, even when the individual codons were favored in general.

CLINICAL CORRELATION 6.2

Missense Mutations: Hemoglobinopathies

The most important missense mutation that affects hemoglobin structure occurs in sickle-cell anemia (see Clin. Corrs. 2.4, p. 46, and 9.6, p. 354). A change from A to U in either the GAA or GAG codon for glutamate gives a GUA or GUG codon for valine in the sixth position of the β-chain. Deoxygenated hemoglobin S (HbS) forms linear polymers that cause erythrocytes to adopt a sickle shape when oxygen tension is low. Hydroxyurea treatment stimulates synthesis of γ-chains and thus increases fetal hemoglobin levels; the HbF interferes in HbS polymerization. A second common hemoglobinopathy is hemoglobin C disease, in which a change from G to A in a GAA or GAG codon for glutamate results in an AAA or AAG codon for lysine in the sixth position of the β-globin. Hundreds of other hemoglobin missense mutations are known.

Platt, O.S. Hydroxyurea for the treatment of sickle cell anemia. *N. Engl. J. Med.* 358:1362, 2008.

CLINICAL CORRELATION 6.3

Mutations to Form a Terminator Codon

In Hemoglobin McKees Rocks (OMIM 141900) the UAU or UAC codon, normally designating tyrosine in position 145 of β-globin, is mutated to the terminator codon UAA or UAG. This shortens the β-globin from its normal 146 residues to 144 residues. Binding of 2, 3-bisphosphoglycerate is disrupted and the mutant hemoglobin has an unusually high oxygen affinity and decreased oxygen delivery. In response, erythropoietin is secreted by the kidney and increased red blood cell production produces a polycythemic phenotype.

Another terminator mutation causes a type of β thalassemia. Thalassemias are characterized by an imbalance in the stoichiometry of α- and β-globin synthesis. β-Globin is not synthesized in β^0 thalassemia. As a result, α-globin, unable to associate with β-globin to form hemoglobin, accumulates and precipitates in erythroid cells. This damages cell membranes, causing hemolytic anemia and stimulation of erythropoiesis. One variety of β^0 thalassemia, common in Southeast Asia, results from a termination mutation at codon 17 of β-globin; the normal AAG codon that designates a lysyl residue becomes a UAG stop codon; no useful β-globin sequence is synthesized, and β-globin is absent. β-Globin mRNA levels are also depressed, probably through the process called nonsense-mediated decay.

Seal Rock	GAA	Glutamate	172
Koya Dora	UCA	Serine	172

CLINICAL CORRELATION 6.4

α-Thalassemia (OMIM 604131)

There are two expressed α-globin genes on each chromosome 16. Many instances of α-thalassemia arise from deletion of two, three, or all four α-globin genes; clinical severity increases with the number of genes deleted. In contrast, the disorders summarized in Table 6.5 are forms of α-thalassemia that arise from abnormally long α-globin molecules. These replace normal α-globin and are present only in small amounts because of a decreased rate of synthesis or, more likely, from an increased rate of breakdown of the abnormal α-globin. The normal stop codon, UAA, mutates to any of four sense codons with resultant placement of four different amino acids at position 142. Normal α-globin is 141 residues long, but the four abnormal α-globins are 172 residues long because a triplet of nucleotides in the normally untranslated region of the mRNA becomes a termination codon at position 173. Elongated globin chains can also result from frameshift mutations or insertions.

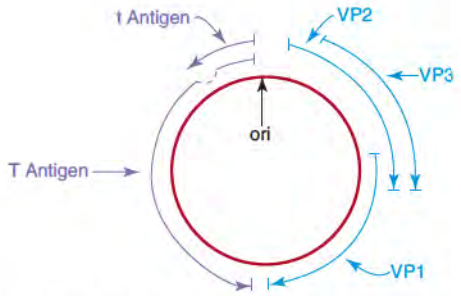

Figure 6.2 Genome of simian virus 40 (SV40). SV40 DNA, shown in red, is a double-stranded circle of slightly more than 5000 base pairs that encodes all information needed for viral survival and replication within a host cell. It shows extremely efficient use of the protein-coding potential of a genome. VP1, VP2, and VP3 are structural proteins of the virus; VP2 and VP3 are translated from different initiation points to the same carboxyl terminus. VP1 is translated in a different reading frame: Its N-terminal section overlaps the VP2/VP3 genes but its amino acid sequence in the overlapping segment is different from that of VP2 and VP3. Two proteins, the large T and small t tumor antigens, promote transformation of infected cells. They are encoded in a common mRNA precursor and have identical N-terminal sequences, but the C-terminal part of small t protein is encoded by a segment of mRNA that is spliced out of the large T message, and the carboxyl-terminal sequence of large T is encoded in RNA that follows termination of small t. The DNA replication origin (ori) is outside of coding regions.

CLINICAL CORRELATION 6.5

Programmed Frameshifting in Biosynthesis of HIV Proteins

Maintaining the reading frame during translation is central to fidelity of translation. Yet many retroviruses, including the AIDS virus HIV, use mRNA slippage and a change in reading frame to generate different proteins from the same messenger. A single mRNA, designated gag-pol, encodes two polyproteins that overlap by about 200 nucleotides and are in different reading frames. The gag polyprotein is translated from the initiation codon to an in-frame termination codon near the gag-pol junction; gag polyprotein is cleaved to generate several structural proteins of the virus. However, about 5% of the time a one-nucleotide frameshift occurs within the overlapping segment of mRNA and the termination codon is bypassed because it is no longer in the reading frame. A gag-pol fusion polyprotein is produced; proteolytic cleavage of the pol polyprotein produces the viral reverse transcriptase and other proteins needed in virus reproduction. (See Clin. Corrs. 4.2, p. 144, and 13.3, p. 523.)

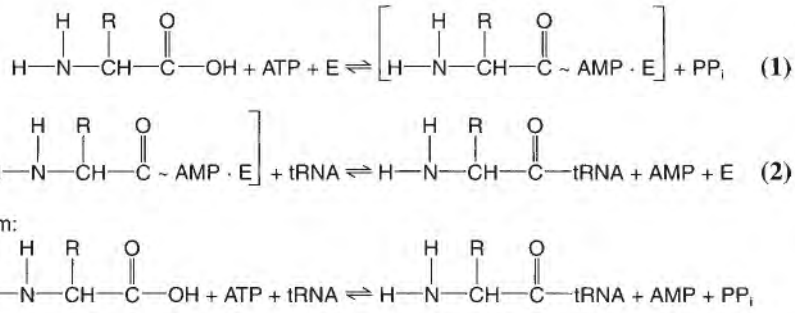
Aminoacylation of Transfer RNA Activates Amino Acids for Protein Synthesis

Amino acids must be *activated* by linkage to their appropriate tRNA carriers before they can be incorporated into proteins. This two-step process is catalyzed by a family of **aminoacyl-tRNA synthetases,** each of which is specific for a single amino acid and its appropriate tRNA species. The reactions are normally written as follows:



Brackets surrounding the aminoacyl-AMP–enzyme complex indicate that it is a transient, enzyme-bound intermediate. The aminoacyladenylate, a mixed acid anhydride with carboxyl and phosphoryl components, is a *high-energy* intermediate. The aminoacyl ester linkage in tRNA is lower in energy than in aminoacyl-adenylate, but still higher than in the carboxyl group of the free amino acid. Pyrophosphatases cleave the pyrophosphate that is produced and the equilibrium is strongly shifted toward formation of aminoacyl-tRNA. From the viewpoint of precision in translation, the amino acid, which had only its side chain (R group) to distinguish it, becomes linked to a large, complex, and easily recognized carrier.

Specificity and Fidelity of Aminoacylation Reactions

Almost all cells contain 20 different aminoacyl-tRNA synthetases, each specific for one amino acid, and at most a small family of carrier tRNAs for that amino acid (see A Closer Look 6.1 for exceptions). Since codon—anticodon interactions define the amino acid to be incorporated, a misacylated tRNA will cause an error in the protein. Correct selection of both tRNA and amino acid by the synthetase is therefore central to fidelity in translation. Aminoacyl-tRNA synthetases share a common mechanism and many occur within the cell in multiprotein complexes. Nevertheless, they are a diverse group of proteins that may contain one, two, or four identical subunits or pairs of dissimilar subunits. Separate structural domains can be involved in aminoacyl-adenylate formation, tRNA recognition, and, if it occurs, subunit interactions. Each enzyme is capable of almost error-free formation of correct aminoacyl-tRNA combinations. Some amino acids are easily recognized by their bulk (e.g., tryptophan) or lack of bulk (glycine) or by positive or negative charges on the side chains (e.g., lysine and glutamate). Others are much more difficult to discriminate. For example, recognition of valine rather than threonine or isoleucine by the valyl-tRNA synthetase is difficult since the side chains differ by either an added hydroxyl or single methylene group.

The amino acid recognition and activation sites of each enzyme have great specificity, but sometimes misrecognition does occur. An additional **proofreading** step increases discrimination by many (but not all) aminoacyl-tRNA synthetases. This most often occurs through hydrolysis of the aminoacyladenylate intermediate, with the release of amino acid and AMP. Valyl-tRNA synthetase efficiently hydrolyses threonyl-adenylate, and it hydrolyses isoleucyl-adenylate in the presence of bound (but not aminoacylated) $tRNA^{val}$. Alternatively, misacylated tRNA is recognized and deacylated. Valyl-, phenylalanyl-, and isoleucyl-tRNA synthetases deacylate tRNAs that have been mischarged with threonine, tyrosine, and valine, respectively. The net result is an average level of misacylation of one in 10^4 to 10^5.

Each synthetase must also correctly recognize one to several tRNA species that can carry the same amino acid, while rejecting incorrect tRNA species. This may be simpler than selection of a single amino acid. However, recall the conformational similarity and common sequence elements of all tRNAs (p. 216). Different synthetases recognize different elements of tRNA structure. Usually multiple structural elements contribute to recognition, but many of these elements are not absolute determinants. One expected element of tRNA recognition is the anticodon. In the case of $tRNA^{met}$, changing the anticodon alters recognition by the synthetase. In other instances, this is only partly true, and sometimes the anticodon is not a recognition determinant. This is shown by **suppressor mutations** that suppress the expression of classes of nonsense mutations. A point mutation in a glutamine (CAG) codon produces a termination (UAG) codon that causes premature termination of the encoded protein. A second suppressor mutation in the anticodon of a $tRNA^{tyr}$, in which the normal GUA anticodon is changed to CUA, allows "read through" of the termination codon. The initial mutation is suppressed and a nearly normal protein is made, with the affected glutamine replaced by tyrosine. Aminoacylation of the mutant $tRNA^{tyr}$ with tyrosine shows that in this case the anticodon does not determine synthetase specificity.

Other tRNA-identification features may include elements of the acceptor stem and parts of the variable loop or the D-stem–loop. In *E. coli* $tRNA^{ala}$, the primary recognition characteristic is a G3-U70 base pair in the acceptor stem; even if no other changes in the $tRNA^{ala}$ occur, any variation at this position destroys its acceptor ability with alanine-$tRNA^{ala}$ synthetase. The X-ray structure of glutaminyl synthetase-tRNA complex shown in Figure 6.3 shows binding at the concave tRNA surface, which is typical and compatible with the biochemical observations.

Ribosomes Are Machines for Protein Biosynthesis

Ribosomes are complex **ribonucleoprotein** particles that provide a workbench and catalytic basis for protein synthesis. They are made up of two dissimilar subunits, each of which contains RNA and many proteins. With one exception, each protein is present in a single

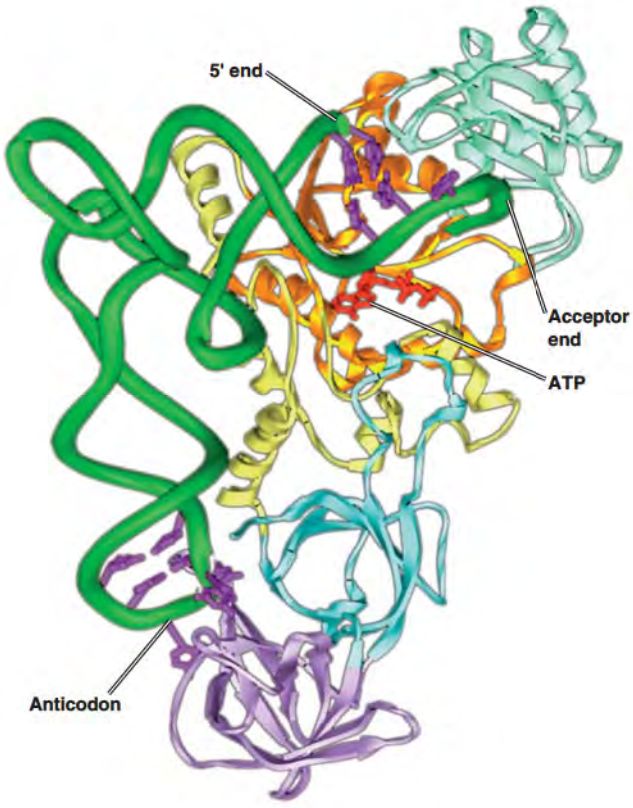


Figure 6.3 Interaction of a tRNA with its aminoacyl-tRNA synthetase. The sugar–phosphate backbone of *E. coli* glutaminyl-tRNA is shown in green and the peptide backbone of the glutaminyl-tRNA synthetase in multiple colors. The synthetase interacts with the partially unwound acceptor stem and the anticodon loop of tRNA. ATP, shown in red, is within a few angstroms of the 3′-end of tRNA. Space-filling models of the complex show both molecules as solid objects with several sites of direct contact. Adapted from Perona, J., Rould, M., and Steitz, T. *Biochem.* 32:8758, 1993.

copy per ribosome, as is each RNA species. The composition of major ribosome types is shown in Table 6.7.

Ribosome architecture and function have been conserved in evolution, and similarities between ribosomes and subunits from different sources are more important than the differences. Structures of ribosomes and their subunits have been determined by X-ray crystallography of particles from microorganisms. Ribosomes and subunits from many sources have also been visualized by electron microscopy; their structure is highly conserved. Prokaryotic ribosomes can self-assemble; native structures can be reconstituted from mixtures of purified individual proteins and RNAs. Reconstitution of subunits from mixtures in which a single component is omitted or modified can show if it is important for assembly of the subunit or for some specific function. Although reconstitution of eukaryotic subunits has not yet succeeded, many studies show prokaryotic and eukaryotic ribosomes not only have similar morphology but also function in the same ways (A Closer Look 6.2).

A CLOSER LOOK 6.2

Ribosome Structure and Function

The complexity of ribosomes requires application of many techniques to decipher their architecture and functional elements, particularly if X-ray structures are not available. Major techniques include

1. Neutron scattering of reconstituted subunits in which two proteins are deuterated: This allows determination of the separation of those two proteins in the subunit.
2. Electron microscopy of complexes of particles with antibodies to a single component protein, RNA element, or functional probe: The Y-shaped antibody serves as a pointer to the location of the component.
3. Chemical cross linking: Determination of cross-linked components allows identification of neighboring proteins, proteins with RNA segments, and RNA elements that may be distant in the sequence but close in the folded structure.
4. Chemical and enzymatic probes: Exposed components can be identified, while internal or hidden components are resistant.
5. Sequence comparison: Sequences can be identified that are conserved in evolution and so are likely to be important in structure and function. This approach was especially important in establishing 2° structures in rRNA.

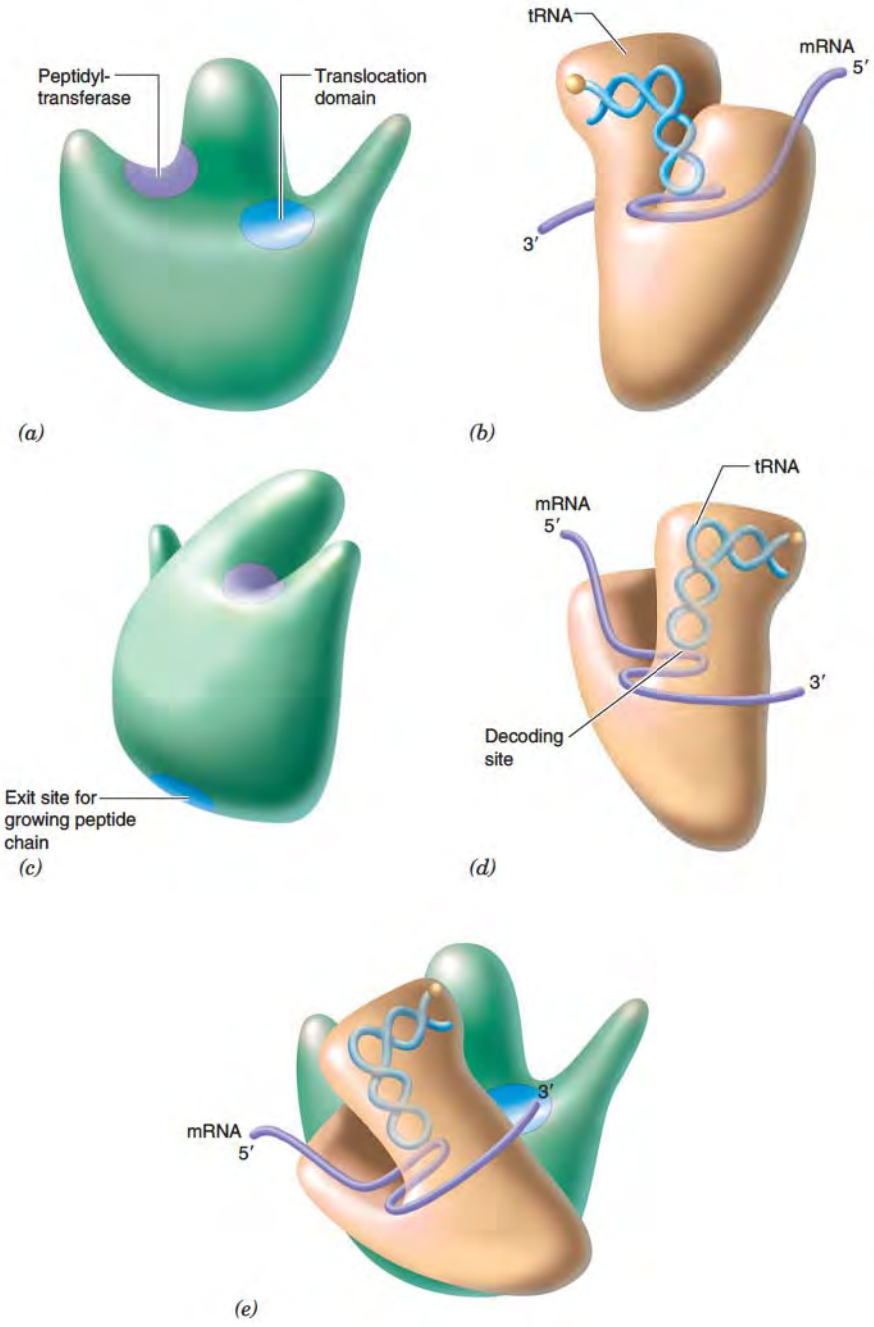

Figure 6.4 Model of ribosome structure and functional sites. Top row: The face of each subunit that interacts in the functional ribosome. In (*a*) the large subunit sites of peptide bond formation (peptidyl transferase) and of elongation factor binding (translocation domain) are seen on opposite sides of the central protuberance. The stalk projects to the right. In (*b*) the small subunit platform protrudes toward the reader. mRNA and tRNAs interact in the decoding site, in a cleft between the platform and the subunit body. In (*c*) the large subunit is rotated 90°, the stalk projects into the page, and the nascent peptide exit site is seen near the subunit base. This site contacts membrane in the bound ribosomes of rough endoplasmic reticulum. The site of peptide bond formation is distant from the exit site; the growing peptide passes through a groove or tunnel in the ribosome to reach the exit site. In (*d*) the small subunit has been rotated 90°; the platform projects into the page. In (*e*) subunits have been brought together to show their orientation in the ribosome. Aminoacyl- tRNA bound by the small subunit is oriented with the acceptor end near peptidyl transferase while the translocation domain is near the decoding site.

Structural and functional studies have led to ribosome models, features of which are described in Figure 6.4, and Figure 6.5 shows X-ray structures of ribosomes and their complexes with mRNA and tRNA. Ribosomes are organized in two more ways. Several ribosomes often translate a single mRNA molecule simultaneously. Electron micrographs of mRNA-linked **polysomes** are shown in Figure 6.6. In eukaryotic cells ribosomes occur free in the cytosol and bound to membranes of the rough **endoplasmic reticulum.** In general, **free ribosomes** synthesize proteins that remain within the cytosol or become targeted to the nucleus, mitochondria, or some other organelle. **Membrane-bound ribosomes** synthesize proteins that will be secreted from the cell or sequestered and function in the plasma membrane, endoplasmic reticulum, Golgi complex, or lysosomes. In cell homogenates, membrane fragments with bound ribosomes constitute the **microsome** fraction; detergents that disrupt membranes release these ribosomes.

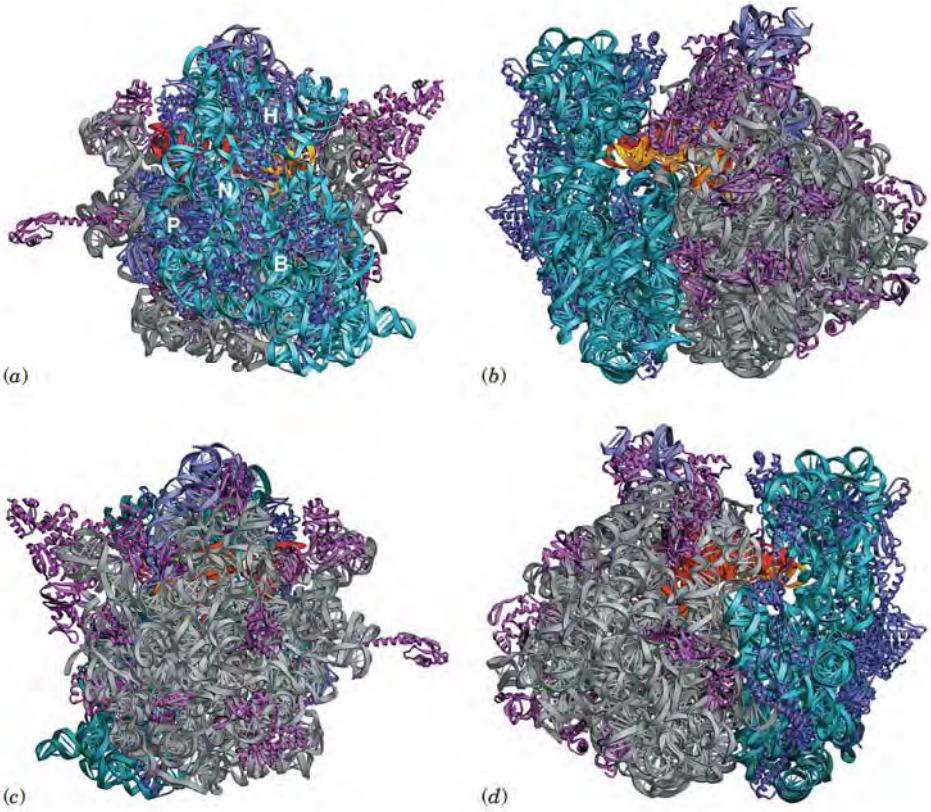

Figure 6.5 Crystallographic structure of a 70S ribosome. The structure of the *Thermus thermophilus* ribosome is shown at 5.5-Å resolution. Successive views are rotated 90° around the vertical axis. (*a*) The small subunit lies atop the large subunit, as in the model of Figure 6.4e. Small subunit features include the platform (P), head (H), body (B), and a connecting neck (N). The 16S RNA is colored cyan, and small subunit proteins are dark blue. (*b*) The large subunit is on the right; 23S RNA is grey, 5S RNA is light blue, and large subunit proteins are magenta. A tRNA molecule (gold) spans the subunits. (*c*) The large subunit lies on top with its stalk protruding to the left. (*d*) The large subunit is on the left and tRNA elements are visible in the subunit interface. Reprinted with permission from Yusupov, M. M., Yusupova, G. Z., Baucom, A., Lieberman, K., Earnest, T. N., Cate, J. H. D., and Noller, H. F. *Science* 292:883, 2001. Reprinted with permission from AAAS. Figure generously supplied by Drs. A. Baucom and H. Noller.

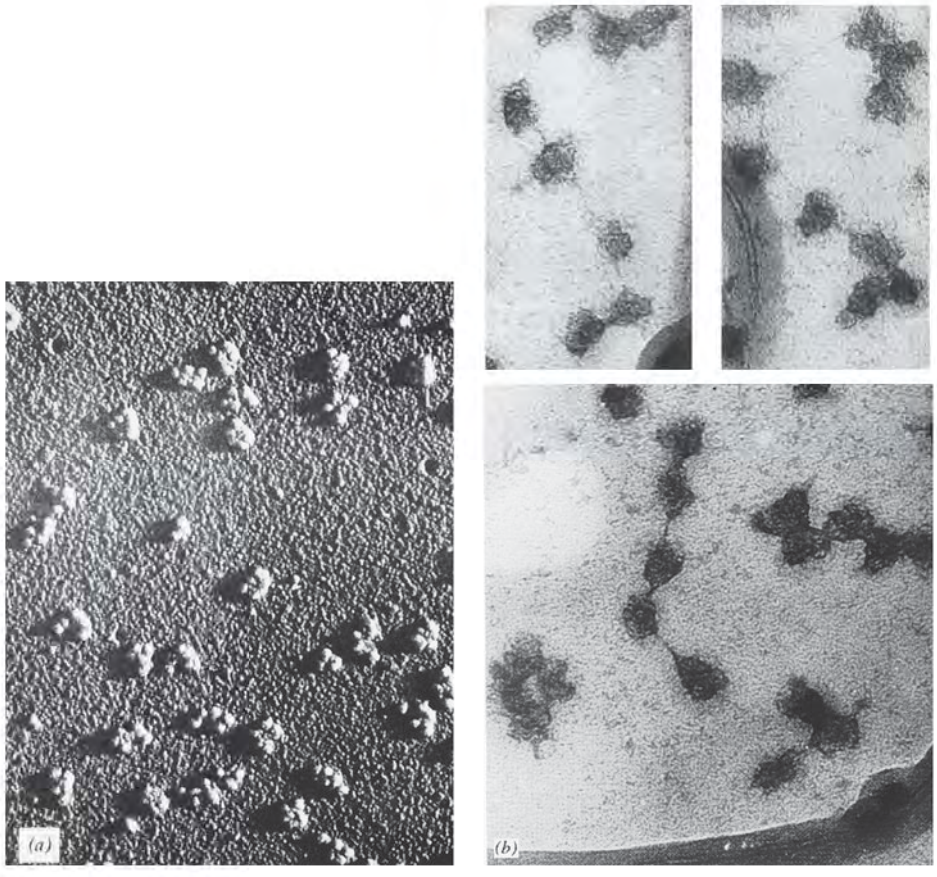

Figure 6.6 Electron micrographs of polysomes. (*a*) Reticulocyte polyribosomes shadowed with platinum are seen in clusters of three to six ribosomes, a number consistent with the size of mRNA for a globin chain. (*b*) Uranyl acetate staining and visualization at a higher magnification shows polysomes; parts of the mRNA are visible. Courtesy of Dr. Alex Rich, M.I.T.

6.3 • PROTEIN BIOSYNTHESIS

Translation Is Directional and Colinear with mRNA

Messenger RNA sequences are transcribed and written 5′ → 3′, and during translation they are read in the same way. Amino acid sequences are both written and synthesized from the amino-terminal residue to the carboxy terminus. A ribosome remains bound to an mRNA molecule: The messenger is moved along its length until a stop codon is reached. Comparison of mRNA sequences with sequences of the proteins they encode shows a perfect, colinear, nonoverlapping and gap-free correspondence of the mRNA coding sequence and that of the polypeptide synthesized. In fact, it is common to deduce the sequence of a protein solely from the nucleotide sequence of its mRNA or the DNA of its gene, although the final sequence of the protein may differ because of posttranslational modifications.

Initiation of Protein Synthesis Is a Complex Process

Initiation requires bringing together a small (40S) ribosomal subunit, an mRNA, and a tRNA complex of the amino-terminal amino acid, all in a proper orientation. This is followed by association of the large (60S) subunit to form a completed initiation complex on an 80S ribosome. This process requires several protein **initiation factors,** listed in Table 6.8, that act transiently and only in initiation. Figure 6.7 shows the initiation process. First, **eukaryotic initiation factor 2 (eIF2)** binds to GTP and the initiator tRNA, Met-tRNA$_i^{met}$ to form a ternary complex. No other aminoacyl-tRNA can replace the initiation-specific Met-tRNA$_i^{met}$ in this step. (Prokaryotes utilize a specific initiator tRNA whose methionine is modified by formylation of its amino group. Only fMet-tRNA$_i^{met}$ is recognized by prokaryotic IF2.)

The second step requires 40S ribosomal subunits associated with a very complex protein, **eIF3.** Mammalian eIF3 contains 13 different polypeptides; it binds to the 40S subunit surface that will contact the 60S subunit and physically blocks subunit association. Hence eIF3 is a ribosome **anti-association factor,** as is eIF6 which binds to 60S subunits. A complex that includes eIF2–GTP, Met-tRNA$_i^{met}$, eIF3–40S, and additional protein factors now forms. In the third step the **pre-initiation complex** is formed; mRNA, **eIF4F,** also

TABLE 6.8 • Major Mammalian Initiation Factors

Factor	*Subunits*	*Functions*
eIF 1	1	Aids pre-initiation complex formation
eIF1A	1	Aids pre-initiation complex formation, binds A-site
eIF2	3 (α, β, γ)	Delivers ternary complex
eIF2B		Recycles eIF2-GDP
eIF3	13 (a-m)	Organizer for other factors on 40S subunit, regulator binding, anti-association factor, other unknown roles
eIF4A	1	RNA helicase
eIF4B	1	Aids eIF4A
eIF4E	1	mRNA cap binding
eIF4F	3	Complex of eIF4A, eIF4E, eIF4G
eIF4G	1	mRNA recruitment, scanning, eIF3 binding
eIF5		GTPase for eIF2, aids 60S association
eIF5B		80S Ribosome formation
eIF6		Binds 60S (anti-association factor)
PAB		Binds polyA of mRNA

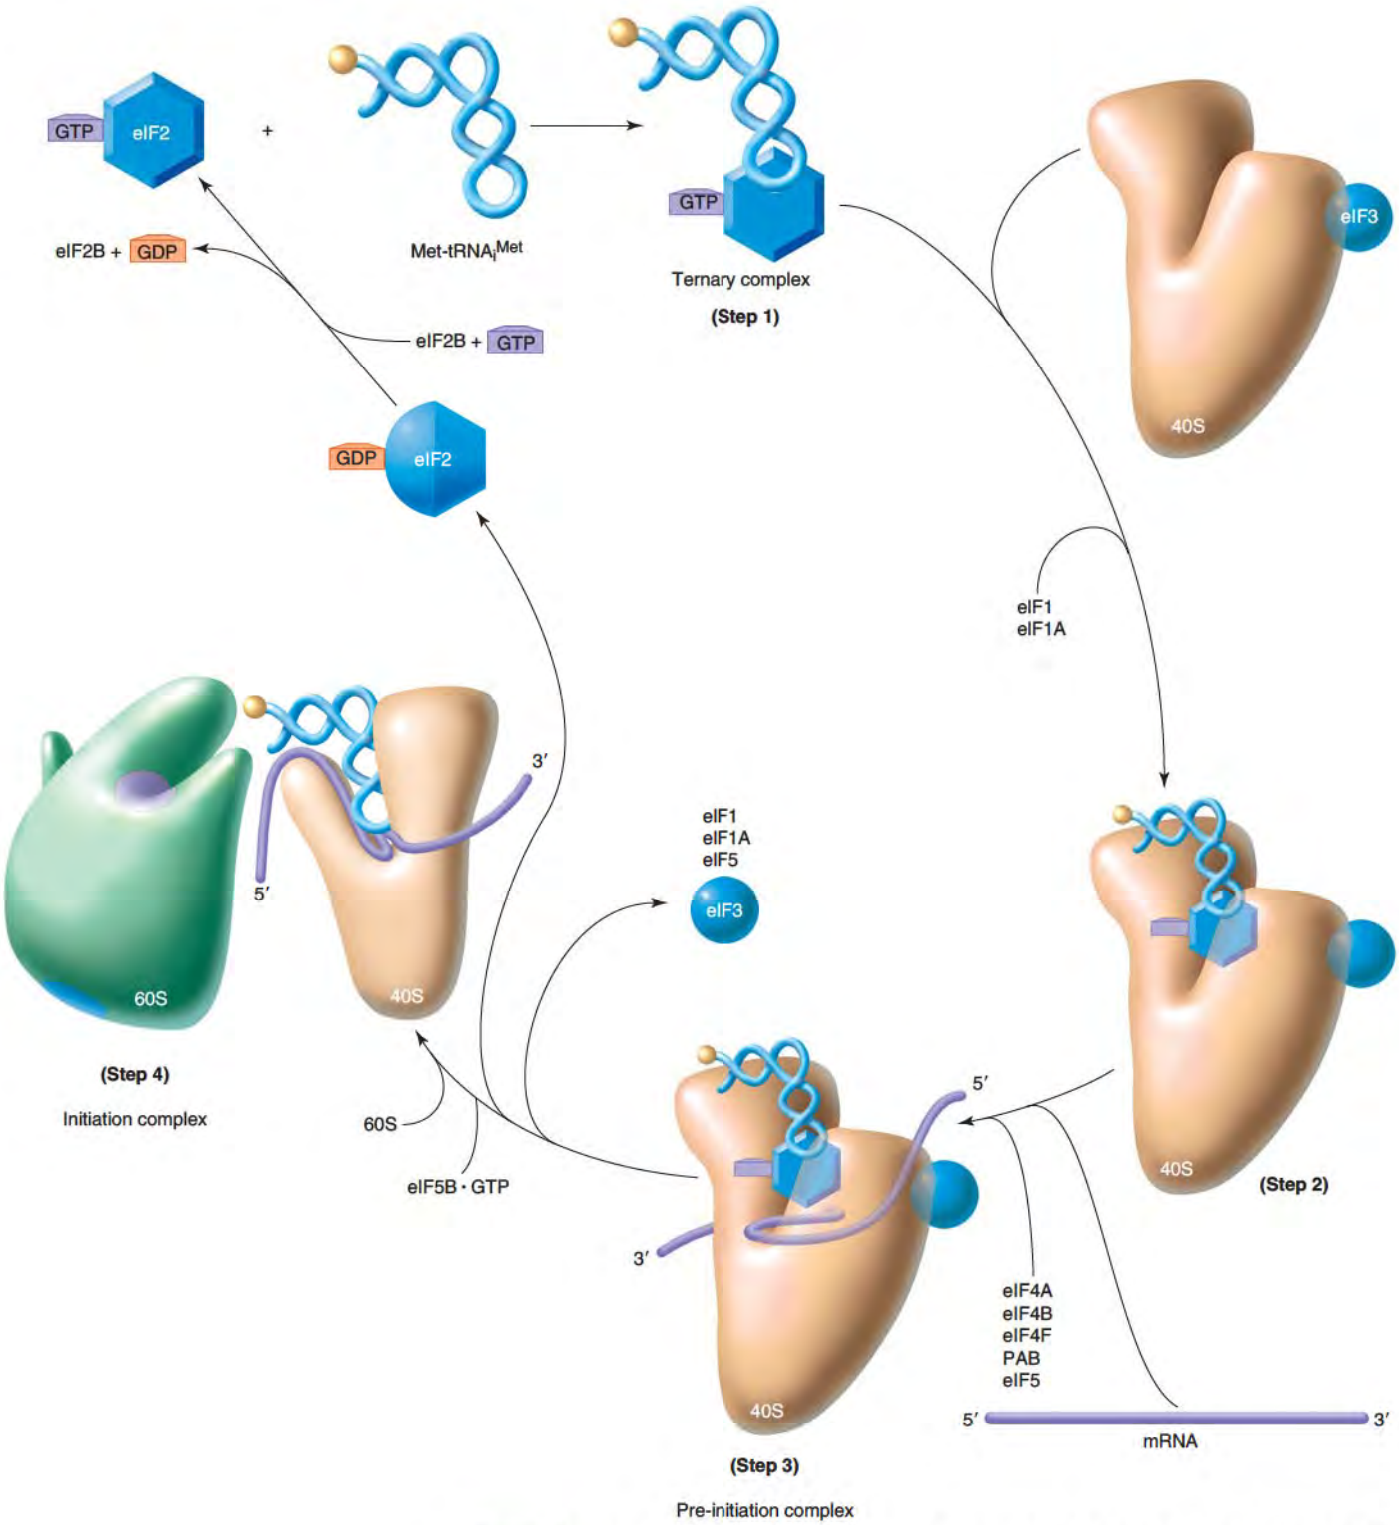

Figure 6.7 Initiation of translation in eukaryotes. Details in text. A ternary complex that includes the initiator tRNA (step 1) combines with a small ribosomal subunit (step 2). Interaction with mRNA forms a pre-initiation complex (step 3). Large subunit binding completes formation of the initiation complex (step 4). The different shape of eIF2 in complexes with GTP and GDP indicates that conformational changes occur on hydrolysis of triphosphate. After elongation has begun, additional small subunits will complex with the same mRNA to form polysomes.

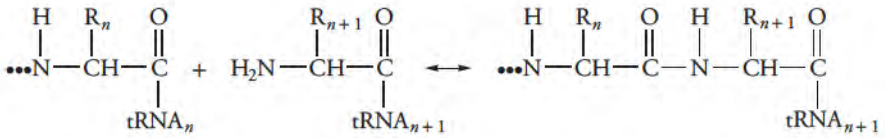
called the **cap-binding complex, eIF4A,** an **RNA helicase** that unwinds secondary structure in the untranslated leader sequence of the mRNA, **PAB,** a polyA-binding protein that loops the 3′-end of the mRNA near to the 5′-cap, and several other proteins are needed. The mRNA is then scanned 5′ → 3′until the first AUG triplet is found. GTP from the ternary complex is hydrolyzed with the help of eIF5, and eIF2–GDP and other factors are released. The eIF2–GDP interacts with the guanine nucleotide exchange factor eIF2B and GTP to regenerate eIF2–GTP for another round of initiation. The final step requires binding of the pre-initiation complex by a 60S subunit and an additional factor, **eIF5B–GTP.** GTP is hydrolyzed, and eIF5B–GDP and other factors are released. The complete **initiation complex** is an 80S ribosome with the mRNA and initiator tRNA correctly positioned to begin translation.

Sometimes the first AUG is not used and a later AUG, characterized by its secondary structure within the mRNA, is selected for initiation. Such **internal ribosome entry sites** (IRES) were first found in viral mRNAs, but they also are common in messengers that encode proteins that protect cells from stress, when the translation of most mRNAs is repressed.

Prokaryotes use fewer initiation factors to form an initiation complex. Their 30S subunits, complexed with a simpler IF3, can first bind either mRNA or a ternary complex of IF2, fMet-tRNA$_i^{met}$, and GTP. Orientation of the mRNA relies in part on base pairing between a pyrimidine-rich sequence of eight nucleotides in 16S rRNA and a purine-rich sequence about 10 nucleotides upstream of the initiator AUG codon. Complementarity between rRNA and mRNA may include several mismatches, but greater complementarity usually leads to initiation that is more efficient. Initiation factor IF1also acts in formation of the preinitiation complex. Finally, a 50S subunit is bound, GTP is hydrolyzed, and the initiation factors are released. It is interesting that prokaryotes rely more on RNA–RNA interactions to position mRNA, whereas eukaryotes use many proteins to attain the same result.

Elongation Is the Stepwise Formation of Peptide Bonds

Protein elongation, as shown in Figure 6.8, occurs by stepwise lengthening of the polypeptide chain. At each step ribosomal **peptidyl transferase** transfers the growing peptide (or in the first step the initiating methionine residue) from its carrier tRNA to the α-amino group of the amino acid residue of the aminoacyl-tRNA specified by the following codon:



peptidyl-tRNA (***n*** residue length) | aminoacyl-tRNA | peptidyl-tRNA (***n*** + **1** residue length)

Efficiency and fidelity are enhanced by nonribosomal elongation factors that use energy released by GTP hydrolysis to ensure placement of the proper aminoacyl-tRNA species and to move the mRNA and associated tRNAs through the ribosome.

During elongation up to three tRNA molecules are bound at specific sites that span both ribosomal subunits. The initiating met-tRNA is positioned so that its methionyl residue can be transferred (or donated) to the free α-amino group of the incoming aminoacyl-tRNA; it thus occupies the **donor site,** also called the **peptidyl site** or **P site** of the ribosome. The aminoacyl-tRNA specified by the next codon of the mRNA is bound at the **acceptor site,** also called the **aminoacyl site** or **A site** of the ribosome. Selection of the correct aminoacyl-tRNA is enhanced by **elongation factor EF1.** A component of EF1, EF1α, first forms a ternary complex with aminoacyl-tRNA and GTP. The EF1α–aminoacyl-tRNA–GTP complex binds to the ribosome, and if codon–anticodon interactions are correct, the aminoacyl-tRNA is placed at the A site, GTP is hydrolyzed, and the EF1α–GDP complex dissociates. The initiating methionyl-tRNA and the incoming aminoacyl-tRNA are now juxtaposed on the ribosome. Their anticodons are paired with successive codons of the mRNA in the P and A sites of the small subunit, and their amino acids are beside one

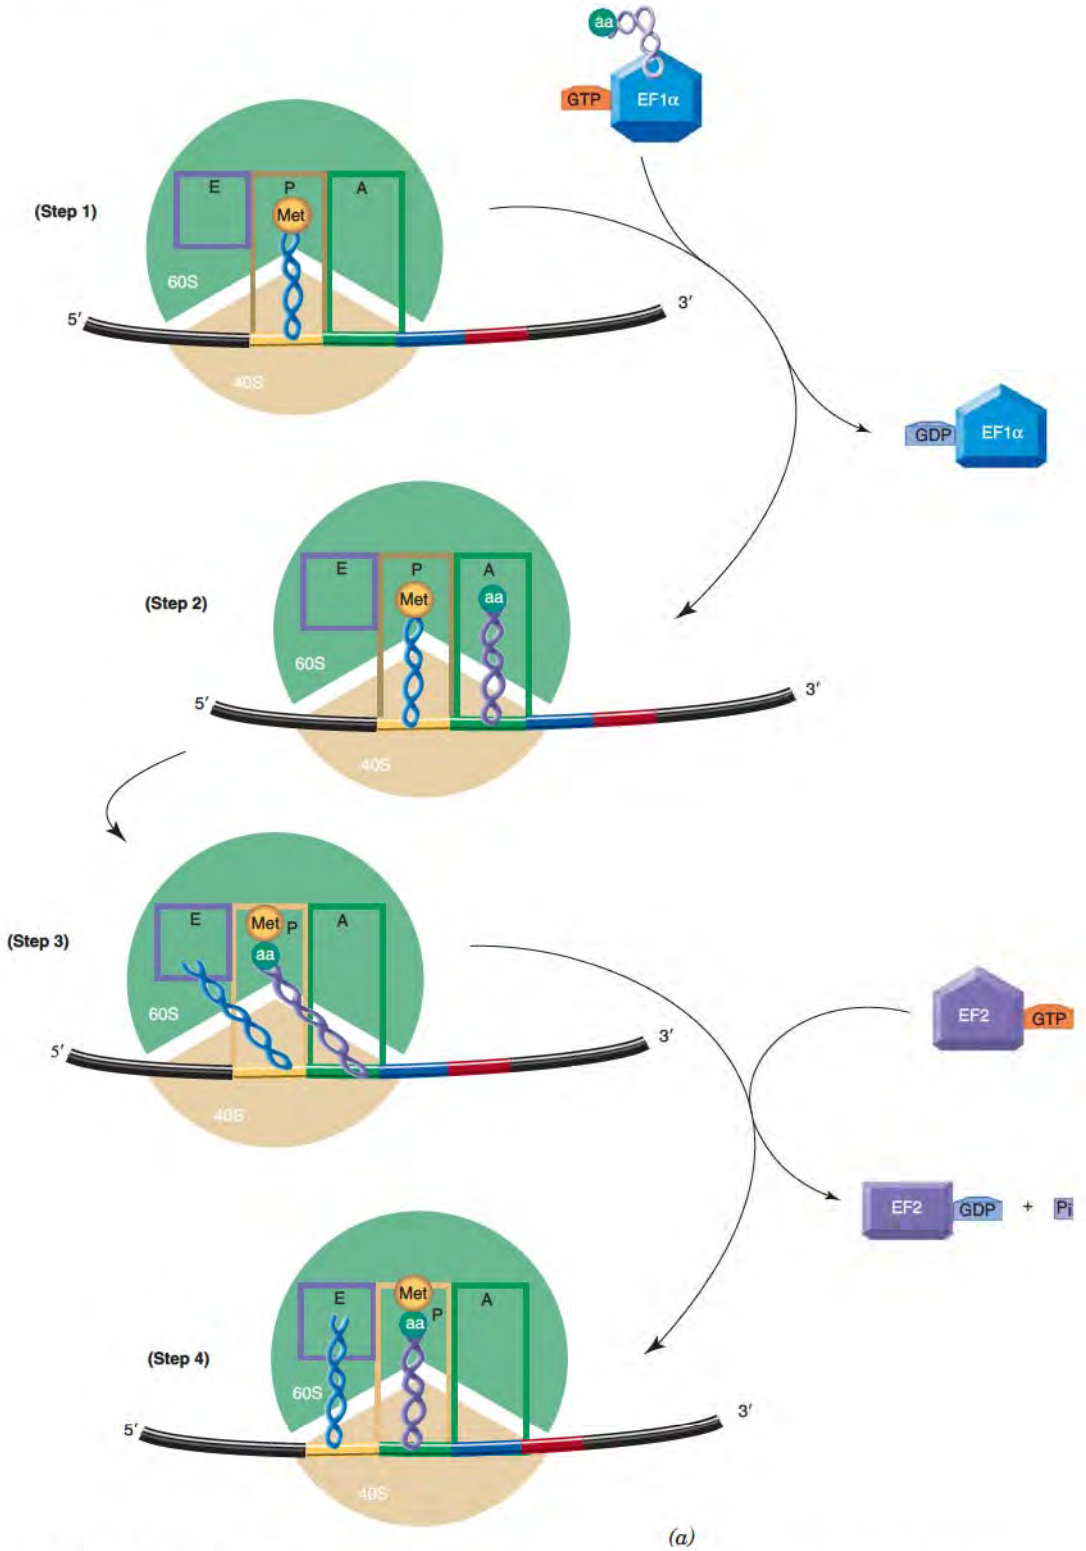


Figure 6.8 Elongation steps in protein synthesis.
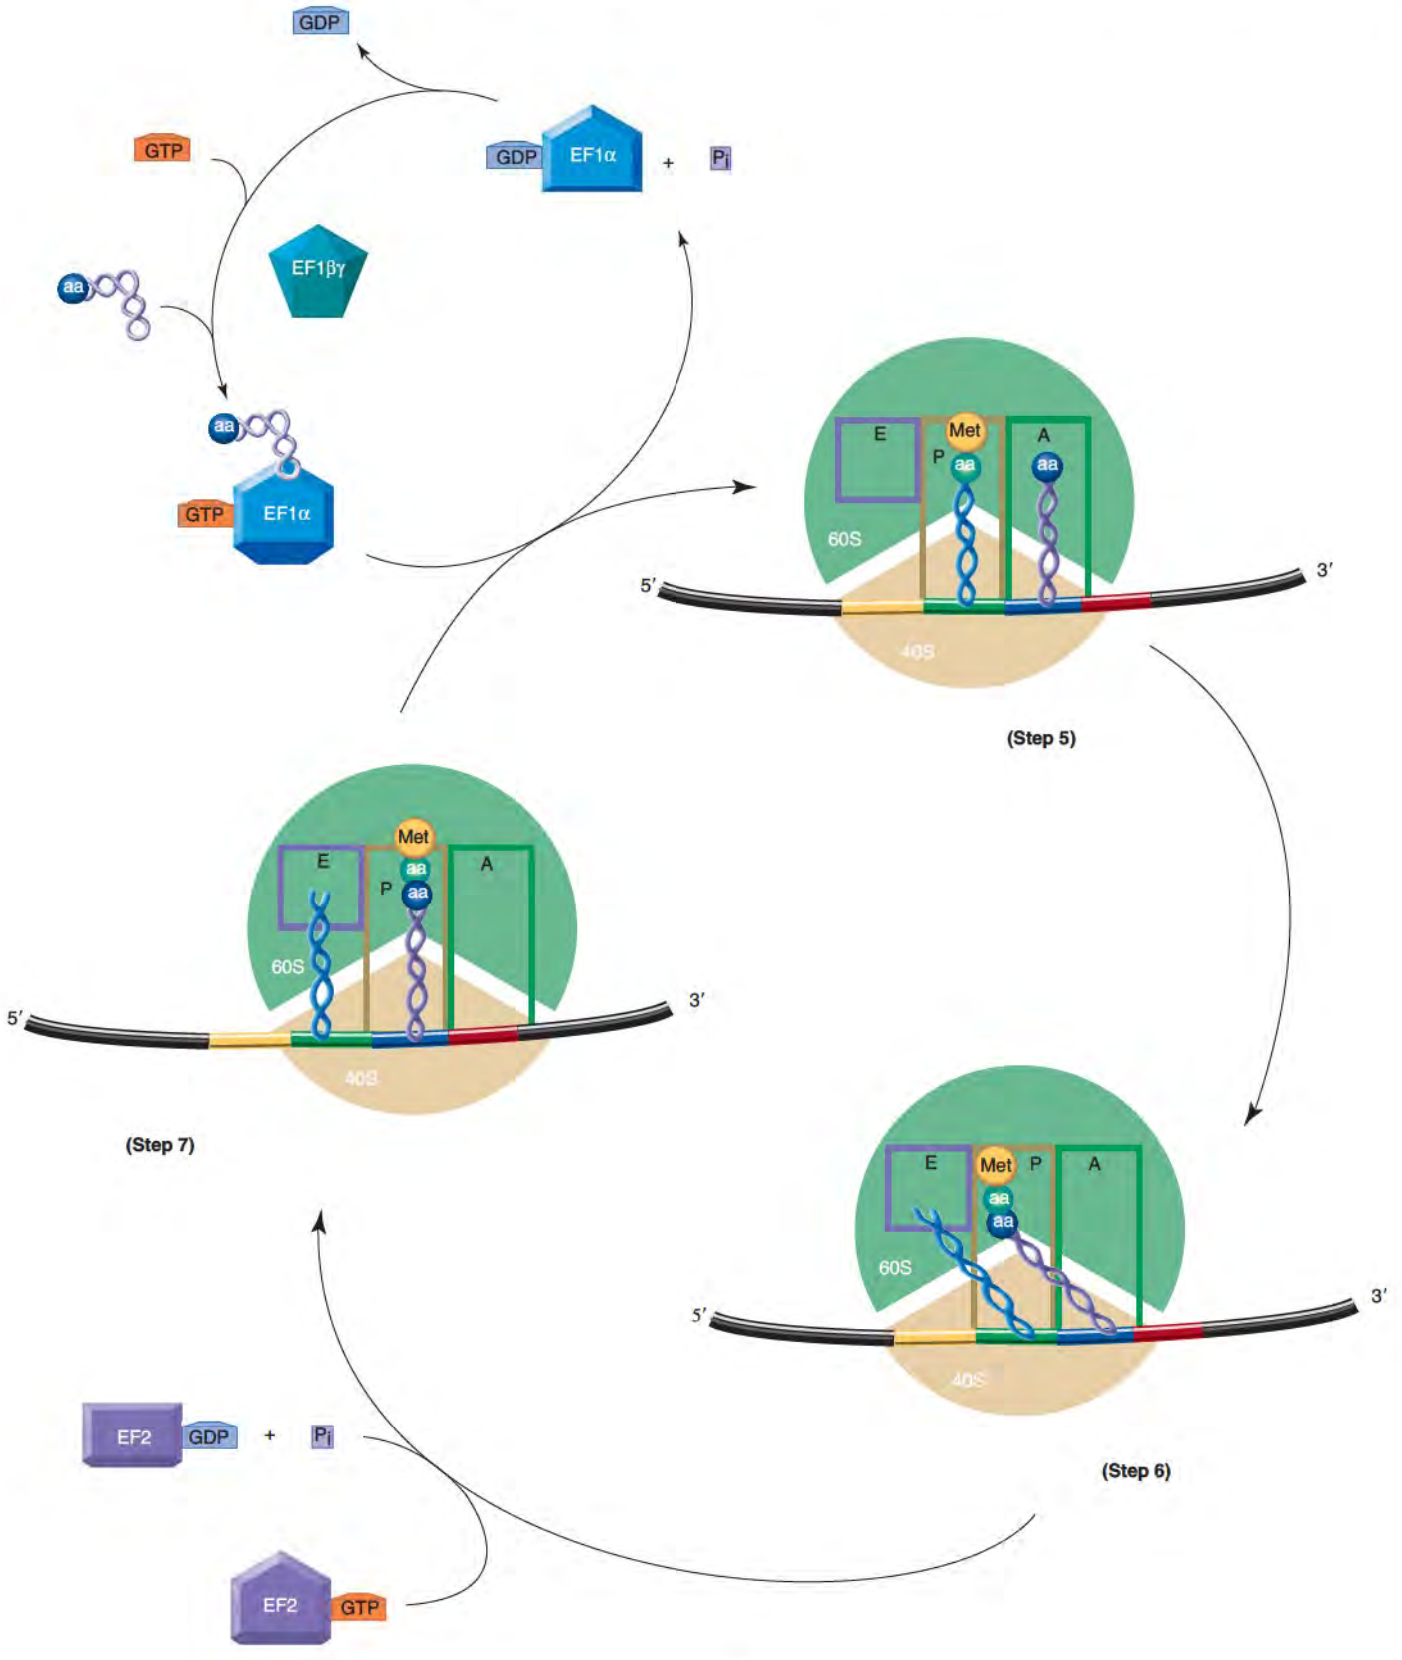
(*a*) The first round of elongation is shown. Step 1: An initiation complex with methionyl $tRNA_i^{met}$ in 80S P site. Step 2: EF1α has placed an aminoacyl-tRNA in the A site. GTP hydrolysis results in a conformational change in EF1α. Step 3: A peptide bond has been formed; new peptidyl tRNA occupies a hybrid (A/P) site on the ribosome and the acceptor stem of deacylated $tRNA_i^{met}$ is in the large subunit E site. Step 4: The mRNA–peptidyl tRNA complex has been translocated to the P site while deacylated initiator tRNA is moved to the E site. (*b*) Further rounds of elongation. Step 5: Binding of aminoacyl-tRNA in the A site causes release of deacylated tRNA from the E site. Step 6: Formation of peptide bond results in the new peptidyl tRNA occupying a hybrid A/P site. Step 7: Translocation moves mRNA and new peptidyl tRNA in register into P site. Additional amino acids are added by successive repetitions of the cycle. Recycling of EF-1α (upper left) is detailed in Figure 6.9. For further details see text.



(b)

Figure 6.8
(*continued*)

another at the peptidyl transferase site of the large subunit. Peptidyl transferase catalyzes attack of the α-amino group of aminoacyl-tRNA on the carbonyl carbon of methionyl-tRNA. The result is transfer of methionine to the amino group of the aminoacyl-tRNA, which then occupies a "hybrid" position on the ribosome with the anticodon in the 40S A site, while the acceptor end and the attached peptide are in the 60S P site. The anticodon of the deacylated tRNA remains in the 40S P site; its acceptor end is located in the 60S **exit,** or **E, site.**

The mRNA and the dipeptidyl-tRNA at the 40S A site must be repositioned to permit another round of elongation to begin. This is done by **elongation factor 2 (EF2),** also called **translocase.** EF2 moves the mRNA and dipeptidyl-tRNA, in codon–anticodon register, from the 40S A site to the P site. In the process GTP is hydrolyzed, providing energy for the movement, and the A site is vacated. As the dipeptidyl-tRNA moves to the P site, the deacylated donor (methionine) tRNA also moves to the E site on the 60S subunit. The ribosome can now enter a new round. The next aminoacyl-tRNA specified by the mRNA is delivered by EF1α–GTP to the A site, and the deacylated tRNA in the E site is released. Peptide transfer again occurs. Successive rounds of binding of aminoacyl-tRNA, peptide bond formation, and translocation result in the stepwise elongation of the polypeptide toward its eventual carboxyl terminus. Whatever the length of the growing chain, peptide bond formation always occurs through attack of the α-amino group of the incoming aminoacyl-tRNA on the peptide carboxyl-tRNA linkage, hence the geometric arrangement of the reacting molecules at the peptidyl transferase site remains constant.

Peptide bond formation does not require an energy source such as ATP or GTP. The energy of the methionyl (or peptidyl) ester linkage to tRNA drives the reaction toward peptide bond formation. Stepwise elongation continues until a termination codon (UGA, UUA, or UAG) occurs in the mRNA. Note that the UGA codon has an additional function, coding for **selenocysteine** (sec) in a small number of proteins (p. 79). Ribosomal RNA is a major part of the tRNA binding sites of the ribosome, and isolated 60S subunits can catalyze peptidyl transferase activity without the involvement of any nonribosomal factors. Evidence from many sources indicates that the large subunit is a complex **ribozyme** in which peptide bond formation is an **RNA-catalyzed** reaction. X-ray crystallography of large subunits shows the transferase region is composed only of RNA, with the nearest amino acid side chain at least 20Å away. Elements of both ribosomal and transfer RNAs are involved in transferase action. The important nucleotides in the transferase site have been universally conserved in evolution, so the same mechanism is believed to occur in mammalian ribosomes, although crystallographic evidence is not yet available. It is speculated that the primordial ribosome was a naked RNA molecule and that transferase activity has been conserved in RNA.

As determined from prokaryotic models, the role of GTP in the action of EF1α and EF2 relates to conformational changes in these proteins. Crystallographic studies show a large rearrangement of domains, with movements of several angstroms on GTP hydrolysis in EF-Tu, the prokaryotic equivalent of EF1α. Both EF1α and EF2 bind ribosomes tightly as GTP complexes, while GDP complexes dissociate from the ribosome more easily. Viewed another way, GTP stabilizes a protein conformation that confers on EF1α high affinity toward aminoacyl-tRNA and the ribosome, while GDP stabilizes a conformation with lower affinity toward either, thus allowing tRNA delivery and EF dissociation. Restoration of the higher affinity GTP-associated conformation of EF1α requires participation EF1$\beta\gamma$, which causes release of GDP from EF1α and forms an EF1α–EF1$\beta\gamma$ complex (Figure 6.9). GTP then causes release of EF1$\beta\gamma$, forming an EF1α–GTP complex that can bind an aminoacyl-tRNA and then a ribosome. Prokaryotes use a similar mechanism in which EF-Tu binds GTP and aminoacyl-tRNA and EF-Ts replaces GDP. Prokaryotes also utilize a GTP-dependent translocase, like EF2 but called **EF-G** or **G factor.**

Termination of Polypeptide Synthesis Requires a Stop Codon

A chain-terminating UAG, UAA, or UGA codon in the A site promotes binding of **release factor (eRF1)** (Figure 6.10). The peptide-tRNA ester linkage is cleaved by peptidyl transferase, acting here as a hydrolase, and the completed polypeptide is released from its tRNA

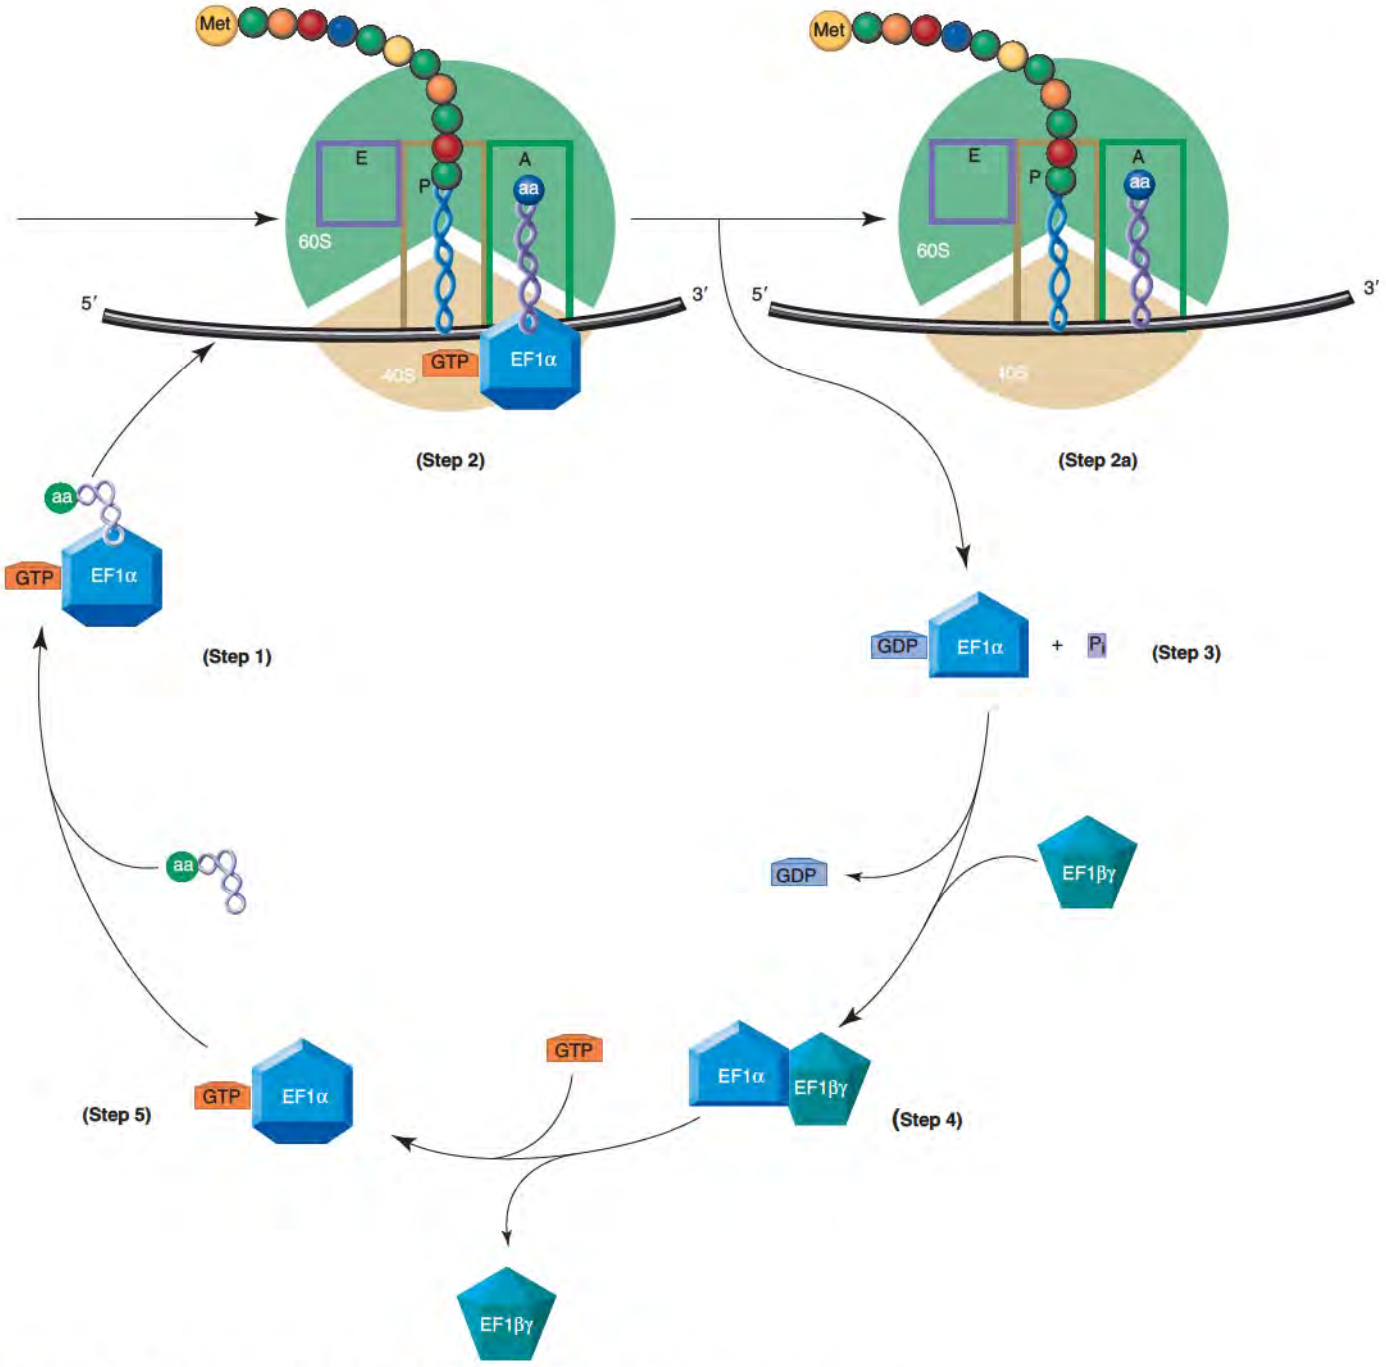


Figure 6.9 EF1 in the elongation cycle. Step 1: EF1α-GTP-aminoacyl-tRNA complex binds the ribosome. Step 2: Aminoacyl-tRNA is placed on the ribosome (step 2a) with hydrolysis of GTP, a change in conformation of EF1α, and its release from tRNA and the ribosome (step 3). Step 4: GDP is displaced from EF1α by EF1$\beta\gamma$. Binding of GTP then displaces EF1$\beta\gamma$ (step 5) and allows binding of an aminoacyl-tRNA by EF1α in its higher affinity conformation (step 1).

and the ribosome. Release of eRF1 from the ribosome follows hydrolysis of the bound GTP and frees the ribosome to dissociate into subunits and then reenter the protein synthesis process. A second protein, eRF3, participates in this process. Although human eRF1 is a protein, it is similar in size and shape to tRNA, and amino acids at one end of a protein domain recognize and interact with a termination codon. This "molecular mimicry" is also apparent in the structure of bacterial EF-G, in which a protein domain mimics the anticodon stem of tRNA and functions in elongation by displacing the tRNA from the A to the P subsite on the small subunit.

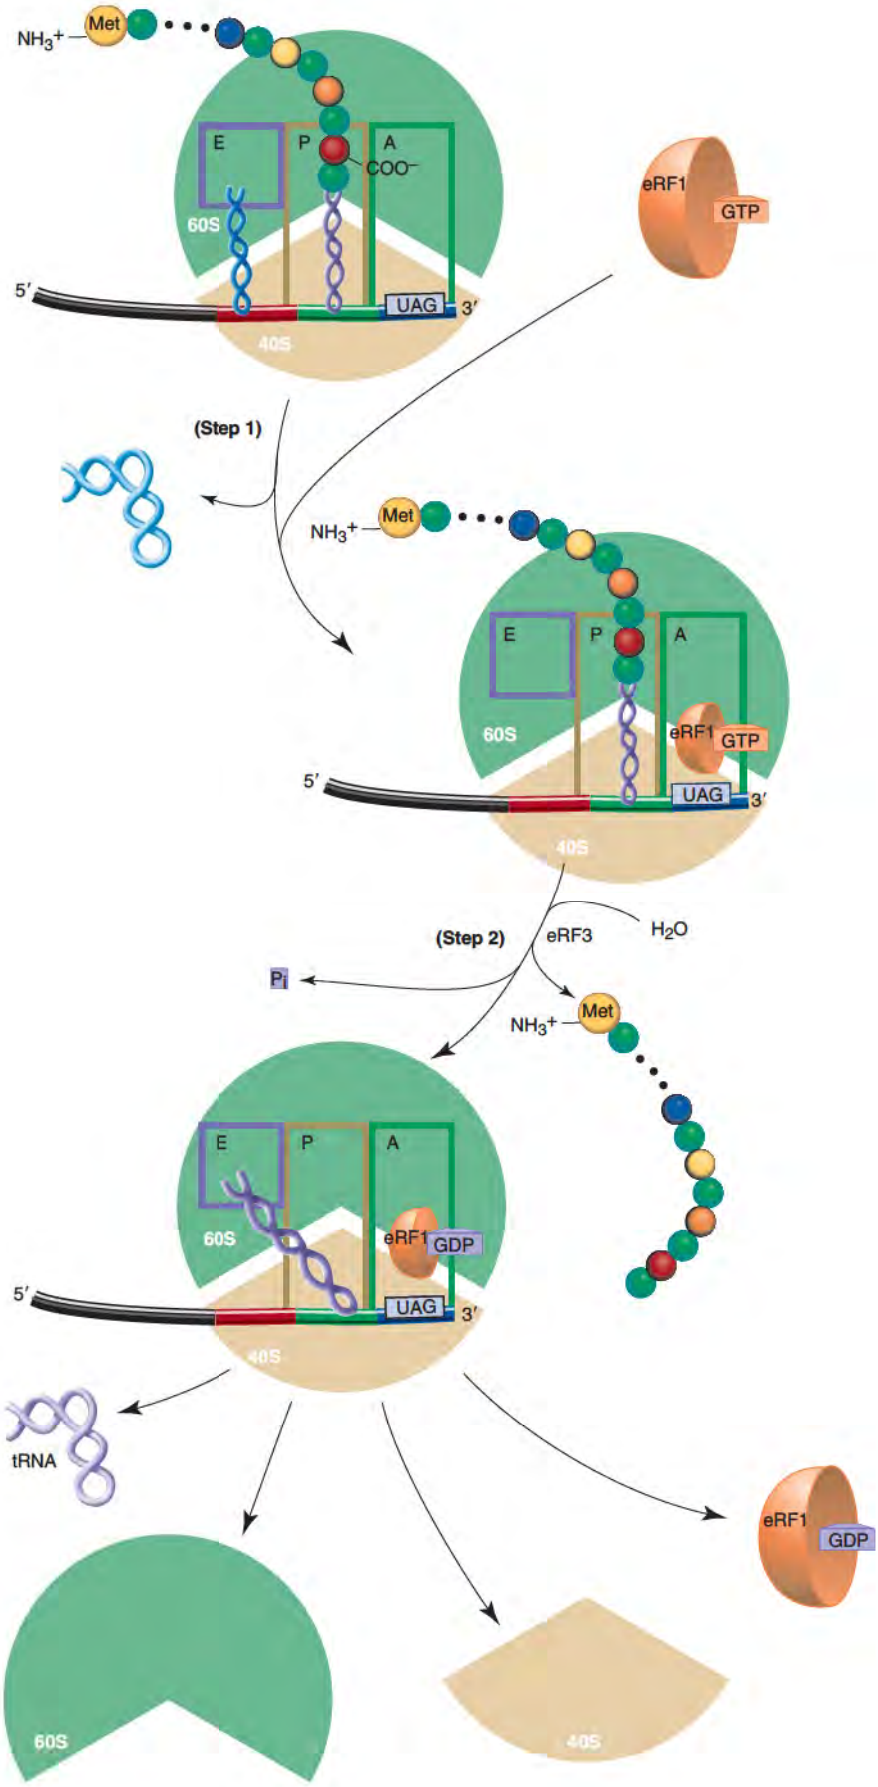

Figure 6.10 Termination of translation. When a termination codon in mRNA occupies the A site, binding of an RF1-GTP complex occurs (step 1) and deacylated tRNA is released. Step 2: Peptidyl transferase acts as a hydrolase; hydrolysis of the ester bond linking protein to tRNA releases the protein. The acceptor end of deacylated tRNA is probably displaced, GTP is hydrolyzed, and release factor-GDP dissociates. eRF3 promotes these events. Dissociated components can now enter additional rounds of protein synthesis.

Translation Has Significant Energy Cost

There is considerable use of energy in making a polypeptide. Amino acid activation converts an ATP to AMP and pyrophosphate, which is hydrolyzed to Pi; the net cost is two high-energy phosphates. Two more high-energy bonds are hydrolyzed in the action of EF1α and EF2, for a total of four per peptide bond formed. Initiation, termination, and posttranslational modifications add to the energy cost. Further energy is needed for biosynthesis of the multiuse mRNA, tRNAs, ribosomes, and protein factors, but these costs are distributed generally among the proteins formed during their lifetimes.

Protein Synthesis in Mitochondria Differs Slightly

Many characteristics of the mitochondrion suggest that it is a descendant of an aerobic prokaryote that formed a symbiotic relationship within a eukaryotic cell. Some independence and prokaryotic character are retained. Although most mitochondrial proteins are encoded in nuclear DNA, synthesized in the cytosol, and imported into the organelle, mitochondrial protein synthesis is important (Clin. Corr. 6.6). Human mitochondria have a circular DNA genome of 16,569 base pairs that encodes 13 proteins, 22 tRNA species, and mitochondrion-specific 12S and 16S rRNA species. Their apparatus for protein synthesis includes RNA polymerase, aminoacyl-tRNA synthetases, tRNAs, and ribosomes that are unique to the mitochondrion. Some details of translation differ: Mitochondrial ribosomes are smaller and the rRNAs are shorter than those of either the eukaryotic cytosol or of prokaryotes (see Table 6.7, p. 618). The genetic code is slightly different (see Table 6.2, p. 211), and like prokaryotes, the initiator Met-tRNA$_i^{met}$ is modified by a **transformylase** that uses N^{10}-formyl H_4-folate to produce **fMet-tRNA$_i^{met}$.** Cells must coordinate protein synthesis within mitochondria with the cytosolic synthesis of proteins destined for import into mitochondria.

Many Antibiotics and Toxins Target Protein Biosynthesis

Protein biosynthesis is central to the life and reproduction of cells. Because an organism can gain a biological advantage by interfering with the ability of its competitors to synthesize proteins, many antibiotics and toxins function in this way. Some are selective for prokaryotic protein synthesis and so are extremely useful in clinical practice. Examples showing several mechanisms of antibiotic action are listed in Table 6.9.

Many antibiotics bind the ribosome to inhibit an aspect of translation. **Streptomycin** binds the small subunit of prokaryotic ribosomes and causes misreading of mRNA (Clin. Corr. 6.6). Mutations in a ribosomal protein or the rRNA of the small subunit can confer streptomycin resistance or dependence. Other aminoglycoside antibiotics, such as

CLINICAL CORRELATION 6.6

Mutations in Mitochondrial rRNA and tRNA Result in Antibiotic-Induced Deafness

Instances of permanent deafness have been linked to use of normally safe and effective amounts of aminoglycoside antibiotics such as streptomycin, paromomycin, and gentamycin. The unusual sensitivity to aminoglycosides is maternally transmitted, suggesting a mitochondrial locus (sperm do not contribute mitochondria to the zygote). Aminoglycosides target bacterial ribosomes, so the prokaryotic-like mitochondrial ribosome is a logical place to look for a mutation site. A single A → G point mutation in mitochondrial DNA at nucleotide 1555 of the 12S rRNA gene has been identified in families with this aminoglycoside susceptibility. The mutation occurs in a highly conserved region of the rRNA sequence that is involved in aminoglycoside binding; some mutations in the same region confer resistance to the antibiotics, and the RNA region is part of the ribosomal decoding site. It is likely that the mutation increases affinity for aminoglycosides and their ability to inhibit protein synthesis. Reduced mitochondrial protein synthesis decreases levels of enzymes of the oxidative phosphorylation system and affected cells become starved of ATP. Many more mutations in mitochondrial rRNA and tRNA are associated with hearing loss and other problems.

Aminonucleosides	Puromycin	Elongation	Large subunit A-site

Source: Hermann, T. Drugs targeting the ribosome. *Curt. Opinion Struct. Biol.* 15: 355 2005. Tenson, T. and Mankin, A. Antibiotics and the Ribosome. *Molec. Microbial.* 59: 1664, 2006.

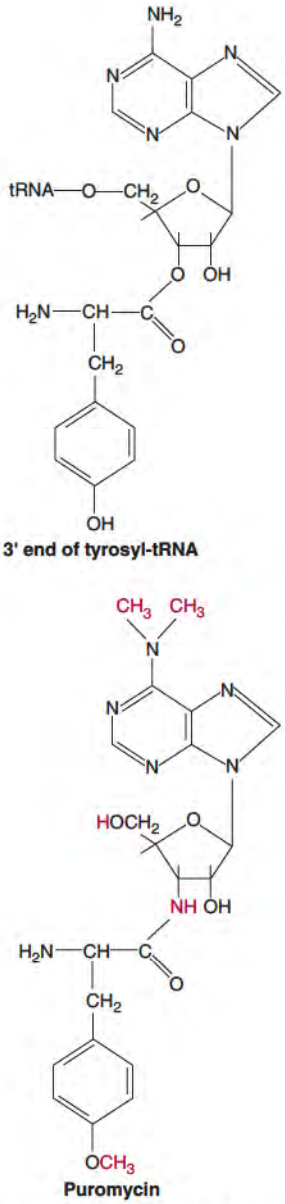

Figure 6.11 Puromycin (bottom) terminates translation by binding at the large subunit A site and acting as an analog of aminoacyl-tRNA (here tyrosyl-tRNA [top]). The α-amino group (arrow) is a peptidyltransferase acceptor, and peptidyl-puromycin dissociates from the ribosome.

the **neomycins** and **gentamycins,** interact with the small ribosomal subunit at a slightly different site but also cause mistranslation. **Erythromycin,** a macrolide antibiotic, interferes with translocation on prokaryotic ribosomes. The macrolides block passage of the elongating peptide through the ribosome. **Kasugamycin** inhibits the initiation of translation; sensitivity to kasugamycin depends on base methylation that normally occurs on two adjacent adenines of small subunit rRNA. **Tetracyclines** bind to ribosomes and interfere in aminoacyl-tRNA binding. **Puromycin** (Figure 6.11) resembles an aminoacyl-tRNA; it binds at the large subunit A site and acts as an acceptor of the nascent peptide in the peptidyl transferase reaction. Peptidyl-puromycin is not translocated, and it cannot serve as a peptide donor. Translation is prematurely terminated, and peptidyl-puromycin is released. **Chloramphenicol** inhibits peptidyl transferase by binding at the transferase center; no transfer occurs, and peptidyl-tRNA remains associated with the ribosome.

Some agents act directly on ribosomal RNA. **Ricin** (from castor beans) and related toxins are *N*-glycosidases that cleave a single adenine from the large subunit rRNA backbone. A fungal toxin, **α-sarcin,** cleaves large subunit rRNA at a single site; in both cases the ribosome is inactivated. Some *E. coli* strains make extracellular toxins that affect other bacteria. One of these, **colicin E3,** is a ribonuclease that cleaves 16S RNA near the mRNA-binding sequence and decoding site; it inactivates the small subunit and halts protein synthesis in competitors of the colicin-producing cell. Other agents affect translation factors: For example, eukaryotic translocation is inhibited by **diphtheria toxin,** a protein produced by *Corynebacterium diphtheriae.* The toxin binds at the cell membrane and a subunit enters the cytoplasm and catalyzes the ADP-ribosylation and inactivation of EF2, as represented in the reaction

$$\underset{\text{(active)}}{\text{EF-2}} + \text{NAD} \rightleftharpoons \underset{\text{(inactive)}}{\text{ADP-ribosyl EF-2}} + \text{nicotinamide} + \text{H}^+$$

ADP-ribose is attached to EF2 at a **diphthamide** residue that is itself a posttranslationally modified form of histidine (see Figure 6.20, p. 243). *Pseudomonas aeruginosa* produces a similar exotoxin.

6.4 • PROTEIN MATURATION: FOLDING, MODIFICATION, SECRETION, AND TARGETING

Some proteins emerge from the ribosome ready to function, whereas others undergo a variety of **posttranslational modifications.** The result may be conversion to a functional form, direction to a specific subcellular compartment, secretion from the cell, or an alteration

CLINICAL CORRELATION 6.7

Deletion of a Codon, Incorrect Folding, and Premature Degradation: Cystic Fibrosis (OMIM 219700)

Cystic fibrosis (CF) is the most common autosomal recessive disease in Caucasians, with a frequency of about 1 per 2000. The CF gene is 230 kb long and includes 27 exons that encode a protein of 1480 amino acids. The protein known as the cystic fibrosis transmembrane conductance regulator or CFTR (p. 494) is a cyclic AMP-regulated chloride channel. It contains two membrane-spanning domains, each having six transmembrane regions, two ATP-binding domains, and one regulatory domain, which includes several phosphorylation sites. Its complex folding pathway is affected by several chaperones.

CF epithelia are characterized by defective electrolyte transport. The organs most strongly affected include the lungs, pancreas, and liver, and the most life-threatening effects involve thick mucous secretions that lead to chronic obstructive lung disease and persistent lung infections. In about 70% of patients there is a deletion of the three nucleotides that encode phenylalanine 508, normally located in ATP-binding domain 1 on the cytoplasmic side of the plasma membrane. As with several other CF mutations, the Phe 508-deletion protein does not fold correctly in the ER and is not properly glycosylated or transported to the cell surface. Instead, it is degraded in the cytoplasm. Yet, in cultured cells at lower temperatures or with added chemical chaperones such as glycerol, the mutant protein folds, is transported, and functions properly. Drugs that foster chaperone interactions with mutant CFTR and/or aid in its folding and transport to the membrane are a potential therapeutic approach to this form of cystic fibrosis.

in activity or stability. Information that determines the posttranslational fate of a protein ultimately resides in its structure; the sequence and conformation of the protein determine whether it will be a substrate for a modifying enzyme and/or identify it for direction to a subcellular or extracellular location.

Chaperones Aid in Protein Folding

Many proteins can spontaneously generate their native conformation. For example, fully denatured pancreatic ribonuclease can, under appropriate laboratory conditions, refold and generate correct disulfide bridges and full activity. Many newly synthesized proteins fold correctly as they emerge from the ribosome. However, other proteins require the assistance of **chaperones** (p. 116) which reversibly bind hydrophobic regions of nascent proteins and proteins in an intermediate stage of folding. Their actions can help a protein attain its functional conformation. Chaperones can stabilize intermediates and promote correct folding, maintain proteins in an unfolded state to allow passage through membranes, help unfold misfolded segments, prevent formation of incorrectly folded intermediates, and prevent aggregation or other inappropriate interactions with other proteins. They can also assist in unfolding proteins destined for degradation. Some use energy from ATP hydrolysis to carry out their functions. Failure to fold correctly usually leads to rapid protein degradation (Clin. Corr. 6.7). Accumulation of misfolded proteins can result in protein aggregation and serious disease (see Clin. Corr. 6.14, p. 250).

Proteins for Export Follow the Secretory Pathway

Proteins destined for export and those destined for the plasma membrane, lysosomes, endosomes or the Golgi apparatus are synthesized on membrane-bound ribosomes of the **rough endoplasmic reticulum** (ER) (Figure 6.12). These proteins have a hydrophobic **signal peptide,** usually at or near the amino terminus. Signal peptides have a positively charged N-terminal region and a core of 8–12 hydrophobic amino acids in an α-helix, followed by a more polar C-terminal segment that eventually serves as a cleavage site for excision of the signal peptide. Translation begins on free cytosolic ribosomes. As the signal peptide of 15–30 amino acids emerges from the ribosome, it binds a **signal recognition particle (SRP)** (Figure 6.13). SRP is composed of six different proteins and a small (7S) RNA molecule. The signal peptide binds in a hydrophobic pocket of

the SRP with the positively charged N-terminal segment in contact with SRP RNA. Translation halts; the complex binds GTP and moves to the ER where the SRP binds to a GTP complex of an **SRP receptor** or **docking protein,** on the cytosolic surface of the ER membrane. The ribosome is transferred to a **translocon,** a ribosome receptor that crosses the membrane and serves as a passageway through the membrane. GTP is hydrolyzed and the SRP is released, relieving the translational block. The translocon passageway opens to allow transit of the nascent protein, the hydrophobic signal sequence is inserted, and translation and extrusion into or through the translocon are now coupled. Even very hydrophilic or charged segments are directed through the membrane into the ER lumen. Chaperones help the protein fold either co- or posttranslationally (A Closer Look 6.3). Disulfide bonds can form with the participation of thiol oxidoreductases, and components of multi-subunit proteins may assemble. The signal peptide is excised by **signal peptidase,** an integral membrane protein at the luminal surface of the ER. Other steps may include proteolytic processing and glycosylation that occur within the ER lumen and during transit of the protein through the Golgi apparatus and into secretory vesicles.

Glycosylation of Proteins Occurs in the Endoplasmic Reticulum and Golgi Apparatus

Glycosylation of proteins to form glycoproteins (p. 112) is important for many reasons. Glycosylation alters the properties of proteins, changing their stability, solubility, and physical bulk. The carbohydrate moieties can be recognition signals that direct protein interactions and targeting. Glycosylation sites are specified by the amino acid and its neighboring sequence in the protein. **Glycosyltransferases,** classes of which are summarized in Table 6.10, all carry out a similar basic reaction: A sugar is transferred from an activated donor substrate to an appropriate acceptor, usually another sugar residue that is part of an oligosaccharide under construction. The enzymes show specificity for the **monosaccharide** that is transferred, the structure and sequence of the **acceptor,** and the site and configuration of the **anomeric linkage** formed.

TABLE 6.10 • Glycosyltransferases in Eukaryotic Cells

Sugar Transferred	*Abbreviation*	*Donor*	*Glycosyltransferase*
Mannose	Man	GDP-Man	Mannosyltransferase
		Dolichol-Man	
Galactose	Gal	UDP-Gal	Galactosyltransferase
Glucose	Glc	UDP-Glc	Glucosyltransferase
		Dolichol-Glc	
Fucose	Fuc	GDP-Fuc	Fucosyltransferase
N-Acetylgalactosamine	GalNAc	UDP-GalNac	*N*-acetylgalactosaminyltransferase
N-Acetylglucosamine	GlcNAc	UDP-GlcNAc	*N*-acetylglucosaminyltransferase
N-Acetylneuraminic acid	NANA or NeuNAc	CMP-NANA	*N*-Acetylneuraminyltransferase
(or sialic acid)	SA	CMP-SA	(sialyltransferase)

In **N-linked glycosylation** an oligosaccharide is linked through the amide nitrogen of asparagine. Formation of N-linked oligosaccharides begins in the ER lumen and continues in the Golgi apparatus. A specific sequence, **Asn-X-Thr** (or **Ser**), in which X can be any amino acid except proline, is required. Not all Asn-X-Thr/Ser sequences are glycosylated because some may be unavailable for modification. The antibiotic tunicamycin prevents *N*-glycosylation.

N-linked glycosylation is initiated with a lipid-linked intermediate (Figure 6.14). **Dolichol phosphate** at the cytoplasmic surface of the ER membrane serves as glycosyl acceptor for *N*-acetylglucosamine. Stepwise glycosylation and formation of a branched $(Man)_5(GlcNAc)_2$-pyrophosphoryl-dolichol on the cytosolic side of the membrane follows. This intermediate is then **reoriented** to the luminal surface of the ER membrane, and four additional mannose and three glucose residues are added. A complex membrane bound **oligosaccharyltransferase** then transfers the complete oligosaccharide from its dolichol carrier to an asparagine residue of the polypeptide as it emerges into the ER lumen. Note that *N*-glycosylation is **cotranslational;** it occurs as the protein is being synthesized and it can affect protein folding.

Glycosidases and **glycosyltransferases** now modify the newly transferred oligosaccharide. Glucose residues, which were required for transfer of the oligosaccharide from the dolichol carrier, are removed. The folded glycoprotein is transported to an ER-Golgi intermediate compartment where sorting occurs, and then to the Golgi apparatus. Further trimming may now occur, or additional sugars can be added. The resulting N-linked oligosaccharides are diverse, but two classes are distinguishable. Each has a common core region ($GlcNAc_2Man_3$) linked to asparagine and originating from the dolichol-linked intermediate. The **high-mannose type** includes mannose residues in a variety of linkages and shows less processing from the dolichol-linked intermediate. The **complex type** is more highly processed and diverse, with a larger variety of sugars and linkages (Figure 6.15).

In **O-linked glycosylation,** oligosaccharides are bound through hydroxyl groups of serine or threonine in proteins (p. 112). O-linked glycosylation occurs only after the protein has reached the Golgi apparatus; hence *O*-glycosylation is **posttranslational** and occurs only on folded proteins. There is no specific amino acid sequence in which the serine or threonine must occur, but only residues on the protein surface serve as acceptors for the **GalNAc-transferase** that attaches *N*-acetyl galactosamine. Stepwise addition of sugars to the GalNAc acceptor follows. The oligosaccharides formed depend on the types and amounts of glycosyltransferases in a given cell. If an acceptor is a substrate for more than one transferase, the amounts of each transferase influence the competition between them. Oligosaccharide growth stops when structures are formed that are not acceptors for any of the glycosyltransferases present. This can result in different oligosaccharide structures on otherwise identical polypeptides, so **heterogeneity** in glycoproteins is common (Figure 6.16).

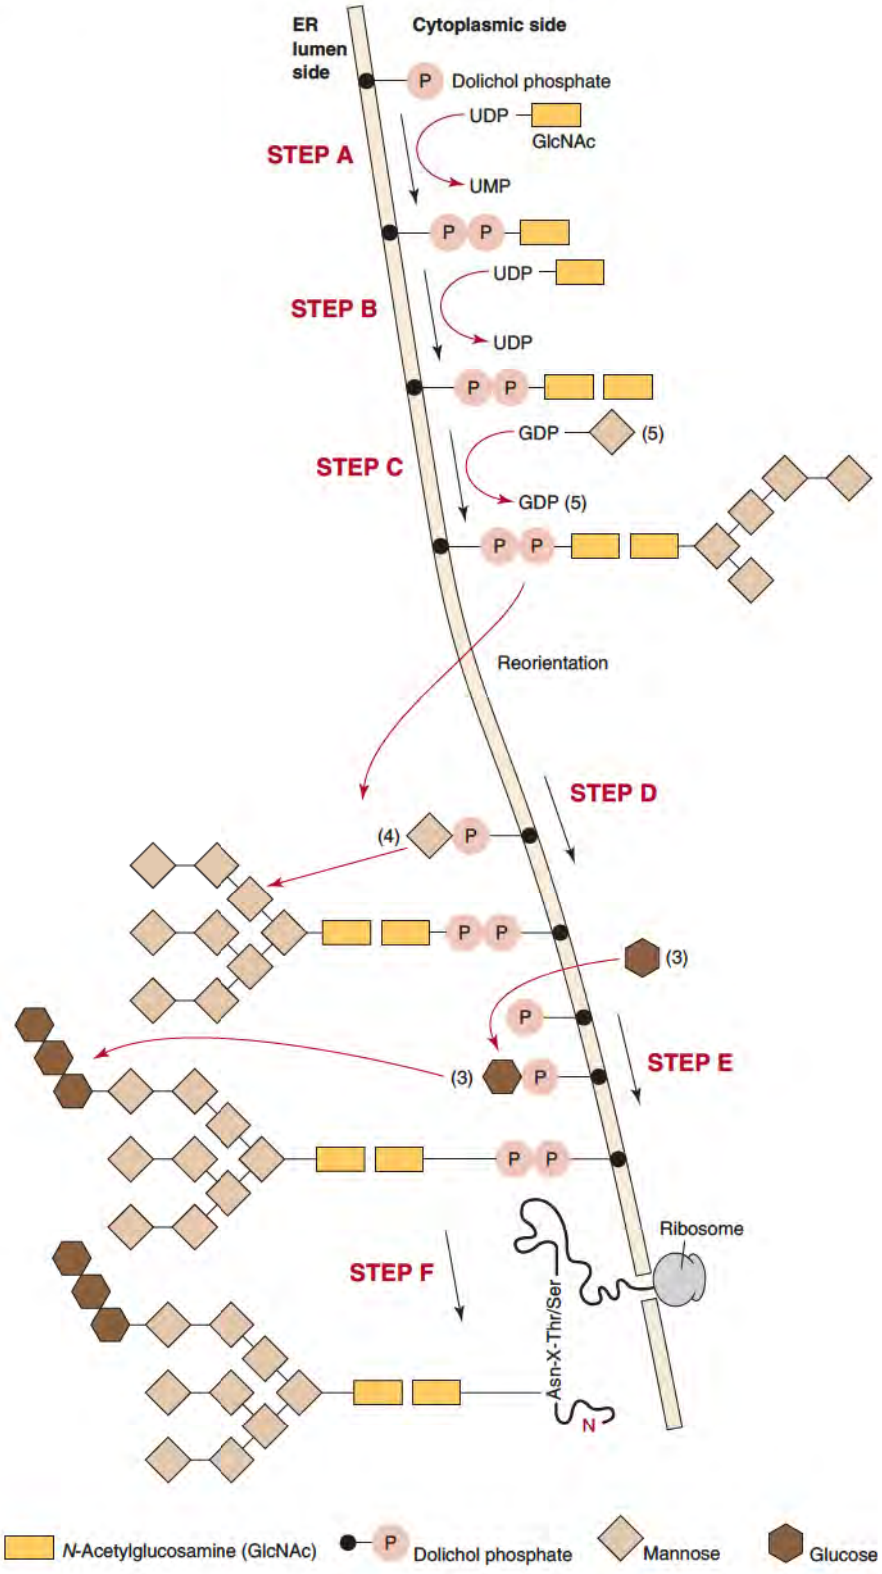

Figure 6.14 Biosynthesis of N-linked oligosaccharides at the endoplasmic reticulum. Step A: Synthesis begins on the cytoplasmic face of the ER membrane with transfer of *N*-acetylglucosamine phosphate to a dolichol acceptor. Step B: Formation of the first sugar-to-sugar glycosidic bond occurs on transfer of a residue of *N*-acetylglucosamine. Step C: Five residues of mannose (from GDP mannose) are added sequentially and the lipid-linked oligosaccharide is reoriented to the lumenal side of the membrane. Step D: Additional mannose and (step E) glucose residues are transferred from dolichol-linked intermediates. Dolichol-sugars are generated from cytosolic nucleoside diphosphate sugars. Step F: The completed oligosaccharide is transferred to a nascent polypeptide at the membrane surface; signal peptide may have already been cleaved at this point.

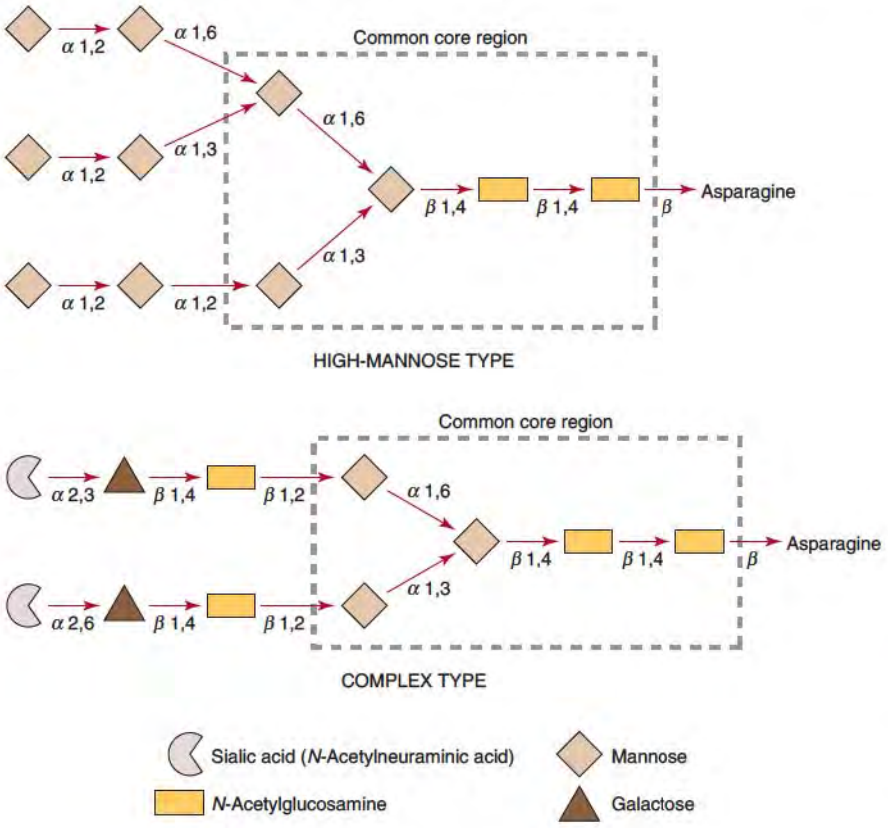

Figure 6.15 Structure of N-linked oligosaccharides.
Basic types of N-linked oligosaccharides are shown. Each structure is derived from the initial dolichol-linked oligosaccharide through action of glycosidases and glycosyltransferases. Note the variety of glycosidic linkages involved.

6.5 • MEMBRANE AND ORGANELLE TARGETING

Protein transport from the ER to and through the Golgi apparatus and beyond uses multiprotein carrier vesicles. Only correctly folded proteins are recognized as cargo for transport, and both general and protein-specific chaperones in the ER assist folding and foster correct disulfide formation. Chaperone networks also act at "checkpoints" in ER-Golgi transport to recognize misfolded or damaged proteins, which are returned to the cytosol for degradation in the process of **ER-associated degradation (ERAD).** Sorting of proteins for their ultimate destinations occurs in conjunction with their glycosylation and proteolytic trimming as they pass through the cis, medial, and trans elements of the Golgi apparatus. Families of vesicle and receptor proteins provide specificity for membrane targeting and fusion.

Sorting of Proteins in the Secretory Pathway

Targeting of specific glycoproteins to **lysosomes** is well understood. In the cis Golgi an aspect of tertiary structure allows lysosomal proteins to be recognized by a glycosyltransferase that attaches *N*-acetylglucosamine phosphate (GlcNAc-P) to high-mannose-type oligosaccharides. A glycosidase then removes the GlcNAc, forming an oligosaccharide that contains **mannose 6-phosphate** (Figure 6.17) that determines the compartmentation and vesicular transport of these proteins to lysosomes. Other oligosaccharide chains on the proteins may be further processed to form complex-type structures, but the mannose 6-phosphate defines their lysosomal destination. Patients with **I-cell disease** lack the GlcNAc-P glycosyltransferase, cannot mark lysosomal enzymes for their destination, and instead secrete them from the cell (Clin. Corr. 6.8). Genetic deficiencies of many lysosomal enzymes lead to diseases, some of which can be modulated by taking advantage of the targeting mechanism (Clin. Corrs. 6.9 and 18.5).

The secretory pathway directs proteins to lysosomes, to the plasma membrane, or for secretion from the cell. Proteins of the ER and Golgi apparatus are targeted through partial

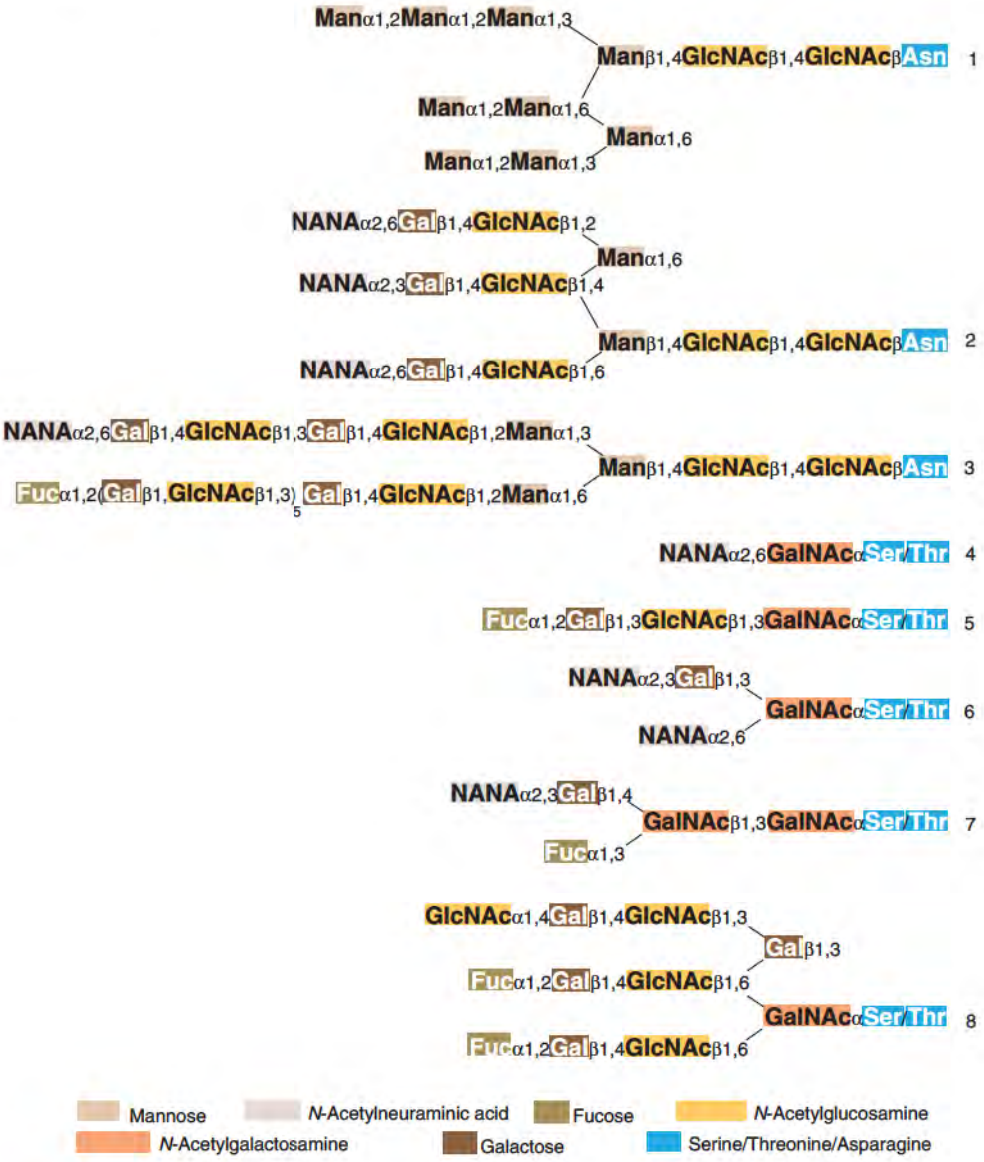

Figure 6.16 Examples of oligosaccharide structure. Structures 1–3 are typical N-linked oligosaccharides of high mannose (1) and complex types (2, 3); note the common core structure from the protein asparagine residue through the first branch point. Structures 4–8 are common O-linked oligosaccharides that may be simple or highly complex. Note that although the core structure (GalNAc-Ser/Thr) is unlike that of N-linked oligosaccharides, the termini can be quite similar (e.g., structures 2 and 6, 3, and 7). Abbreviations: Man = mannose, Gal = galactose, Fuc = fucose, GlcNAc = N-acetylglucosamine, GalNAc = N-acetylgalactosamine, and NANA = N-acetylneuraminic acid (sialic acid).
Adapted from Paulson, *J. Trends Biochem. Sci.* 14:272, 1989.

use of the pathway. For example, localization of proteins on either side of or spanning the ER membrane can utilize the signal recognition particle in different ways (Figure 6.18). Sometimes a signal sequence is not near the amino terminus of the protein but somewhere downstream where it is bound by SRP. An amino terminal domain remains on the cytoplasmic surface, and the signal sequence and C-terminal segment are passed into and through the translocon. Hydrophobic **anchoring sequences** in a protein can embed in the membrane yet allow much of the sequence to remain at the cytosolic surface or to be retained on the luminal surface of the ER membrane. Multiple anchoring sequences in a single polypeptide can cause it to span the membrane several times and thus retain it, largely buried in the membrane. Such hydrophobic sequences are separated by polar loops whose orientation is determined by positively charged flanking residues that predominate on the cytoplasmic side of the membrane.

Other sorting signals determine how proteins are directed (as cargo) to Golgi sub compartments, various storage and secretory granules, and specific elements of the plasma membrane. For example, soluble proteins are retained in the ER lumen in response to a C-terminal **KDEL** (Lys-Asp-Glu-Leu) sequence. A different sequence in an exposed C-terminus signals retention in the ER membrane. Some transmembrane domains result in retention in the Golgi. Polypeptide-specific glycosylation and sulfation of some glycoprotein hormones in the anterior pituitary mediates their sorting into storage granules.

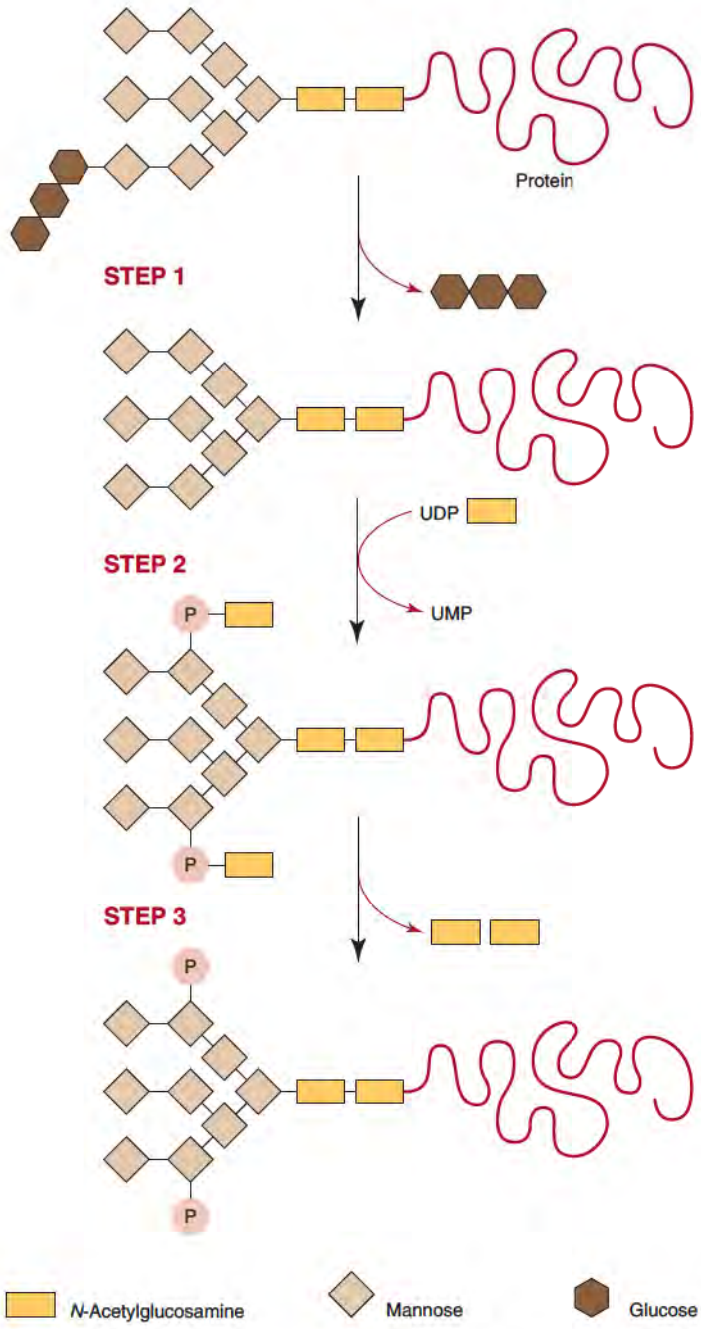

Figure 6.17 Targeting of proteins to lysosomes. Complete folded N-linked glycoprotein is released from the ER membrane and, prior to transport to the Golgi apparatus, glycosidases remove glucose residues (step 1). A mannose residue may also be removed. Step 2: In the Golgi apparatus a glycosyl transferase links one or sometimes two N-acetylglucosamine phosphate residues to the oligosaccharide. Step 3: A glycosidase removes N-acetylglucosamine, leaving one or two mannose 6-phosphate residues on the oligosaccharide. The protein is then recognized by a mannose 6-phosphate receptor and directed to vesicles that are targeted to lysosomes. Adapted from Kornfeld, R., and Kornfeld, S. *Annu. Rev. Biochem.* 54:631, 1985.

Polysialic acid modification of a neural cell adhesion protein is specific to the protein and regulated in development.

Import of Proteins by Mitochondria Is Complex

Mitochondria provide a special targeting problem, and defects in the system can lead to disease (Clin. Corr. 6.10). Most mitochondrial proteins are synthesized in the cytosol on free ribosomes as larger **preproteins.** N-terminal **presequences** mark the protein for the mitochondrion; the targeting signal is not a specific sequence, but rather a positively charged amphiphilic α-helix that is recognized by a mitochondrial receptor. The preproteins are transported with the aid of chaperones to the mitochondrion and translocated (unfolded) first across the outer membrane by the **translocase of the outer membrane (TOM) complex** and then into the mitochondrial matrix (or the inner membrane) by a **translocase of**

CLINICAL CORRELATION 6.8

Diseases of Lysosome Targeting: I-Cell Disease

I-cell disease (mucolipidosis II) arises from defects in lysosomal enzyme targeting because of a deficiency of **GlcNac-1-phosphotransferase,** the enzyme that transfers N-acetylglucosamine phosphate to the high-mannose-type oligosaccharides of proteins destined for the lysosome. The hexameric enzyme includes three types of subunit encoded in two genes, GNPTAB and GNPTG. Fibroblasts from affected individuals show dense inclusion bodies (hence I cells) and lack phosphotransferase activity; multiple lysosomal enzymes are secreted into the medium, and high levels of lysosomal enzymes are present in plasma and other body fluids of patients. The disease is characterized by severe psychomotor retardation, many skeletal abnormalities, coarse facial features, and restricted joint movement. Symptoms are usually present at birth and progress until death, usually by age 8. Almost all patients show frameshift or chain termination mutations in the GNPTAB gene.

Pseudo Hurler polydystrophy (mucolipidosis III) is a related but less severe disease in which phosphotransferase activity is reduced but not completely absent. Onset is usually delayed until the age of 2–4 years, the disease progresses more slowly, and patients can survive into adulthood. Prenatal diagnosis of both diseases is possible, but there is as yet no definitive treatment.

CLINICAL CORRELATION 6.9

Enzyme Replacement Therapy for Lysosomal Storage Diseases

Several diseases arise from a genetic deficiency of a single hydrolytic enzyme in lysosomes (see Clin. Corr. 18.5, p. 737), leading to accumulation of undegraded material. Several of these diseases are targets for **enzyme replacement therapy (ERT)** in which intravenous administration of purified human enzyme that is competent for lysosomal uptake can ameliorate symptoms (but not cure the underlying defect).

Mucopolysaccharidosis type I is caused by defects in α-L-iduronidase, a lysosomal enzyme that acts in the degradation of glycosaminoglycans. More than 70 mutations have been identified, and symptoms vary from severe mental retardation and early childhood death (Hurler syndrome) to milder effects including hearing loss and corneal clouding, but normal intelligence and lifespan. Enzyme replacement therapy using recombinant normal human enzyme was approved in 2003 and results in significant reduction in symptoms. Mucopolysaccharidosis type II (iduronate-2-sulfatase deficiency) and Mucopolysaccharidosis type VI (Maroteaux–Lamy syndrome, *N*-acetylgalactosamine deficiency) also are approved for ERT.

Gaucher disease results from deficiency of a glucocerebrosidase and the accumulation of glucocerebroside. Symptoms in type 1 Gaucher disease include hepatosplenomegaly and many bone problems; ERT, especially of young children, has been successful in reducing the severity of the disease. Infantile Pompe disease results from acid α-1, 4-glucosidase deficiency; it leads to glycogen accumulation in lysosomes and cardioskeletal myopathy. Fabry disease, caused by defective α-galactosidase-A, results in sphingolipid accumulation and organ damage that first appears at age 6–8 and death in middle age. ERT of these diseases has shown some success, but cost of purified enzymes for all of these therapies is very high.

Yogalingam, G., Guo, X.-H., Muller, V. J., Brooks, D. A., et al. Identification and molecular characterization of α-L-iduronidase mutations present in mucopolysaccharidosis type I patients undergoing enzyme replacement therapy. *Hum. Mutat.* 24:199, 2004; and Burrow, T. A., Hopkin, R. J., Leslie, N. D., Tinkle, B. T. and Grabowski, G. A. Enzyme reconstitution/replacement therapy for lysosomal storage diseases. *Curr. Opin. Pediatr.* 19:628, 2007.

the inner membrane (TIM) complex in energy-dependent reactions. Passage occurs at adhesion sites where inner and outer membranes are close together, and several intermembrane proteins are involved. Proteases remove the matrix targeting signal, but may leave other sequences that further sort the protein within the mitochondrion, back to the inner membrane, via a different TIM complex, or to the intermembrane space.

For example, in response to a hydrophobic sequence, a clipped precursor of cytochrome b_2 is moved from the matrix back across the inner membrane; further proteolysis frees it in the intermembrane space. In contrast, cytochrome c apoprotein (without heme) binds at the outer membrane and is passed into the intermembrane space. There it acquires its heme and undergoes a conformational change that assures retention. Outer membrane proteins are also targeted to the TOM complex, but anchoring sequences orient and retain them, either embedded in the membrane or with globular domains on the outer mitochondrial membrane surface.

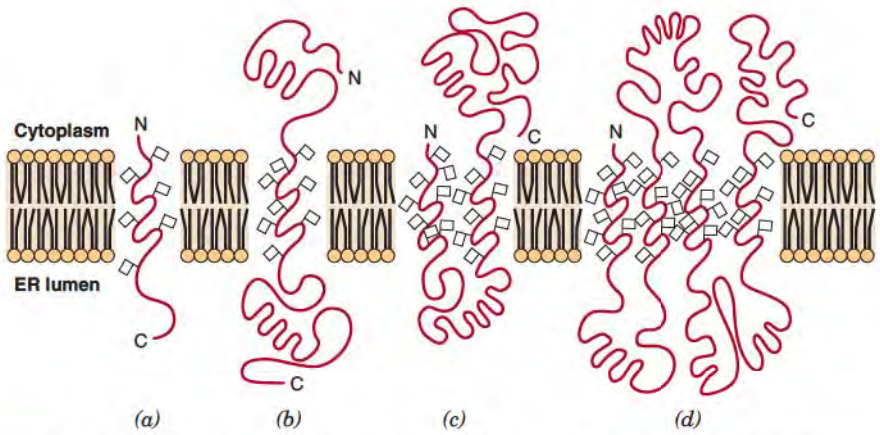

Figure 6.18 Topology of proteins at membranes of endoplasmic reticulum. Proteins are shown in several orientations with respect to membrane. In (*a*) the protein is anchored to lumenal surface of membrane by an uncleaved signal peptide. In (*b*) the signal sequence is not at the N-terminus; a domain of the protein was synthesized before emergence of signal peptide. Insertion of internal signal sequence, followed by completion of translation, resulted in a protein with a cytoplasmic N-terminal domain, a membrane-spanning central segment, and a C-terminal domain in the ER lumen. (*c*) A protein with the opposite orientation: an N-terminal signal sequence, which might also have been cleaved by signal peptidase, resulted in extrusion of a segment of protein into the ER lumen. A hydrophobic anchoring sequence remained membrane associated and prevented further passage of protein through the membrane, thus formatting a C-terminal cytoplasmic domain. In (*d*) several internal signal and anchoring sequences allow various segments of the protein to be oriented on each side of membrane.

CLINICAL CORRELATION 6.10

Defective Mitochondrial Protein Import and Disease

Inefficient targeting to mitochondria can have major consequences. Lactic acidemia resulting from deficiencies in the pyruvate dehydrogenase (PDH) complex has been linked to mutations in several genes, most commonly the X-linked E1α subunit. A point mutation resulting in an Arg → Pro substitution in the mitochondrial targeting signal results in decreased importation of E1α, lowered PDH activity, and multiple neurological and other symptoms. Mistargeting to the mitochondrion occurs in some cases of primary hyperoxaluria type 1. Alanine/glyoxylate aminotransferase normally catalyzes the conversion of glyoxalate to glycine in peroxisomes. Separate point mutations that create a mitochondrial targeting signal and alter enzyme folding and dimerization result in localization of the enzyme in the mitochondria; reduced peroxisome function; oxalate deposition in the kidney, urinary tract, and elsewhere; and eventual kidney failure. Improper sorting and localization in the mitochondrion is a factor in some cases of severe alcoholic liver disease. Manganese superoxide dismutase (MnSOD) is normally located in the mitochondrial matrix. Valine (rather than alanine) at position 16 in the targeting sequence results in partial retention of the enzyme in the inner mitochondrial membrane, reduced MnSOD activity, and reduced ability to detoxify reactive oxygen species that are generated by alcohol consumption.

Defects in proteins of the import and sorting mechanism also can result in disease. Deafness dystonia syndrome has been linked to defects in a TIM component Tim 8 (see Clin. Corr. 6.6 for a different cause of deafness linked to mitochondria). Defects in Tim 14 have been linked to a rare cardiomyopathy with ataxia. Decreased levels of the mitochondrial matrix chaperone Hsp60 are linked to reduced numbers and atypical morphology of mitochondria and cases of spastic paraplegia and multisystem failure.

Targeting Signals Direct Proteins to Specific Organelles

The nucleus must import proteins that are synthesized in the cytosol. Nuclear proteins are targeted by localization signals that include two closely separated clusters of basic amino acids or sometimes a single basic sequence. They interact with carrier proteins (e.g., importins) that transport them through cylindrical **nuclear pore complexes** that span the nuclear membrane. Transport requires the GTPase Ran. A different class of regulatory proteins shuttles between cytoplasm and nucleus to transmit signals to activate transcription.

Phosphorylation of an SPS (Ser-Pro-Ser) or TPT (Thr-Pro-Thr) sequence induces nuclear uptake.

Peroxisomes import their matrix proteins from the cytosol, and may need to adjust their enzyme content to meet cellular needs. One targeting signal is a carboxy-terminal tripeptide, **Ser-Lys-Leu (SKL),** which interacts with a cargo-binding transporter for movement to the peroxisome membrane for docking, translocation, and release into the matrix. An N-terminal nonapeptide targeting signal also functions, using a different transporter complex. Some proteins of the peroxisome membrane are synthesized in the cytoplasm, and are localized to the membrane by internal targeting signals. A second class of proteins are synthesized in the ER and exported to the peroxisome membrane.

Some proteins reside in more than one subcellular compartment. A suboptimal localization signal can lead to inefficient targeting and a dual location, as in the partial secretion of an inhibitor of the plasminogen activator. A protein can contain two targeting signals, resulting in dual localization. Gene duplication and divergence can result in different targeting signals in closely related mature polypeptides. Alternative transcription initiation sites or alternative splicing of pre-mRNA can generate different messages from a single gene. Alternatively spliced mRNAs for calcium/calmodulin-dependent protein kinase differ with respect to the presence of an internal segment that encodes a nuclear localization signal. Without this segment, the protein remains in the cytosol.

Finally, the first initiation codon in an mRNA is sometimes bypassed. **Alternative translation initiation** leads to two forms of rat liver fumarase; one includes a mitochondrial targeting sequence, while the other does not and remains in the cytosol.

6.6 • FURTHER POSTTRANSLATIONAL MODIFICATIONS

Additional maturation events can modify proteins to generate their final, functional forms. Some are very common, while others are highly restricted. Many reversible modifications regulate protein activity.

Partial Proteolysis Releases Insulin and Activates Zymogens

Partial proteolysis is a common maturation step. Sequences can be removed from either end or from within the protein. Proteolysis in the ER and Golgi apparatus helps to mature the protein hormone insulin (Figure 6.19). Preproinsulin encoded by mRNA is inserted into the ER lumen. Signal peptidase cleaves the signal peptide to generate proinsulin, which folds to form the correct disulfide linkages. Proinsulin is transported to the Golgi apparatus where it is packaged into secretory granules. An internal **connecting peptide (C-peptide)** is removed by proteolysis, and mature insulin is secreted. In familial hyperproinsulinemia processing is incomplete (Clin. Corr. 6.11). The pathway for insulin biosynthesis ensures production of equal amounts of A and B chains. Moreover, proinsulin folds into a conformation in which the cysteine residues are positioned for correct disulfide bond formation. Reduced and denatured proinsulin can refold correctly, whereas renaturation of reduced and denatured insulin is inefficient and leads to incorrect disulfide linkages.

Cleavage of precursor proteins is a common means of enzyme activation. Digestive proteases are classic examples (p. 1033). Inactive **zymogen** precursors are packaged in storage granules and activated by proteolysis after secretion. Thus, **trypsinogen** is cleaved to give **trypsin** plus an amino terminal hexapeptide, and **chymotrypsinogen** is cleaved to form **chymotrypsin** and two peptides (p. 1044).

Amino Acids Can Be Modified after Incorporation into Proteins

Although 20 amino acids are encoded genetically, **posttranslational modification** allows formation of many amino acid derivatives in proteins. Modification may be permanent or easily reversible. While the number of modified amino acids in a protein may be small, they often

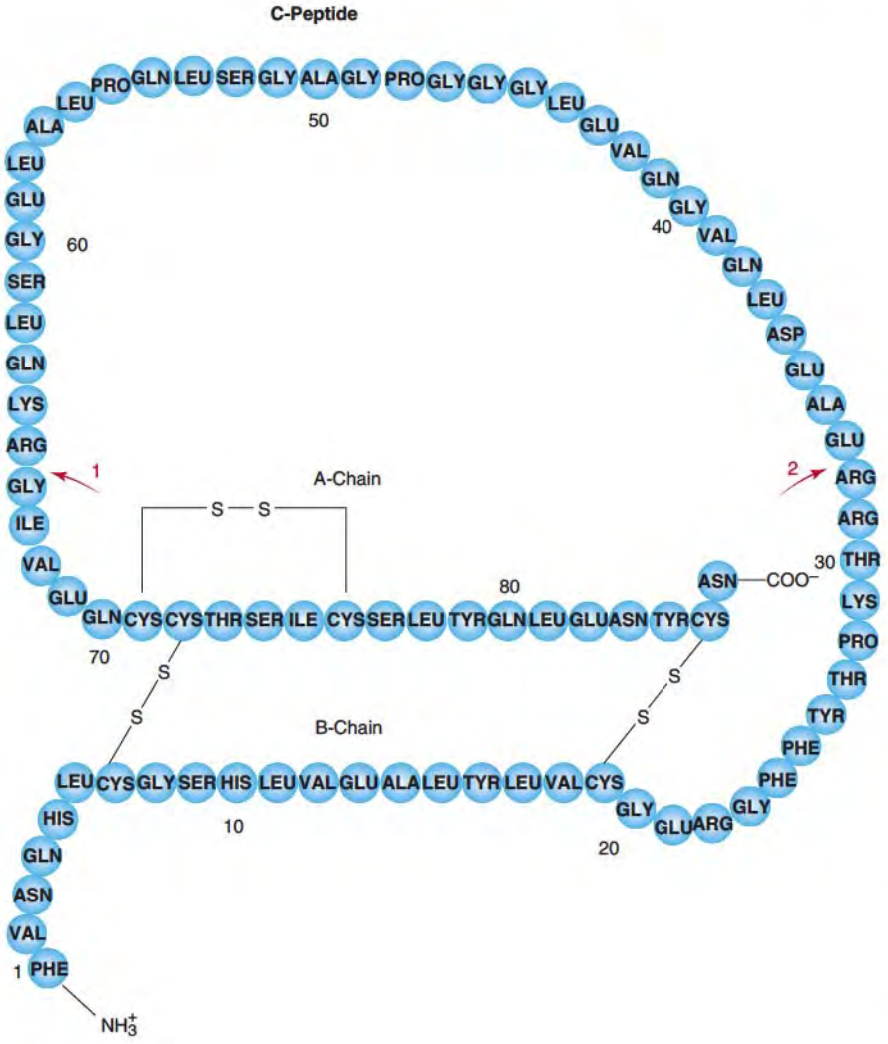

Figure 6.19 Maturation of human proinsulin. After cleavage at the two sites indicated by arrows, arginine residues 31, 32, and 65 and lysine residue 64 are removed to produce insulin and C-peptide. Redrawn from Bell, G. I., Swain, W. F., Pictet, R., Cordell, B., Goodman, H. M., and Rutter, W. J. *Nature* 282:525, 1979.

CLINICAL CORRELATION 6.11

Familial Hyperproinsulinemia (OMIM 176730)

Familial hyperproinsulinemia, an autosomal dominant condition, results in approximately equal amounts of insulin and an abnormally processed proinsulin being released into the circulation. Although affected individuals have high concentrations of proinsulin in their blood, they are apparently normal in terms of glucose metabolism, being neither diabetic nor hypoglycemic. The defect was originally thought to result from a deficiency of one of three proteases that process proinsulin: endopeptidases that cleave the Arg31-Arg32 and Lys64-Arg65 peptide bonds, and a carboxypeptidase. In several families the defect is the substitution of Arg65 by His or Leu which prevents cleavage between the C-peptide and the A chain of insulin resulting in secretion of a partially processed proinsulin. In one family a point mutation (His10 → Asp10) causes the hyperproinsulinemia, but how this mutation interferes with processing is not known.

Zhou, A., Webb, G., Zhu, X., and Steiner, D. F. Proteolytic processing in the secretory pathway. *J. Biol. Chem.* 274:20745, 1999.

have a major role in its function. Modified amino acids in proteins are listed in Table 6.11. Important examples include

- Amino-terminal modification: Protein synthesis is initiated using methionine, but proteolysis often removes one to several amino-terminal residues. The new amino-terminus is then often altered, for example, by acetylation. The α subunits of signal transducing G-proteins (p. 520) are derivatized with myristic or palmitic acid.

Amino-terminal glutamine often spontaneously cyclizes to form a pyroglutamyl residue. The amino terminus can also be lengthened by addition of an amino acid (see Section 6.8 on protein degradation).

- Interchain and intrachain disulfide bond formation: As catalyzed by **disulfide isomerase,** disulfide formation can prevent unfolding of proteins and their passage across membranes, so it also is a means of localization. As in the case of insulin, disulfide bonds can covalently link separate polypeptides and be necessary for function.
- Cysteine modification: *S*-palmitoylation aids membrane interactions and trafficking of some proteins. The γ-subunits of the heterotricyclic G proteins (p. 525) are modified by thioester linkage of an isoprenoid to a cysteine at or near the carboxy terminus. Multiple sulfatase deficiency arises from reduced ability to carry out a posttranslational modification of cysteine (Clin. Corr. 6.12).
- Lysine modification: Acetylation and methylation of lysine ε-amino groups in histones modulates their interactions with DNA. A fraction of the H2A histone is also modified through isopeptide linkage of a lysine ε-amino group to the C-terminal glycine of ubiquitin, a small protein with many regulatory functions. Biotin is also linked to a few carboxylases through amide linkages to lysine (p. 777).

TABLE 6.11 • Modified Amino Acids in Proteins[a]

Amino Acid	*Modifications Found*
Amino terminus	Formylation, acetylation, aminoacylation, myristoylation, glycosylation
Carboxy terminus	Methylation, ADP-ribosylation, glycosyl-phosphotidylinositol anchor formation
Arginine	N-Methylation, ADP-ribosylation
Asparagine	N-glycosylation, N-methylation, deamidation
Aspartic acid	Methylation, phosphorylation, hydroxylation, isomerization (iso Asp)
Cystine	Cystine formation, palmitoylation, heme linkage, S-glycosylation, prenylation, ADP-ribosylation, S-hydroxylation
Glutamine acid	Methylation, γ-carboxylation, ADP-ribosylation, polyglycination, polyglutamylation
Glutamine	Pyroglutamate formation, deamidation, crosslinking
Histidine	Methylation, phosphorylation, diphthamide formation, ADP-ribosylation
Lysine	N-Acetylation, N-methylation, hydroxylation, oxidation, ubiqutinylation, biotinylation, allysine formation, cross-linking
Methionine	Sulfoxide formation
Phenylalanine	β-Hydroxylation, glycosylation
Proline	Hydroxylation, glycosylation
Serine	Phosphorylation, glycosylation, acetylation, α-formylglycine formation, phosphopantetheinylation
Threonine	Phosphorylation, glycosylation,methylation
Tryptophan	β-Hydroxylation, dione formation, C-mannosylation
Tyrosine	Phosphorylation, iodination, adenylation, sulfonation, hydroxylation, nitration

Source: Krishna, R. G. and Wold, F. Post-translational modification of proteins. In: A. Meister (Ed.), *Advances in Enzymology,* Vol. 67, New York: Wiley InterScience, 1993, pp265–298. Walsh, C. T., Gameau-Tsodikova, S. and Gatto, G. J. Protein posttranslational modifications: the chemistry of proteome diversifications. *Angew. Chem. Int. Ed Engl.* 44: 7342, 2005.

[a]The listing is not comprehensive, and some modifications are rare. Note that no modifications of glycine alanine, leucine, isoleucine and valine have been reported in proteins.

- Serine and threonine hydroxyl groups: In addition to glycosylation, reversible phosphorylation by protein kinases and protein phosphatases is very common and functionally important. A classic example is phosphorylation of a serine residue of glycogen phosphorylase by phosphorylase kinase (p. 635). Tyrosine residues are phosphorylated by highly specific tyrosine kinases. Kinase activity is a property of many growth factor receptors in which growth factor binding stimulates cell division. Oncogenes, responsible in part for cell transformation and proliferation of tumor cells, often have tyrosine kinase activity and show strong homology with normal growth factor receptors. Dozens of other examples exist; together the protein kinases and protein phosphatases control the activity of many proteins that are central to normal and abnormal cellular development.
- ADP-ribosylation: **Diphtheria toxin** further modifies **diphthamide,** a modified histidine residue (Figure 6.20) of EF2, by ADP-ribosylation. EF2 activity and thus protein synthesis is inhibited. Physiological ADP-ribosylation, not mediated by bacterial toxins, usually involves reversible modification of arginine and cysteine residues and is important in cell signaling, and regulatory and surface proteins.
- **γ-carboxyglutamate** formation: Glutamic acid residues in several blood-clotting proteins including prothrombin and factors VII, IX, and X are modified. The γ-carboxyglutamate chelates calcium ion, which is required for blood clotting (p. 987). This modification requires vitamin K. It can be blocked by coumarin derivatives (p. 995), which antagonize vitamin K. Coumarin derivatives are therapeutic anticoagulants.

Collagen Biosynthesis Requires Many Posttranslational Modifications

Collagens are the most abundant proteins in humans. The collagen family includes at least 28 different species of mostly fibrous proteins that provide the structural framework for tissues and organs, and additional collagen-like proteins share structural characteristics. Collagens undergo many posttranslational modifications that illustrate the complexity of these processes, their effect on structure and function, and modification defects that result in serious diseases. Different collagens, designated Type I, II, III, IV, and so on (see p. 105 for details of structure) are encoded on several chromosomes and expressed in different tissues. Their amino acid sequences differ, but a repeating Gly-X-Y sequence of about 1000 residues predominates. Every third residue is glycine, about one-third of the X positions are occupied by proline, and a similar number of Y positions are 4-hy-

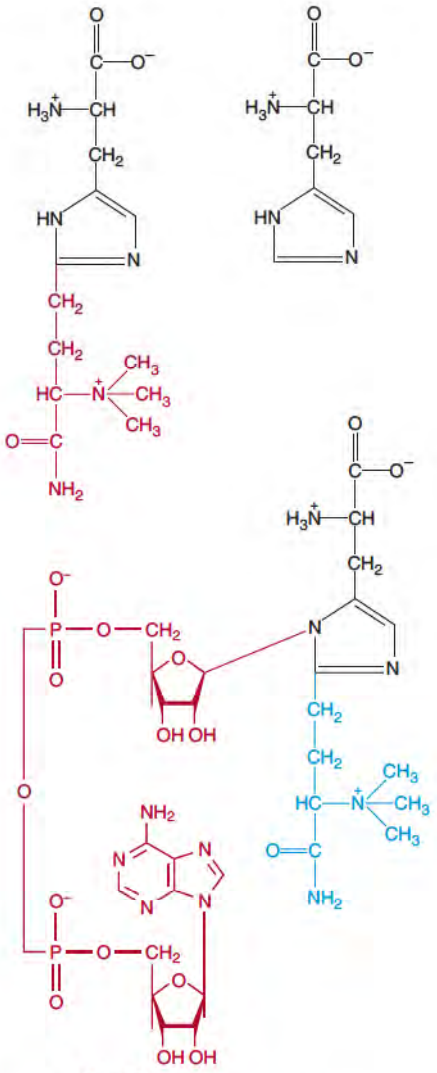

Figure 6.20 Diphthamide (top left) is a posttranslational modification of a specific residue of histidine (top right) in EF2. ADP-ribosyl-diphthamide is shown at the bottom.

CLINICAL CORRELATION 6.12

Absence of Posttranslational Modification: Multiple Sulfatase Deficiency (OMIM 272200)

Multiple sulfatase deficiency is a rare lysosomal storage disorder. Affected individuals develop slowly and from their second year of life lose the ability to stand, sit, or speak; physical deformities and neurological deficiencies develop and death before age 10 is usual. There is a severe lack of all sulfatase types. Degradation of sulfated molecules depends on the activity of several related sulfatases, most of which are lysosomal. Deficiencies in individual sulfatases are also known, and several distinct diseases are linked to single enzyme defects.

Multiple sulfatase deficiency arises from a defect in a posttranslational modification that is common to all sulfatase enzymes. In each case a cysteine residue of the enzyme is normally converted to C_α-formylglycine. Fibroblasts from individuals with multiple sulfatase deficiency catalyze this modification with significantly lowered efficiency, and the unmodified sulfatases are catalytically inactive.

Many biological molecules are sulfated, for example, glycosaminoglycans, steroids, and glycolipids. Poor sulfation is also responsible for diseases. For example, ineffective sulfation of the glycosaminoglycans chondroitin sulfate and keratan sulfate (p. 665) of cartilage results in major skeletal deformities.

A novel amino acid modification in sulfatases that is deficient in multiple sulfatase deficiency. *Cell* 82:271, 1995; and Dierks, T., Schmidt, B., Borissenko, L. V., Peng, J., et al. Multiple sulfatase deficiency is caused by mutations in the gene encoding the human C-formylglycine generating enzyme. *Cell* 113:435, 2003.

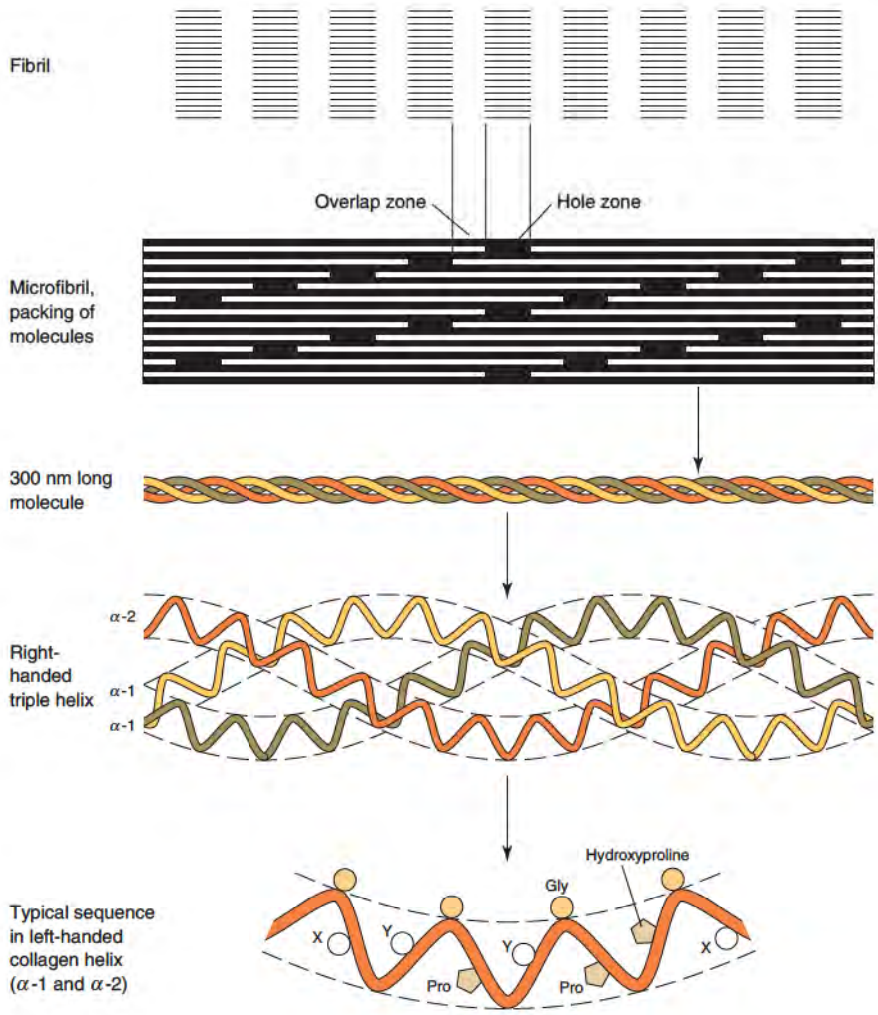

Figure 6.21 Collagen structure, illustrating (bottom to top) the regularity of primary sequence in a left-handed polyproline type II helix; the right-handed triple helix; the 300-nm molecule; and the organization of molecules in a typical fibril, within which collagen molecules are cross-linked.

droxyproline, a posttranslationally modified form of proline. Proline and hydroxyproline residues impart rigidity to their polyproline type II helix structure (Figure 6.21). Each collagen polypeptide is designated an α-chain; a collagen molecule has three α-chains intertwined in a collagen triple helix in which glycine residues occupy the center of the structure (p. 105).

Procollagen Formation in the Endoplasmic Reticulum and Golgi Apparatus

Collagen α-chain synthesis starts in the cytosol. Amino terminal signal sequences bind signal recognition particles and precursor forms, designated for example prepro α 1(I), are extruded into the ER lumen. Tissue-specific hydroxylation of proline and lysine residues occurs cotranslationally, before assembly of a triple helix. Prolyl 4-hydroxylase requires an -X-Pro-Gly- sequence (hence, 4-hydroxyproline is found only at Y positions in the -Gly-X-Y- sequence). Prolyl 3-hydroxylase modifies a smaller number of proline residues, and lysyl hydroxylase modifies some of the Y-position lysine residues. These hydroxylases require Fe^{2+} and ascorbic acid (vitamin C). Proline hydroxylation stabilizes collagen while lysine hydroxylation provides sites for interchain crosslinking and for glycosylation by specific glycosyltransferases of the ER. The extent of modification depends on the specific α-chain type and cell in which it occurs.

Chaperone-mediated **triple-helix assembly** occurs after the polypeptide chains have been completed and the signal peptides are cleaved. Carboxy-terminal globular proprotein domains fold and disulfide bonds are formed between them. This initiates winding of the triple helix from the carboxyl- toward the amino-termini. The completed triple helix, with globular proprotein domains at each end, moves to the Golgi apparatus where oligosaccharides

TABLE 6.12 • Selected Disorders in Collagen Biosynthesis and Structure

Disorder	*Collagen Defect*	*Clinical Manifestations*
Osteogenesis imperfecta 1	Decreased synthesis of type I	Long bone fractures prior to puberty
Osteogenesis imperfecta 2	Point mutations and exon rearrangements in triple helical regions	Perinatal lethality; malformed and soft, fragile bones
Ehlers—Danlos IV	Poor secretion, premature degradation of type III	Translucent skin, easy bruising, arterial and colon rupture
Ehlers—Dardos VI	Decreased hydroxylysine in types I and III	Hyperextensive skin, joint hypermobility
Ehlers—Danlos VII	Type I procollagen accumulation: N-terminal propeptide not cleaved	Joint hypermobility and dislocation
Cutis laxa (occipital horn syndrome)	Decreased hydroxylysine due to poor Cu distribution	Lax, soft skin; occipital horn formation in adolescents
Scurvy	Hydroxyproline decreased due to ascorbic acid deficiency	Poor bone growth, poor wound healing, severe bruising

are processed and matured. Sometimes tyrosine residues are modified by sulfation and some serines are phosphorylated. The completed procollagen is then released from the cell via secretory vesicles.

Collagen Maturation

Conversion of procollagen to collagen occurs extracellularly. In fibril-forming collagens (e.g., type I) the amino- and carboxyl-terminal propeptides are cleaved by separate proteases, while the carboxyl-terminal propeptides are retained in network-forming collagens (e.g., type IV). Concurrently, the triple helices assemble into fibrils by end-to-end and side-to-side aggregation, and the collagen is stabilized by extensive cross-linking. **Lysyl oxidase** converts some lysine or hydroxylysine to the reactive aldehydes, allysine, or hydroxyallysine. These residues condense with each other or with lysine or hydroxylysine residues in adjacent chains to form Schiff's base and aldol cross-links. Less well-characterized reactions can involve other residues including histidine and can link three α-chains. Defects at many of these steps are known and some of the best characterized are listed in Table 6.12 and described in Clin. Corr. 6.13.

6.7 • REGULATION OF TRANSLATION

The amount of protein in cells is regulated at the levels of transcription, translation, and degradation. Regulation of translation can be global, affecting protein synthesis in general, or it can be much more specific for individual proteins or groups of proteins. The most effective and common mechanisms for regulation of translation are at the initiation stage, and **phosphorylation** of initiation factors can serve, depending on circumstances, to either suppress or stimulate translation.

The best-understood mechanism of global regulation of translation involves reversible phosphorylation of serine 51 of the α-subunit of eIF2. Under conditions such as nutrient starvation, heat shock, and viral infection, eIF2 is phosphorylated. It remains functional, but phosphorylated eIF2–GDP binds very tightly to eIF2B, the guanine nucleotide exchange factor. eIF2B is present in limiting amounts and becomes unavailable for nucleotide exchange; hence no eIF2–GTP is available for initiation. Paradoxically, phosphorylated eIF2 stimulates translation of a transcription factor that that upregulates stress response genes.

CLINICAL CORRELATION 6.13

Defects in Collagen Synthesis

Osteogenesis Imperfecta (OMIM 166210)

Osteogenesis imperfecta is a group of at least seven clinically, genetically, or biochemically distinguishable disorders characterized by bone fragility, deformities, and low bone mass. Several variants result from mutations that produce modified α(I) chains, and the effect on severity of the symptoms varies widely. In the clearest example a deletion mutation causes absence of 84 amino acids in the α1(I) chain. The shortened α1(I) chains associate with normal α1(I) and α2(I) chains and prevent normal collagen triple helix formation, with resultant degradation of all of the chains. Three-fourths of all of the collagen molecules formed have at least one defective α1(I). Other forms of osteogenesis imperfecta result from point mutations that substitute another amino acid for a glycine. Since glycine has to fit into the interior of the collagen triple helix, these substitutions destabilize that helix.

Cheung, M. S., and Glorieux, F. H. Osteogenesis imperfecta: update on presentation and management. *Rev. Endocr. Metab. Disord.* 9:153, 2008; and Barsh, G. S., Roush, C. L., Bonadio, J., Byers, P. H., and Gelinas, R. E. Intron mediated recombination causes an α1(I) collagen deletion in a lethal form of osteogenesis imperfecta. *Proc. Natl. Acad. Sci. USA* 82:2870, 1985.

Ehlers–Danlos Syndrome, Type IV (OMIM 130050)

Ehlers–Danlos syndrome is a group of at least 10 disorders that are clinically, genetically, and biochemically distinguishable but that share manifestations of structural weaknesses in connective tissue. The usual problems are with fragility, hyperextensibility of skin, and hypermobility of joints. Type IV Ehlers–Danlos syndrome is caused by defects in type III collagen (p. 105), which is particularly important in skin, arteries, and hollow organs. Characteristics include thin, translucent skin through which veins are easily seen, marked bruising, and sometimes an appearance of aging in the hands and skin. Clinical problems arise from arterial rupture, intestinal perforation, and rupture of the uterus during pregnancy or labor. Surgical repair is difficult because of tissue fragility. Defects in type IV Ehlers–Danlos arise from changes in the structure of type III chains, due to point mutations that replace glycine residues and disrupt the collagen triple helix, and from exon skipping which shortens the polypeptide and can result in inefficient secretion, decreased stability of the collagen, and abnormal formation of type III collagen fibrils. In some cases, type III collagen accumulates in the rough ER and is degraded very slowly.

Germain, D. P. Ehlers–Danlos syndrome type IV. *Orphanet J. Rare Dis.* 2:32, 2007; and Superti-Furga, A., Gugler, E., Gitzelmann, R., and Steinmann, B. Ehlers–Danlos Syndrome type IV: A multi-exon deletion in one of the two COL 3A1 alleles affecting structure, stability, and processing of type III procollagen. *J. Biol. Chem.* 263:6226, 1988.

Deficiency of Lysylhydroxylase (OMIM 225400)

In type VI Ehlers–Danlos syndrome lysylhydroxylase is deficient. At least 20 different mutations are known that result in type I and III collagens (p. 105) with lowered hydroxylysine content and subsequently less stable cross linking of collagen fibrils. Some cross-links between lysine and allysine form but these are not as stable and do not mature as readily as hydroxylysine-containing cross links. Hydroxylysine is also a site of glycosylation, but the function of this modification is unclear. Clinical features include marked hyperextensibility of skin and joints, poor wound healing, and musculoskeletal deformities. Some patients have a mutant form of lysylhydroxylase with a higher Michaelis constant for ascorbic acid than the normal enzyme. Accordingly, they respond to high doses of ascorbic acid.

Pinnell, S. R., Krane, S. M., Kenzora, J. E., and Glimcher, M. J. A heritable disorder of connective tissue: hydroxylysine deficient collagen disease. *N. Engl. J. Med.* 286:1013, 1972; and Yeowell, H. N., and Walker, L. C. Mutations in the lysyl hydroxylase 1 gene that result in enzyme deficiency and the clinical phenotype of Ehlers–Danlos syndrome type VI. *Mol. Gen. Metab.* 71:212, 2000.

Ehlers–Danlos Syndrome, Type VII (OMIM 225410)

In this condition skin bruises easily and is hyperextensible, but the major manifestations are dislocations of major joints, such as hips and knees. Laxity of ligaments can be caused by incomplete removal of the amino-terminal propeptide of procollagen chains. One variant results from deficiency of procollagen *N*-protease known as ADAMTS2. A similar deficiency occurs in the autosomal recessive disease called dermatosparaxis of cattle, sheep, and cats, in which skin frailty is so extreme as to be lethal. In other variants the proα1(I) and proα2(I) chains lack amino acids at the cleavage site because of skipping of one exon in the genes. This prevents normal cleavage by procollagen *N*-protease.

Cole, W. G., Chan, D., Chambers, G. W., Walker, I. D., and Bateman, J. F. Deletion of 24 amino acids from the proα1(I) chain of type I procollagen in a patient with the Ehlers–Danlos syndrome type VII. *J. Biol. Chem.* 261:5496, 1986; and Tang, B. L. ADAMTS: A novel family of extracellular matrix proteases. *Int J. Biochem. Cell Biol.* 33:33, 2001.

Occipital Horn Syndrome (OMIM 304150)

Occipital horn syndrome is also known as type IX Ehlers–Danlos syndrome or cutis laxa and is related to Menkes' kinky hair syndrome. Defects in a gene encoding a trans-Golgi copper-transporting ATPase underlie these disorders, which appear as a deficiency in copper-dependent lysyl oxidase activity and thus cross-linking defects in collagen. In occipital horn syndrome characteristics include lax, soft skin and the appearance during adolescence of bony occipital horns. In Menkes' kinky hair syndrome, a variable but usually more severe disorder, patients show neurological problems such as seizures and developmental delay, failure to thrive, peculiar hair, and sometimes death in infancy or early childhood. A woman taking high doses of the copper-chelating drug, penicillamine, gave birth to an infant with an acquired Ehlers–Danlos-like syndrome, which subsequently improved. Side effects of d penicillamine therapy include poor wound healing and hyperextensible skin. Copper-deficient animals also show poor cross-linking of elastin and collagen, again because of the requirement for cuprous ion by lysyl oxidase.

Alterations of copper and collagen metabolism in the Menkes syndrome and a new subtype of Ehlers–Danlos syndrome. *Biochem.* 22:6156, 1983.

Continued on Page 247

Clinical Correlation 6.13 (continued)

Scurvy and Hydroxyproline Synthesis

Most animals, but not humans, can synthesize ascorbic acid (vitamin C). Scurvy is historically associated with long sea voyages and vitamin C deficiencies due to a lack of fresh fruit and vegetables. Clinical manifestations include poor wound healing, increased capillary fragility and severe bruising, gingival bleeding, and suppression of the orderly process of bone growth in children. Among other problems, ascorbic acid deficiency causes decreased hydroxyproline synthesis because prolyl hydroxylase requires ascorbic acid. Hydroxyproline provides additional hydrogen-bonding atoms that stabilize the collagen triple helix. Collagen containing insufficient hydroxyproline is significantly less stable than normal collagen at body temperature. Severe ascorbic acid deficiency leads secondarily to a decreased rate of procollagen synthesis.

Peterofsky, B. Ascorbate requirement for hydroxylation and secretion of procollagen: relationship to inhibition of collagen synthesis in scurvy. *Am. J. Clin. Med.* 54:1135S, 1991; and Olmedo, J. M., Yiannias, J. A., Windgassen, E. B., and Gornet, M. K. Scurvy: A disease almost forgotten. *Int. J. Dermatol.* 45:909, 2006.

Phosphorylation of eIF2 can be catalyzed by a **heme-regulated kinase** that is active in the absence of heme. This kinase is present in many cells, but has been best studied in reticulocytes that synthesize hemoglobin. A deficiency in energy supply or any heme precursor activates the kinase. A related **double-stranded RNA-dependent kinase** is activated by binding of ds-RNA that results from viral infection. Production of this kinase is also induced by interferon.

In contrast, initiation factor eIF4E is **activated** by phosphorylation of a serine residue in response to, for example, growth factors. Phosphorylation interferes with the binding of inhibitory eIF4E-binding proteins. Reversal by a protein phosphatase follows, for example, viral infection. These effects are mediated by eIF4G that is also activated by phosphorylation.

Regulation of translation of specific mRNAs is important in regulating the amounts and balance of proteins in a cell. Localization and packaging of mRNAs allows specific messages to be translated where they are needed or for mRNAs to be stored for future use. Localization within the cell relies on RNA sequences called **targeting elements** (or zip codes or localization elements), which interact with RNA binding proteins that concentrate the mRNAs at a subcellular site. Messages are sometimes packaged into storage granules during development or into **P bodies:** aggregates of translationally repressed mRNAs, regulatory proteins, and mRNA decay enzymes. These mRNAs may be degraded, but they can also be stored and returned to the cytoplasm for translation. P bodies help reprogram translation at times of stress.

A clear example of messenger-specific regulation is synthesis of the iron-binding protein ferritin. In the absence of iron a repressor protein binds to the **iron response element (IRE),** a stem–loop structure in the 5′-leader sequence of ferritin mRNA (p. 1089). This mRNA is sequestered for future use. δ-Aminolevulinic acid synthase, an enzyme of heme biosynthesis, is also regulated by a 5′-IRE in its mRNA. In contrast, more **ferritin receptor** is needed if iron is limited; its mRNA has IREs in its 3′-untranslated region. Binding of the repressor protein stabilizes the mRNA and prolongs its lifetime. Many growth-regulated mRNAs, including those for ribosomal proteins, have a polypyrimidine tract in their leader sequence. A polypyrimidine binding protein helps regulate their translation.

In addition to its roles in information transfer (mRNA) and translation (tRNA, rRNA), RNA is very important in regulation of gene expression in multiple biological functions, often in a tissue specific manner. Several classes of small RNAs bind specific groups of proteins and interact with mRNA to regulate transcription and translation in processes called **RNA silencing** and **RNA interference.** In humans almost 500 different **micro-RNA (miRNA)** genes exist. Larger hairpin RNAs are processed in the nucleus by a **Drosha** nuclease and then by a cytoplasmic endonuclease called **Dicer** to generate 21–23 nucleotide-long double-stranded RNAs. An RNA helicase separates the strands, one of which is bound by an **RNA-induced silencing complex (RISC),** the central component of which is an **Argonaute** protein. The RISC guides the miRNA to complementary sequences of mRNA, often in the 3′-untranslated region. Formation of an imperfect mRNA–miRNA duplex represses translation but does not immediately affect mRNA

stability. Cooperative interaction of multiple miRNAs with an mRNA increases efficiency of inhibition. The miRNAmRNA complexes may be directed to cytoplasmic **P bodies** for storage or degradation. Dicer and the RISC also generate perfectly complementary duplexes of small RNA molecules with mRNA. These complexes result in cleavage and inactivation of the target mRNA by an RISC endonuclease called **slicer** and other nucleases that degrade the mRNA.

Several more classes of small RNA have been identified. **Small interfering RNAs (siRNAs)** are generated from double-stranded RNA; they can be endogenous or virally derived and function like miRNA. Other classes are transcribed from repetitive DNA sequences, derived from single-stranded transcripts, and may be larger than miRNAs. Chemically synthesized interfering **RNA**$_i$ mimics miRNA and is a valuable laboratory tool and potential therapeutic agent.

6.8 • PROTEIN DEGRADATION AND TURNOVER

Protein lifetimes vary widely. Lens cells are not replaced and their proteins are not recycled. Hemoglobin lasts the 120-day life of the red blood cell. Some blood-clotting proteins survive only a few days, so hemophiliacs are only protected for a short period by transfusion or injection of required factors. Diabetics require frequent insulin injections since hormone needs vary (see Clin. Corr. 21.8, p. 868). Metabolic enzymes vary quantitatively depending on need or changing situation; for example, the concentration of urea cycle enzymes changes in response to diet. Proteins are also damaged by oxidation, proteolysis, denaturation, or other irreversible modifications. Errors in translation and folding lead to nonfunctional proteins, and proteolytic processing generates nonfunctional peptides such as the C-peptide of proinsulin. Disposal mechanisms are needed; proteolysis reduces unwanted proteins to peptides and eventually amino acids. Most of these amino acids are recycled to synthesize new proteins, but some are metabolized and their degradation products excreted. Digestive proteases such as pepsin, trypsin, chymotrypsin, and elastase hydrolyze dietary protein and have no part in intracellular protein turnover, but the amino acids they generate contribute to the metabolic pool used in translation. This is particularly necessary for the essential amino acids (see Table 19.1, p. 753).

Figure 6.22 Model of the proteasome. A 20S central segment that includes 12–15 different polypeptides is made up of four stacked heptameric rings, with a hollow core that includes several proteases with different specificities. V-shaped segments at each end cap the cylinder and act in ATP-dependent substrate recognition, unfolding, and translocation into the core. The upper cap structure is shown displaced from the central segment in order to illustrate the hollow core of the cylinder. Adapted from Rubin, D., and Finley, D. *Cur. Biol.* 5:854, 1995; and Peters, J.-M. Trends *Biochem. Sci.* 19:377, 1994.

ATP-Dependent Proteolysis Occurs in Proteasomes

The best-described proteolytic pathway uses proteasomes, dumbbell-shaped structures that contain about 28 polypeptides (Figure 6.22). A cylindrical core is capped at each end by V-shaped complexes that help recognize and unfold polypeptides and transport them to the proteolytic core in an ATP-dependent mechanism. Targeting to proteasomes normally requires **ubiquitin,** a highly conserved 76 amino acid protein. Proteins are marked for degradation by **polyubiquitinylation,** as shown in Figure 6.23. Ubiquitin is activated by enzyme E1 to form a thioester; ATP is required and a transient AMP-ubiquitin complex forms. The ubiquitin is then passed to enzyme E2, and finally via one of a group of E3 multiprotein complexes to a targeted protein. Linkage of ubiquitin is through **isopeptide** bonds between ϵ-amino groups of lysine residues of the protein and the carboxyl-terminal glycine residues of ubiquitin. Several ubiquitin molecules are attached to the protein and to each other, and the polyubiquitinylated protein is brought to the proteasome and degraded; an **isopeptidase** releases intact ubiquitin for reuse. Damaged, defective, misfolded, and mutant proteins are rapidly degraded via the ubiquitin pathway, and accumulation of undegraded protein can lead to disease (Clin. Corr. 6.14). For example, deletion of one amino acid alters the stability of CFTR protein (see Clin. Corr. 6.7, p. 231) in cystic fibrosis. Selection of native proteins for degradation depends on E3 enzyme specificity; both conformation and amino acid sequence are important. Destabilizing PEST sequences (rich in Pro, Glu, Ser, and Thr) occur in several short-lived proteins, and an ubiquitin-interacting motif that binds ubiquitin and sometimes also promotes ubiquitinylation has been identified. Another determinant is the identity

of the amino-terminal amino acid. In accord with the **N-end rule,** proteins with different amino-terminal residues are degraded at widely differing rates, and the lifetime of a protein can be modified by incorporation of an N-terminal destabilizing residue from an aminoacyl-tRNA donor. Misfolded proteins in the ER are usually degraded through the ubiquitin pathway. Chaperones and lectins in the ER keep misfolded N-linked glycoproteins from aggregating and target them for retrotranslocation back to the cytosol in the process called **ERAD** (**ER-associated degradation**).

Ubiquitin-dependent proteolysis plays a major role in the regulation of cellular events. Cyclins (p. 1016) and receptor protein tyrosine kinases (p. 509) are involved in control of cell division. Ubiquitin-dependent destruction of a cyclin allows cells to pass from the M phase into G1, while degradation of receptors prevents signal transduction and halts cell proliferation. Other proteins degraded by ubiquitin-dependent proteolysis include transcription factors, the p53 tumor suppressor and other oncoproteins, protein kinases, and immune system and other cell surface receptors.

Polyubiquitinylation is necessary to signal proteolysis; for example, polyubiquitinyl-p53 is degraded, while monoubiquitinyl-p53 is targeted for export from the nucleus. Defects in ubiquitin-dependent proteolysis lead to disease (Clin. Corr. 6.15). Other roles of ubiquitin are described in A Closer Look 6.4.

Like proteasomes, the complex prokaryotic proteases Lon and Clp and FtsH require ATP hydrolysis for their action, but ubiquitin is absent in prokaryotes. These proteases also are assembled into barrel-like structures and the ATPase powers unfolding of the substrate protein. An N-end rule applies through a smaller number of N-terminal destabilizing amino acids.

Intracellular Digestion of Some Proteins Occurs in Lysosomes

Intracellular digestion of proteins from the extracellular environment occurs within protease-rich **lysosomes.** Material that does not permeate the plasma membrane is imported by endocytosis. In **pinocytosis** large particles, molecular aggregates, or other material in the extracellular fluid are engulfed. Macrophages ingest bacteria and dead cells by this mechanism. **Receptor-mediated endocytosis** uses cell surface receptors to bind specific molecules at pits in the cell surface that are coated with the multisubunit protein clathrin. Invagination of the plasma membrane and the ligand-bound receptors forms intracellular clathrin-coated vesicles, one fate of which is fusion with a lysosome and degradation of the contents. Some intracellular protein turnover may also occur within lysosomes, and under some conditions significant amounts of cellular material can be degraded by lysosomes. For example, serum starvation of fibroblasts or starvation of rats leads to the lysosomal degradation of a subpopulation of cellular proteins. Recognition of a specific peptide sequence is involved, again indicating that the lifetime of a protein is ultimately encoded in its sequence.

Other Proteolytic Systems

Apoptosis (p. 1010), also called programmed cell death, follows on proteolytic activation of proteases known as **caspases** (cysteine aspartyl proteases). Stresses such as inflammation, cell damage, or a deficiency of growth factors can either directly activate caspases or cause mitochondria to release cytochrome c and other factors that activate a caspase cascade and result in the rapid degradation of cellular proteins. A caspase in the ER acts in ER stress-induced apoptosis, while other Golgi and ER proteases degrade misfolded proteins and peptide fragments that arise during maturation of proteins in the secretory pathway. Proteins are also exported from the ER for degradation by proteasomes.

Calcium-dependent thiol proteases, also called calpains, are present in most cells and function in, for example, cellular proliferation, differentiation, and progression through the cell cycle through selective and limited proteolysis. Calpains also function with proteasomes in protein turnover, and other roles are indicated but less well established. It appears that protein degradation is as complex and important a process as protein biosynthesis.

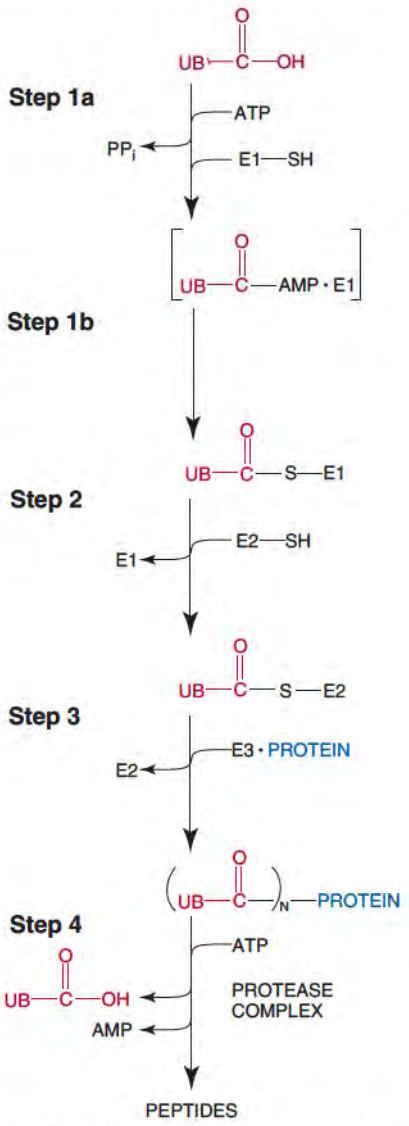

Figure 6.23 ATP and ubiquitin-dependent protein degradation. Ubiquitin is activated in a two-step reaction involving formation of a transient mixed anhydride of AMP and the carboxy-terminus of ubiquitin (step 1a), followed by generation of a thioester with enzyme E1 (step 1b). Enzyme E2 forms a thioester with ubiquitin (step 2) and serves as a donor in E3-catalyzed transfer of ubiquitin to a targeted protein (step 3). Several more ubiquitin molecules are attached to lysine residues of the ubiquitin and/or other lysines of the targeted protein at this stage. Polyubiquitinylated protein is degraded by ATP-dependent proteolysis (step 4); ubiquitin is not degraded, and can reenter the process at Step 1.

CLINICAL CORRELATION 6.14

Protein Misfolding and Aggregation: Huntington Disease and Alzheimer Disease

Misfolded proteins are usually degraded, as occurs with mutant CFTR protein in cystic fibrosis (see Clin. Corr. 6.7, p. 231). Several neurological diseases illustrate the result of cellular aggregation of misfolded proteins or their partial-degradation products.

Huntington disease (OMIM 143100) is an autosomal dominant neurodegenerative disorder in which patients show spasmodic movements in voluntary muscles, personality changes, and cognitive dysfunction; all grow more severe over time. Huntington disease is associated with accumulation of protein aggregates derived from **huntingtin,** a primarily cytoplasmic protein. Huntington is essential for embryonic development and is involved in transcription regulation, vesicle trafficking, and synapsis; mechanisms are not well understood. Variants of huntingtin are involved in Huntington disease; a CAG codon within the gene is expanded, resulting in polyglutamine repeats of 35 to 180 residues within huntingtin. Longer polyglutamine repeats are associated with more severe disease. Protein and peptides derived from huntingtin accumulate in inclusions in the nucleus, and transcription is affected. Mitochondrial function is also disturbed and reactive oxygen species increase, and the ubiquitin-proteasome pathway is impaired. Several other neurodegenerative disorders are also linked to polyglutamine tract expansion and protein deposition

Alzheimer disease (OMIM 104300) is characterized by progressive loss of memory and cognition, and it is most common in elderly people. Mitochondrial dysfunction in neural cells is prevalent. Alzheimer disease is characterized by accumulation of intraneuronal and extracellular bundles and filaments that form plaques. The major component of the plaque is β-amyloid, a 39–43 residue peptide derived from a larger amyloid precursor protein. Other components include the GM1 ganglioside, a microtubule-associated protein Tau, and other highly ubiquitinylated but protease-resistant components in compacted and tangled fibers that appear to overwhelm the proteasome degradative pathway. Disturbed calcium ion regulation may underlie neuronal death.

Amyotrophic lateral sclerosis (ALS or Lou Gehrig's disease) is a neurodegenerative disease characterized by progressive degeneration of motor neurons and accumulation of ubiquinated proteins in cellular inclusions. Superoxide dismutase 1 and TAR DNA-binding protein have both been identified in inclusions in both familial and sporadic forms of the disease.

Parkinson disease (see Clin. Corr. 19.19, p. 785) is also linked to accumulations of undegraded protein aggregates. Misfolding of the presynaptic protein alpha-synuclein (α-Syn) in the endoplasmic reticulum (ER) of neurons leads to the formation of cytoplasmic Lewy Bodies in which α-Syn is a major component. ER-associated degradation of proteins is impaired. In early onset Parkinson disease Lewy bodies are usually absent and mutations in parkin protein are common (Clin. Corr. 6.15). Prion diseases are also associated with protein aggregation (see Clin. Corr. 3.6, p. 114).

CLINICAL CORRELATION 6.15

Defects in the Ubiquitin-Proteasome System

The following are diseases linked to malfunctions of the ubiquitin-proteosome pathway.

Liddle syndrome (OMIM 177200): A mutation in a subunit of the renal epithelial sodium channel interferes in binding of Nedd4, an E3 ligase that mediates its degradation. Channel accumulation results in excessive Na^+ resorption and severe hypertension.

Autosomal recessive juvenile Parkinsonism (OMIM 605909): A small percentage of patients have an early onset familial form of Parkinson disease. Many have mutations in the parkin protein causing loss of E3 enzyme activity and accumulation of parkin substrates. A second cause of familial Parkinson disease is linked to a mutation in an ubiquitin-recycling enzyme, possibly resulting in a shortage of free ubiquitin.

Breast and ovarian cancer: Heterozygous mutations in BRCA1 (the breast cancer susceptibility locus) are seen in some cases of breast and ovarian cancer. BRCA1 protein is an E3 enzyme whose activity is abolished by mutations found in familial breast cancer.

HPV-induced cervical cancer: Infection with some strains of human papilloma virus can lead to invasive cervical cancer. A virus-encoded oncoprotein E6 interacts with the cellular p53 tumor suppressor protein; an E3 enzyme recognizes the complex, leading to p53 degradation via the ubiquitin-proteasome pathway.

A CLOSER LOOK 6.4

Ubiquitin and SUMO

Ubiquitin has important roles beyond protein degradation. Reversible linkage of ubiquitin to histones H2A and H2B is unrelated to turnover since the proteins are stable, but modification affects chromatin structure and transcription. Ubiquitin participates in chromosome alignment and segregation, in DNA repair, and in regulating transcription in the inflammatory response. Ubiquitination is a signal for endocytosis and a sorting signal directing contents to lysosomes. Often these functions employ ubiquitin linkages that are different from those in the proteasome pathway. Small ubiquitin-related modifier (SUMO) proteins, whose conformation and ligation to target proteins are very similar to that of ubiquitin, also function in transcriptional regulation and other aspects of cellular regulation, sometimes with effects opposite to that of ubiquitin.

RNA silencing
RNA-induced silencing complex
proteasome
ubiquitin
N-end rule

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. Degeneracy of the genetic code denotes the existence of
- **A.** multiple codons for a single amino acid.
- **B.** codons consisting of only two bases.
- **C.** base triplets that do not code for any amino acid.
- **D.** different systems in which a given triplet codes for different amino acids.
- **E.** codons that include one or more of the unusual bases.

2. In the formation of an aminoacyl-tRNA,
- **A.** ADP and Pi are products of the reaction.
- **B.** aminoacyl adenylate appears in solution as a free intermediate.
- **C.** aminoacyl-tRNA synthetase is believed to recognize and hydrolyze incorrect aminoacyl-tRNAs it may have produced.
- **D.** separate aminoacyl-tRNA synthetases exist for every amino acid in the functional protein.
- **E.** there is a separate aminoacyl-tRNA synthetase for every tRNA species.

3. During initiation of protein synthesis,
- **A.** methionyl-tRNA appears at the A site of the 80S initiation complex.
- **B.** eIF3 and the 40S ribosomal subunit participate in forming a preinitiation complex.
- **C.** eIF2 is phosphorylated by GTP.
- **D.** the same methionyl-tRNA is used as is used during elongation.
- **E.** a complex of mRNA, 60S ribosomal subunit, and certain initiation factors is formed.

4. During the elongation stage of eukaryotic protein synthesis,
- **A.** the incoming aminoacyl-tRNA binds to the P site.
- **B.** a new peptide bond synthesized by peptidyl transferase requires GTP hydrolysis.
- **C.** the peptidyl- tRNA is translocated to a different site on the ribosome.
- **D.** streptomycin can cause premature release of the incomplete peptide.
- **E.** peptide bond formation occurs by the attack of the carboxyl group of the incoming amino acyl tRNA on the amino group of the growing peptide chain.

5. Formation of mature insulin includes all of the following except
- **A.** removal of a signal peptide.
- **B.** folding into a three-dimensional structure.
- **C.** disulfide bond formation.
- **D.** removal of a peptide from an internal region.
- **E.** γ-carboxylation of glutamate residues.

6. Streptomycin binds the small subunit of prokaryotic ribosomes and
- **A.** causes premature release of the incomplete peptide.
- **B.** prevents binding of the 40S and 60S subunits.
- **C.** interferes with initiation of protein synthesis.
- **D.** inhibits peptidyl transferase activity.
- **E.** acts as an N-glycosidase.

Questions 7 and 8: Cystic fibrosis is a frequent genetic disease of Caucasians. The CF gene codes for a protein called the cystic fibrosis transmembrane conductance regulator (CFTR) which functions as a cAMP-regulated chloride channel. The protein has two membrane-spanning domains, two domains that interact with ATP, and one regulatory domain. The most common defect is in the gene for one of the ATP binding domains. The result is a protein that does not fold correctly in the endoplasmic reticulum, is not properly glycosylated, and is not transported to the cell surface. Rather, it is degraded in the cytosol within proteasomes. Drugs that foster chaperone interaction with the mutant protein are a potential therapeutic approach.

7. Chaperones
- **A.** are always required to direct the folding of proteins.
- **B.** when bound to protein increase the rate of protein degradation.
- **C.** usually bind to strongly hydrophilic regions of unfolded proteins.
- **D.** sometimes maintain proteins in an unfolded state to allow passage through membranes.
- **E.** foster aggregation of proteins into plaques.

8. Targeting a protein to be degraded within proteasomes usually requires ubiquitin. In the function of ubiquitin all of the following are true except
- **A.** ATP is required for activation of ubiquitin.
- **B.** a peptide bond forms between the carboxyl terminal of ubiquitin and an ϵ-amino group of a lysine.
- **C.** linkage of a protein to ubiquitin does not always mark it for degradation.
- **D.** the N-terminal amino acid is one determinant of selection for degradation.
- **E.** ATP is required by the enzyme that transfers the ubiquitin to the protein to be degraded.

Questions 9 and 10: Collagen is unusual in its amino acid composition and requires a wide variety of posttranslational modifications to convert it to a functional molecule. Because of the complexity of collagen synthesis, there are many diseases, resulting in structural weaknesses in connective tissue, caused by defects in the process. Scurvy leads to a less stable collagen lacking sufficient hydroxyproline.

9. 4-Hydroxylation of specific prolyl residues during collagen synthesis requires all of the following except
- **A.** Fe^{2+}.
- **B.** a specific amino acid sequence at the site of hydroxylation.
- **C.** ascorbic acid.
- **D.** co-hydroxylation of lysine.
- **E.** individual α chains, not yet assembled into a triple helix.

10. Much of procollagen formation occurs in the endoplasmic reticulum and Golgi apparatus which requires signal peptide. All of the following statements about targeting a protein for the ER are true except
- **A.** signal peptide usually has a positively charged N-terminus and a stretch of hydrophobic amino acids.
- **B.** signal peptide emerging from a free ribosome binds signal recognition particle (SRP).
- **C.** signal peptide is usually cleaved from the protein before the protein is inserted into the ER membrane.
- **D.** docking protein is actually an SRP receptor and serves to bind the SRP to the ER.
- **E.** SRP and docking protein do not enter the ER lumen but are recycled.

Questions 11 and 12: A number of diseases occur because of defects in targeting signals that direct proteins to particular organelles. I-Cell disease (mucolipidosis II), characterized by severe psychomotor retardation and skeletal abnormalities, arises from a defect in targeting proteins to lysosomes. Mistargeting can also cause problems. In primary hyperoxaluria type I, an enzyme that normally functions in peroxisomes, because of mutations that create a mitochondrial targeting signal, is localized in the mitochondria instead.

11. I-Cell patients lack the enzyme that transfers N-acetylglucosamine phosphate to high mannose type oligosaccharides on the protein. This *N*-linked glycosylation
- **A.** occurs only after the protein has been completely translated and folded.
- **B.** does not require any specific amino acid sequence.
- **C.** occurs by transfer of an oligosaccharide chain from a dolichol phosphate carrier to the protein.
- **D.** has the oligosaccharide chain attached to serine or threonine.
- **E.** contains only mannoses in the chain.

12. The targeting signal for mitochondria is
- **A.** a hydrophobic anchoring sequence.
- **B.** a positively charged amphipathic α-helix.
- **C.** mannose 6-phosphate.
- **D.** one or two clusters of basic amino acids.
- **E.** a carboxy-terminal Ser-Lys-Leu (SKL) sequence.

Problems

13. The most common mutation in cystic fibrosis is a deletion of three consecutive bases in the gene for one of the ATP binding domains. How would the protein from this gene most likely be related to the normal protein?

14. Some proteins may be degraded in lysosomes. How does this differ from protein degradation within proteasomes?

Answers

1. A This is the definition of degeneracy. B and E are not known to occur, although sometimes tRNA reads only the first two bases of a triplet (wobble), and sometimes unusual bases occur in anticodons. C denotes the stop (nonsense) codons. D is a deviation from universality of the code, as found in mitochondria.

2. C Bonds between a tRNA and an incorrect smaller amino acid may form but are rapidly hydrolyzed. A and B: ATP and the amino acid react to form an enzyme-bound aminoacyl adenylate; PPi is released into the medium. D: Some amino acids, such as hydroxyproline and hydroxylysine, arise by co- or posttranslational modification. E: An aminoacyl-tRNA synthetase may recognize any of several tRNAs specific for a given amino acid.

3. B This then binds the mRNA. A: Methionyl-$tRNA_i^{met}$ appears at the P site. C: Phosphorylation of eIF-2 inhibits initiation. D: Methionyl-$tRNA_c^{met}$ is used internally. E: mRNA associates first with the 40S subunit.

4. C This is necessary to free the A site for the next incoming tRNA. A: Incoming amino acyl tRNA binds to the A site. B: Peptide bond formation requires no energy source other than the aminoacyl-tRNA. D: Streptomycin inhibits formation of the prokaryotic 70S initiation complex and causes misreading of the genetic code. E: The electron pair of the amino group carries out a nucleophilic attack on the carbonyl carbon.

5. E γ-Carboxylation is of special importance in several blood-clotting proteins but not in insulin formation. A: Preproinsulin is inserted into the ER. B: All proteins, except fibrous ones, have to fold into a three-dimensional structure. C: A proinsulin folds and forms disulfide bonds before the chain is cleaved. D: This is called the C-peptide.

6. C By altering interactions of tRNA, mRNA, and ribosomal subunit, it interferes with initiation and also causes misreading. A: Puromycin, resembling aminoacyl-tRNA, does this. B: These are eukaryotic subunits. D: Chloramphenicol does this. E: This is the action of ricin and related toxins.

7. D This is only one of many functions chaperones serve. A: Many proteins spontaneously fold correctly. B: Misfolded proteins are recognized and rapidly degraded. C: Chaperones bind to hydrophobic regions of unfolded proteins. E: Misfolded proteins are more likely to do this.

8. E ATP is required in the ubiquitin activation and the protease steps but not here. B and D: These are both correct. C: Linkage to histones does not result in their degradation.

9. D Lysine is hydroxylated but by a different enzyme. A and C: Prolyl hydroxylase requires both Fe^{+2} and ascorbic acid. B: The sequence is -X-Pro-Gly-. E: Hydroxylation is a cotranslational event.

10. C Signal peptidase is located on the luminal surface of the ER. A: These are common features along with a polar segment that signal peptidase recognizes. B, D, and E: These are all essential features of the process.

11. C The chain is linked to the amide of asparagine in an Asn-X-Thr/Ser sequence. A, B, and D: These are characteristics of the O-linked type. E: *N*-Acetylglucosamine is also present.

12. B This is recognized by a mitochondrial receptor. A: This would embed the protein in the ER membrane. C: This is the signal for the lysosome. D: This targets the nucleus. E: This is the signal for peroxisomes.

13. Deletion of an entire codon means that particular amino acid is not present in the protein. It is not usual for the deletion of three nucleotides to span two codons so you would not expect a frameshift mutation.

14. Degradation in proteasomes usually requires ubiquitin adding to the protein. Proteins are taken into lysosomes by endocytosis, and enzymes present in the lysosomes degrade them. Specific extracellular proteins bind to cell surface receptors in clathrin-coated pits. Invagination of the membrane and ligand-bound receptors forms vesicles which may fuse with lysosomes. Again the proteins are degraded by the lysosomal enzymes.

Key Concepts

- The polymerase chain reaction (PCR) is used to determine nucleic acid sequences of genes, their regulatory sites, and their products.
- Restriction endonucleases (RE) generate DNA molecules for synthesis of recombinant DNA molecules. DNA molecules from two different species can be cleaved with the same RE-yielding molecules with complementary single-stranded ends, which can be annealed and ligated. Many copies of the recombinant DNA can be generated if one DNA species is a vector that will replicate in a bacterium or cell.
- Cloning a cell with a specific recombinant molecule requires techniques to select a single bacterium or cell with the DNA of interest, then replicating the cell so that all daughter cells have the same recombinant DNA.
- Genomic libraries are generated with the multitude of recombinant DNA molecules that have pieces of DNA from a whole genome linked to a vector and transformed into bacteria or cells. Specific clones can be selected.
- Nucleic acid hybridization techniques with labeled DNA or RNA probes can detect polymorphic DNA patterns of restriction endonuclease digested genomic DNA from different individuals, specific RNA species, and cell clones carrying a specific recombinant DNA.
- Reverse transcription generates cDNA from cellular mRNA. A cDNA library consists of all the cDNAs produced from total cellular mRNA.
- Different vectors can be recombined with foreign DNA with the number of base pairs ranging from a few thousand to hundreds of thousands. Small DNA inserts can represent cDNA of an expressed gene while much larger inserts are required to carry a genomic gene with introns and exons along with upstream and downstream regulatory sites.
- Expression vectors are DNA species that combine with functional foreign "genes" such that when introduced into a bacterium or cell the recombinant "gene" is transcribed and translated.
- Site-directed mutagenesis with cloned recombinant DNA can result in the selective loss of a DNA region, the addition or loss of one or a few nucleotides, or the selective change of a single nucleotide. Altered "genes" are utilized to study the structure and function of the encoded protein.
- Regulation of gene expression in diseased or altered metabolic states can be studied by recombinant DNA technologies, including antisense nucleic acid technologies, introduction of normal genes for altered genes, and gene destruction in whole animals (knockout animals).

7.1 • INTRODUCTION

By 1970, the stage was set for modern molecular biology based on the studies of numerous scientists in the previous 30 years during which ignorance of what biochemical entity orchestrated the replication of life forms with such fidelity gave way to a state where sequencing and manipulation of the expression of genes would become commonplace. The relentless march toward a full understanding of gene regulation under normal and pathological conditions has moved with increasing rapidity since then. Identification, purification, and characterization of restriction endonucleases permitted the development of recombinant DNA methodologies. Development of DNA sequencing revealed the secrets within the organization of diverse biological genomes with the complete sequencing of numerous prokaryotes and eukaryotes including the human genome. The delineation of all of the human genes and their regulatory sequences should greatly enhance our understanding of many genetic diseases. This knowledge along with our technological advances to manipulated genes and gene expression should also open new avenues to regulate or cure these diseases. Hundreds of clinical trials in gene therapy involving many patients have been initiated. Genetic diseases now identified and to be identified should eventually be curable by gene replacement therapy when the technical roadblocks are surmounted. If one looks at the enormous advances made in molecular biology in just the past three decades, it is reasonable to believe the when will not be that far off. The old challenge confronting scientists was how to sequence the human genome; the new challenge is how to effectively manipulate that knowledge to benefit mankind.

7.2 • POLYMERASE CHAIN REACTION

Prior to 1987 the analysis of the sequence and function of a selected region of DNA required relatively large amounts of the purified DNA segment. The rapid production of large quantities of a specific DNA sequence took a leap forward with the development

of the **polymerase chain reaction (PCR)**. This requires two nucleotide oligomers that hybridize to the complementary DNA strands in a region of interest. The oligomers serve as primers for a DNA polymerase that extends each strand. Repeated cycling of the PCR yields large amounts of each DNA molecule of interest in a matter of hours as opposed to days and weeks required for cloning techniques.

The amplification of a specific DNA sequence by PCR is accomplished with purified DNA or with a complex mixture of DNA. The principles of the reaction are shown in Figure 7.1. The nucleotide sequence of the DNA to be amplified must be known, or it must be cloned in a vector (p. 277) for which the sequence of the flanking DNA has been established. The product of PCR is a double-stranded DNA (dsDNA) molecule and the reaction is completed in each cycle when all of the template molecules are copied. In order to initiate a new round of replication, the sample is heated to melt the dsDNA and, in the presence of excess oligonucleotide primers, cooled to permit hybridization of the single-stranded template with free oligomers. DNA replication will start in the presence of DNA polymerase and all four dNTPs. Heating to about 95°C as required for melting DNA inactivates most DNA polymerases, but a heat-stable polymerase, termed Taq DNA polymerase isolated from *Thermus aquaticus,* is now employed and obviates the need for fresh polymerase being added after each cycle. This has permitted the automation of PCR with each DNA molecule capable of being amplified one million-fold.

A unique temperature stable DNA polymerase—Phusion™ High-Fidelity DNA polymerase—was commercially developed for PCR under routine and more demanding PCR applications. This enzyme was constructed by the fusion of a unique dsDNA-binding domain to a *Pyrococcus*-like proofreading polymerase. The processivity of this fused enzyme is about twice the Taq DNA polymerase and an error rate 50-fold lower. Also, unlike Taq DNA polymerase the enzyme is not inhibited by any quantity of blood. Therefore, genomic DNA can be amplified directly from blood drops without the costly and time-consuming purification steps required with the Taq enzyme.

Nested PCR

When the DNA to be amplified is present in very low concentrations relative to the total DNA in the sample, the DNA region of interest along with other spurious sequences can be amplified. In this situation, the specificity of the amplification can be enhanced by nested PCR. After conducting the first PCR with one set of primers for 10–20 cycles, a small aliquot is removed for a second PCR. However, this is conducted with primers that are **complementary** to the template DNA just downstream of the first primers or "nested" between the original set of primers. This process amplifies the DNA region of interest twice with a greatly enhanced specificity. PCR has many applications in gene diagnosis; forensic investigations, for which only a drop of dried blood or a single hair is available; and evolutionary studies on preserved biological material (Clin. Corr. 7.1). In 2008 a new technology, touch DNA/PCR, was applied to clear the parents of the murder of their young daughter, Jon Benet Ramsey. This methodology could take one or a few cells adhering to any surface touched by a person (in this case Jon Benet's pants touched by the murderer) as a sufficient source of DNA to amplify by PCR and analyze by DNA fingerprinting. After more than a decade of doubt, the results finally cleared the parents in this horrific and highly publicized case.

Quantitative Real-Time PCR

Quantitative real-time PCR (qRT-PCR) couples the traditional PCR amplification reaction with the simultaneous quantification of the DNA synthesized after each cycle. This technique allows one to calculate the number of copies of a DNA sequence within a genome. One can also use the method to determine the relative level of expression of a gene in a cell by initiating the reaction with RT-PCR (reverse transcriptase–PCR) producing cDNA as the template for PCR. In each case the quantification of DNA product must be compared to an internal housekeeping gene whose level of expression is nearly equal in all cells being studied. There are currently a few variations to the techniques employed, some being more rigorous in the calculated quantification than others, but only the most straightforward process will be described here.

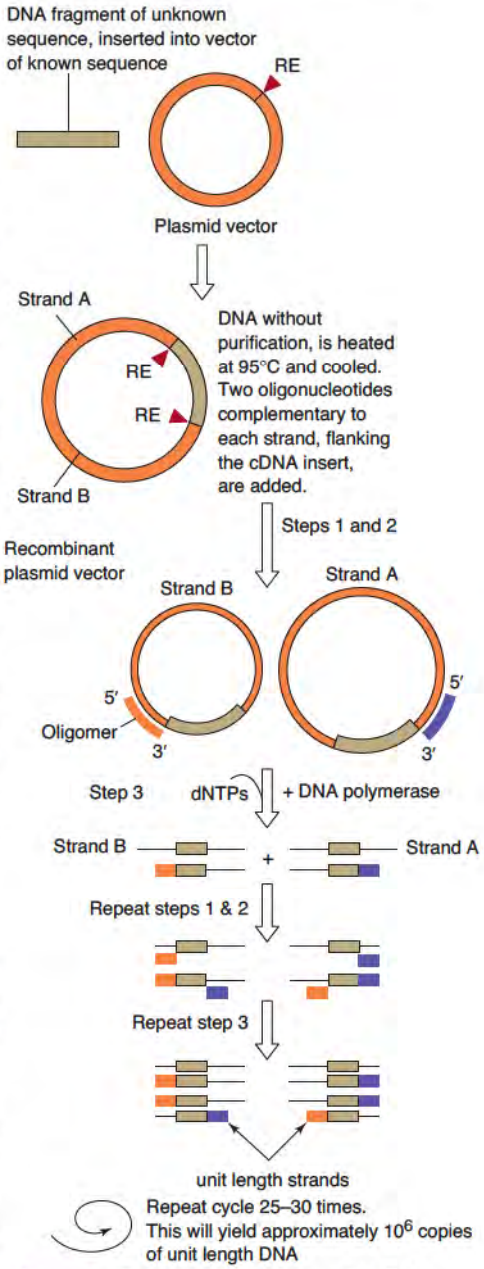

Figure 7.1 Polymerase chain reaction (PCR). A DNA fragment of unknown sequence is inserted into a vector of known sequence by normal recombinant methodology. The recombinant DNA of interest does not need to be purified. The DNA is heated to 95°C to dissociate the double strands and cooled in the presence of excess amounts of two different complementary oligomers that hybridize to the known vector DNA sequences flanking the foreign DNA insert. Only recombinant single-stranded DNA species can serve as templates for DNA replication yielding double-stranded DNA fragments of foreign DNA bounded by the oligomer DNA sequences. The heating-replication cycle is repeated many times to rapidly produce large amounts of the original foreign DNA. The DNA fragment of interest can be purified from the PCR mixture by cleaving it with the original restriction endonuclease (RE), electrophoresing the DNA mixture through an agarose gel, and eluting the band of interest from the gel.

CLINICAL CORRELATION 7.1

The Polymerase Chain Reaction

A. PCR in Screening for Human Immunodeficiency Virus

The use of PCR to amplify minute quantities of DNA has revolutionized the detection and analysis of DNA species. With PCR it is possible to synthesize sufficient DNA for analysis. Conventional detection and identification of the human immunodeficiency virus (HIV), for example by Southern blot–DNA hybridization and antigen analysis, is labor intensive and expensive and has low sensitivity. An infected individual, with no sign of AIDS (acquired immunodeficiency syndrome), may test false negative for HIV by these procedures. Early detection of HIV infections is crucial to initiate treatment or monitor the progression of the disease. In addition, a sensitive method is required to ensure that blood contributed by donors does not contain HIV. PCR amplification of potential HIV DNA sequences within DNA isolated from an individual's white blood cells permitted the detection of infection prior to appearance of antibodies, the so-called seronegative state. With the advent of new combination antiviral (protease inhibitors) treatments for HIV the potential for viral mutations leading to drug resistance has been reduced. However, some patients do present with multidrug resistance. A common viral genome mutation, L9OM, leads to protease inhibitor resistance. The viral gag-pro region was amplified and sequenced using L9OM allele specific PCR with samples from 15 patients early in their diseased state. Results were then compared to samples analyzed after the patients failed drug treatment. The L9OM viruses were a minority of the total viruses in the early samples. However, these mutant species became the dominant species in the plasma of drug resistant patients. It appears that the emergence of the dominant L9OM containing viruses occurred on multiple occasions in many of the patients as determined by Bayesian evolutionary analysis. Early detection of the conversion of drug sensitive to drug resistant viruses by PCR analysis could help determine clinical treatment of these patients.

B. Nested PCR to Detect Microchimerism

Donor leukocytes transferred to patients during blood transfusion have been shown to survive in the recipient's peripheral blood. The significance, if any, of this microchimeric population of leukocytes remains to be resolved. One of the best ways to detect donor-derived cells in the recipient's blood is to use PCR detection of polymorphisms in the HLA–DR region of the major histocompatibility complex (MHC). A nested PCR assay was at least 100-fold more sensitive than a standard PCR assay. However, because of the increased sensitivity, nonspecific products may appear due to mispriming events that are generally associated with pseudogenes. As such it is essential to establish a baseline pattern with pre-transfusion blood samples. Once potential false positives are excluded with these baseline patterns, the detection of donor leukocytes is greatly enhanced.

Although RT-PCR/PCR usually uses forward and reverse primers that generate DNA products in the 300–600-bp range, qRT-PCR more often employs primers that are only about 100 bases apart. The method described here takes advantage of the fact that the chromofluor, SYBR green, only binds to double-stranded DNA and not to single-stranded DNA. When it is bound to double-stranded DNA, it fluoresces many times more brightly than when it is free in solution. DNA is amplified from either DNA or cDNA templates in the presence of SYBR green in a PCR instrument that measures the fluorescence of the SYBR green–DNA complex after each cycle. Therefore, the increase in fluorescence with each cycle is proportional to the real time synthesis of the amplified DNA. A plot of the log of the fluorescence units versus cycle number will yield a linear relationship during the logarithmic amplification phase of PCR. The linear part of the curve is compared to a known internal housekeeping standard for quantification of the DNA/cDNA product. This technique is employed to identify the differential expression of specific genes in normal versus diseased tissues where the gene product may have a role in the development of abnormal cells (Clin. Corr. 7.2).

7.3 • RESTRICTION ENDONUCLEASE, RESTRICTION MAPS, AND DNA SEQUENCING

Restriction Endonucleases Selectively Hydrolyze DNA

Restriction endonucleases are capable of selectively dissecting DNA molecules of many sizes and origins into smaller fragments. They confer some protection on bacteria against invading viruses (bacteriophage). Bacterial DNA sequences normally recognized by a restriction

endonuclease are protected from cleavage in host cells by methylation of bases within the palindrome. The unmethylated viral DNA is recognized as foreign and is hydrolyzed. Numerous Type II restriction endonucleases are now commercially available (see p. 58 for discussion of restriction endonuclease activities).

Restriction endonucleases permit construction of a **restriction map**, in which the site of cleavage within the DNA is identified. Purified DNA species that contain susceptible sequences are subjected to restriction endonuclease cleavage. By regulating the time of exposure of the purified DNA for cleavage, a population of DNA fragments of different sizes is generated. Separation of these fragments by agarose gel electrophoresis allows for the construction of a restriction map; an example is presented in Figure 7.2. The sequential use of different restriction endonucleases has permitted a detailed restriction map of numerous circular DNA species including bacterial plasmids, viruses, and mitochondrial DNA. The method is equally amenable to linear DNA fragments that have been purified to homogeneity.

Restriction Maps Permit Routine Preparation of Defined Segments of DNA

Restriction maps may yield little information as to the genes or regulatory elements within the various DNA fragments. They are used to demonstrate sequence diversity of organelle DNA, such as mitochondrial DNA, within species (Clin. Corr. 7.3). They are

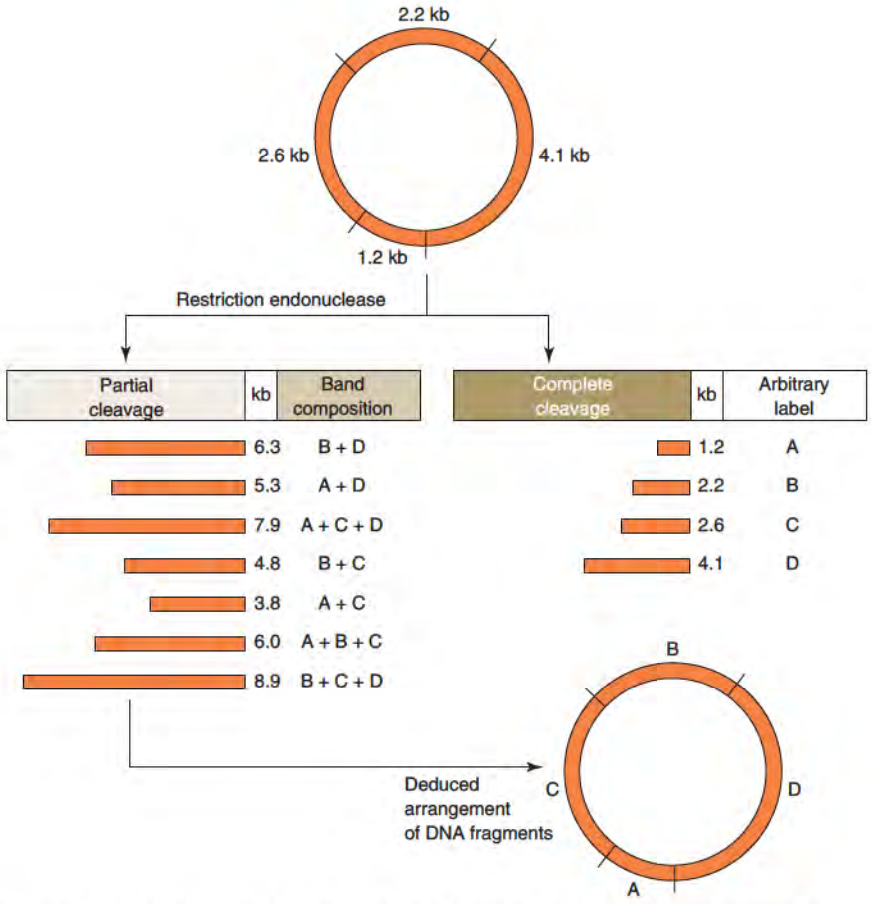

Figure 7.2 Restriction endonuclease mapping of DNA. Purified DNA is subjected to restriction endonuclease digestion for varying times which generates partially to fully cleaved DNA fragments. The fragments are separated by agarose gel electrophoresis and stained with ethidium bromide. The bands are visualized with a UV light source and photographed. The size of the fragments is determined by the relative migration through the gel as compared to co-electrophoresed DNA standards. The relative arrangement of each fragment within the DNA molecule can be deduced from the size of the incompletely hydrolyzed fragments.

CLINICAL CORRELATION 7.2

Quantitative Real-Time PCR (qRT–PCR in the Analysis of a Gene Associated with Prostate Cancer

Prostate cancer is the predominant malignancy found in North American males. There is no known cure for prostate cancer once it has metastasized. Therefore, it is very important to identify biomarkers which are associated with the metastatic disease and which may serve as new therapeutic targets. Two cell lines were developed from a prostate cancer patient that when transplanted into immunodeficient mice, either had metastatic potential or were nonmetastatic. The differential analysis of genes expressed in the two cell lines detected one gene, ASAP1, in the metastatic cell line that had not previously been associated with the metastatic process in prostate cancer. qRT-PCR confirmed that ASAP1 (encodes an ADP-ribosylation factor GTPase-activating protein) was up-regulated in the metastatic cell line. Furthermore, the inhibition of expression of ASAP1 in prostate cancer cells by small interfering RNA (siRNA; see p. 201) greatly reduced the metastatic potential of these cells by *in-vitro* analysis. This gene may be an important target for the clinical treatment of metastatic prostate cancer.

Lin, D., Watahiki, A., Bayani, J., Zhang, F., et al. ASAP1, a gene at 8q24, is associated with prostate cancer metastasis. *Cancer Res.* 68:4352, 2008.

CLINICAL CORRELATION 7.3

Restriction Mapping and Evolution

In the past, evolutionary studies of species have depended solely on anatomical changes observed in fossil records and on carbon dating. These studies are being supported by the molecular analysis of the sequence and size of selected genes or whole DNA molecules. Alterations in a selected DNA molecule from different species can be rapidly assessed by restriction mapping which requires a pure preparation of DNA. Mammalian mitochondria contain a closed circular DNA molecule of 16,569 bps that can rapidly be purified from cells. The mitochondrial DNA (mtDNA) can be employed directly for the study of evolutionary changes in DNA without the need of cloning a specific gene.

mtDNA has been purified from the Guinea baboon, rhesus macaque, guenon, and human and cleaved with 11 different restriction endonucleases. Restriction maps were aligned relative to the direction and the nucleotide site where DNA replication is initiated. A comparison of restriction endonuclease sites permitted the calculation of the degree of divergence in nucleotide sequence between species. The rate of base substitution (calculated from the degree of divergence versus the time of divergence) has been about 10-fold greater than in the nuclear genome. This high rate of mutation of the readily purified mtDNA molecule makes this an excellent model to study evolutionary relationships between species.

Analysis of mtDNA can be used to study the migration patterns of people who settled in diverse geographic regions but possess the same restriction enzyme-generated patterns (restriction fragment length polymorphism [RFLP]). Native Americans have been grouped into four major haplogroups based upon their mtDNA restriction patterns. These groups are thought to be descended from the Clovis people (Paleoindian) who migrated from Asia and Siberia and entered North America, just before the major ice age period. The timing of this migratory event is quite variable from study to study. However, analysis of mtDNA, amplified from fossil feces (human coprolites) in Oregon, appears to prove that humans populated the Americas before the so-called Clovis people. The mtDNA sequences represent the Native American founding haplogroups A_2 and B_2 and the samples predate the Clovis remains by at least 1000 years.

Brown, W. M., George, M., Jr., and Wilson, A. C. Rapid evolution of animal mitochondrial DNA. *Proc. Natl. Acad. Sci. USA* 76:1967, 1979; Schurr, J. G. Mitochondrial DNA and the people of the new world. *Amer. Sci.* 88:246, 2000; Gilbert, M. T., Jenkins, D. L., Gotherstrom, A., Naveran, N., et al. DNA from pre-Clovis human coprolites in Oregon, North America. *Science* 320:786, 2008; and Balter, M. DNA from fossil feces breaks Clovis barrier. *Science* 320:37, 2008.

also used to detect deletion mutations in which a DNA fragment from the parental strain migrates as a smaller fragment in the mutated strain. Most importantly, the restriction endonucleases cut DNA into defined homogeneous fragments that can be readily purified. These maps are crucial for cloning and for sequencing genes and their flanking DNA regions.

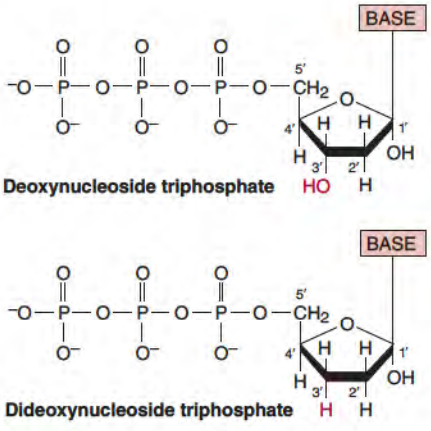

Figure 7.3 Structure of deoxynucleoside triphosphate and dideoxynucleoside triphosphate. The 3′-OH group is lacking on the ribose component of the dideoxynucleoside triphosphate (ddNTP). This molecule can be incorporated into a growing DNA molecule through a phosphodiester bond with its 5′-phosphates. Once incorporated the ddNTP blocks further synthesis of the DNA molecule since it lacks the 3′-OH acceptor group for an incoming nucleotide.

Interrupted Enzymatic Cleavage Method: Sanger Procedure

In the late 1970s two different sequencing techniques were developed, one by A. Maxam and W. Gilbert, the chemical-cleavage approach, and the other by F. Sanger, the enzymatic approach. Both procedures employed labeling of a terminal nucleotide, followed by the separation and detection of generated oligonucleotides. The Sanger method has become the method of choice due to the relative ease of the procedure and its ability to sequence longer stretches of DNA (400 bases) relative to the Maxam and Gilbert method (250 bases).

The **Sanger procedure** is based on the random termination of a DNA chain during enzymatic synthesis. The technique depends on the dideoxynucleotide analog of each of the four normal nucleotides (Figure 7.3) being incorporated into a growing DNA chain by DNA polymerase and blocking further elongation. The ribose of the **dideoxynucleoside triphosphate (ddNTP)** lacks the OH group at both the 2′ and 3′ positions whereas dNTP lacks only the OH group at the 2′ position. Thus, the ddNTP incorporated into the growing chain cannot form a phosphodiester bond with another dNTP because the 3′ position of the ribose does not contain a OH group. The growing DNA molecule is terminated at random points by including in the reaction system the normal dNTP and the ddNTP (e.g., dATP and ddATP) at concentrations such that the two nucleotides compete for incorporation. Identification of DNA fragments requires labeling of the 5′-end of the DNA molecules or the incorporation of labeled nucleotides during synthesis. The technique, outlined in Figure 7.4, is best conducted with pure single-stranded DNA; however, denatured double-stranded DNA can also be used. The DNA to be sequenced is

frequently isolated from a recombinant single-stranded bacteriophage (p. 276) in which a region that flanks the DNA of interest contains a sequence that is complementary to a universal primer. The primer can be labeled with either ^{32}P or ^{35}S nucleotide. Primer extension is accomplished with one of several DNA polymerases; one with great versatility is a genetically engineered form of the bacteriophage T 7 DNA polymerase. The reaction mixture, composed of the target DNA, labeled primer, and all four dNTPs, is divided into four tubes, each containing a different ddNTP. ddNTPs are randomly incorporated during the enzymatic synthesis of DNA and cause chain termination. Since the ddNTP is present in the reaction tube at a low level relative to the corresponding dNTP, termination of DNA synthesis occurs randomly at all possible complementary sites of the DNA template. This yields DNA molecules of varying sizes, labeled at the 5′-end that can be separated by polyacrylamide gel electrophoresis. The labeled species are detected by X-ray autoradiography, and the sequence is read.

Initially, this method required a single-stranded DNA template, production of a specific complementary oligonucleotide primer, and a relatively pure preparation of the Klenow fragment of *E. coli* DNA polymerase I. These difficulties have been overcome and modifications have simplified the procedure.

The PCR and the Sanger methods are combined for **direct sequencing** of small DNA regions of interest. The double-stranded PCR product is employed directly as template. Conditions are set so that one strand of melted DNA (template) anneals with the primer in preference to reannealing with the complementary strand. Sequencing then follows the standard dideoxy chain termination reaction (typically with Sequenase replacing the Klenow polymerase) with synthesis of random length chains occurring as extensions of the PCR primer. This method has been successfully employed for diagnosis of genetic disorders (Clin. Corr. 7.4).

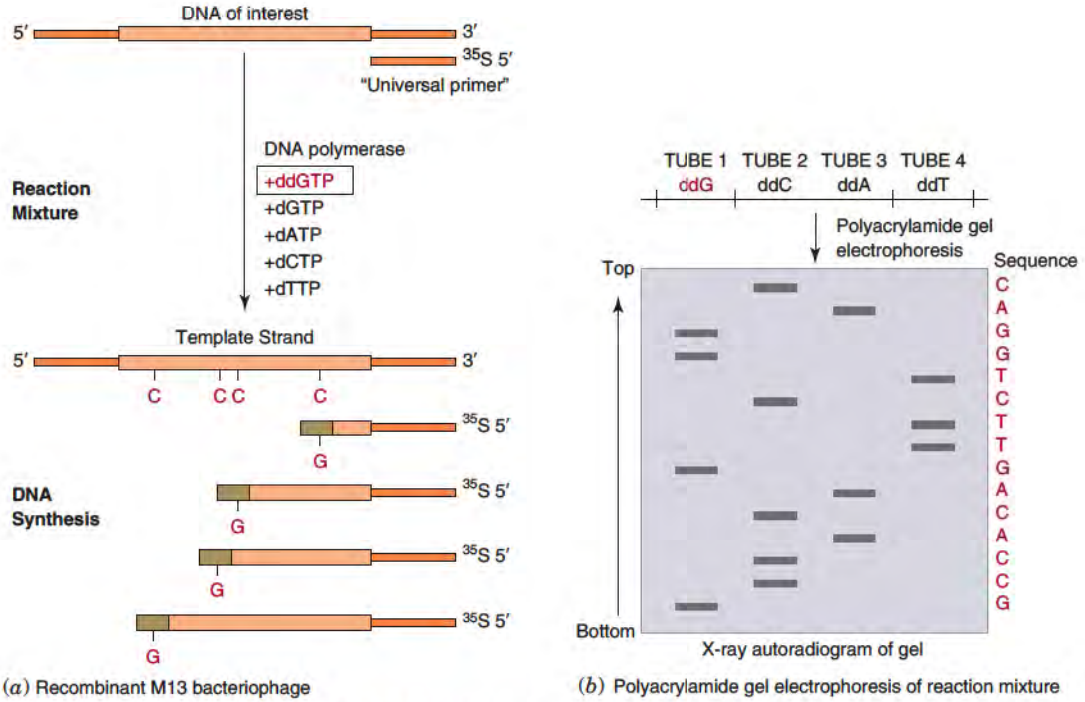

Figure 7.4 The Sanger dideoxynucleoside triphosphate method to sequence DNA. The DNA region of interest is inserted into bacteriophage DNA molecule. Replicating bacteriophage produces a single-stranded recombinant DNA molecule that is readily purified. The known sequence of the bacteriophage DNA downstream of the DNA insert serves as a hybridization site for an end-labeled oligomer with a complementary sequence, a universal primer. Extension of this primer is catalyzed with a DNA polymerase and all four dNTPs plus one ddNTP, for example ddGTP. Synthesis stops whenever a ddNTP is incorporated into the growing molecule. Note that the ddNTP competes for incorporation with the dNTP. This generates end-labeled DNA fragments of all possible lengths that are separated by electrophoresis. The DNA sequence can then be determined from the electrophoretic patterns.

CLINICAL CORRELATION 7.4

Direct Sequencing of DNA for the Diagnosis of Bloom Syndrome: A Genetic Disorder

Early methodologies to determine the sequence of DNA regions or genes that may be associated with genetic disorders have been costly, time consuming, and all too often inaccurate. Direct sequencing of PCR-amplified genomic DNA circumvents these shortcomings. Bloom syndrome (BS) (OMIM 210900) is a rarely encountered autosomal recessive disease. Patients with BS present with all types of cancer far more often than the general population. Cells from BS patients are characterized by a high level of genetic instability. The current diagnosis of BS is based on the detection of a high level (~10-fold) of sister chromatid exchanges in cells of the patient. Direct genomic DNA sequencing was employed to screen for mutations in the BLM (Bloom syndrome) gene of suspected BS patients. This method detected four mutations in the BLM gene. All of the mutations (three were frameshift and one was nonsense mutation) resulted in the introduction of a stop codon. It is postulated that this methodological approach will allow for a direct correlation of mutations to the clinical status of the patient.

Amor-Gueret, M., Dubois-d'Enghien, C., Lauge, A., Onciercq-Delic, R., et al. Three new BLM gene mutations associated with Bloom syndrome. *Genet. Testing* 12:257, 2008.

Dye-Terminator Sequencing

The development of the dye-terminator sequencing method has greatly simplified, sped up, and reduced the cost of DNA sequencing. The basic principles of the Sanger enzymatic method are employed; however, each ddNTP is fluorescently labeled with a different colored fluor. Since each colored ddNTP terminates the reaction yielding different-sized oligonucleotides with a different fluoresent color, it is not necessary to run four different reaction tubes. A single reaction is run with the products separated by capillary electrophoresis and sequenced by an automated, high-throughput DNA sequencer. A sample scan of a chromatogram and derived sequence is shown in Figure 7.5.

The dye-terminator sequencing method is, like the Sanger method, able to sequence only about 400 bases at a time. New methods are being developed and explored that would greatly lower the cost and concominantly greatly increase the size of DNA chains being sequenced. The ultimate goal of these improved methods is the ability to rapidly sequence the entire genome of individuals at costs below $1000. Achieving this goal would allow clinicians and scientists to correlate altered or mutated genes with genetic diseases, predict clinical progression of diseased states, and develop drug or genetic therapies for each individual.

The ability to routinely sequence the individual's genome is likely to be achieved several years from now. However, other technologies are currently available to detect human genetic variations that give clues to an individual's potential to develop specific diseased states. It is postulated that as many as 15 million sites within the human genome may vary from one individual to another as single-nucleotide polymorphisms (SNP). Using array technologies (p. 295), one can search for as many as 500,000 SNPs at a time in hundreds to thousands of individuals. By October 2007 a human haplotype map (HapMap) of over 3.1 million SNPs had been generated. The appearance of specific SNPs or combinations of SNPs is being correlated to diseases such as type 1 diabetes and autism.

7.4 • RECOMBINANT DNA, CLONING, AND SELECTION OF CLONES

DNA from Different Sources Can Be Ligated to Form a New DNA Species: Recombinant DNA

The ability to cleave a population of DNA molecules selectively with restriction endonucleases led to the technique for joining two different DNA molecules termed **recombinant DNA**. This procedure combined with techniques for replication, separation, and identification permits the production of large quantities of purified DNA fragments. The combined techniques, referred to as recombinant DNA technology, allow removal of a piece of DNA out of a larger complex molecule, such as the genome of a virus or human, and amplification of the DNA fragment. Recombinant DNAs have been prepared that combine DNA fragments from bacteria with fragments from humans, viruses with viruses, and so on. The joining of two different pieces of DNA is achieved by a restriction endonuclease and a DNA ligase. Many restriction endonucleases, varying in their nucleotide sequence specificity, are used (Section 7.3, p. 258). Some hydrolyze the two strands of DNA in a staggered fashion to produce sticky, or cohesive, ends (Figure 7.6) whereas others cut both strands symmetrically to produce a blunt end. A specific restriction enzyme cuts DNA at exactly the same sequence site regardless of source of DNA (bacteria, plant, mammal, etc.). A DNA molecule may have none or numerous recognition sites for a particular restriction endonuclease. The staggered cut results in DNA fragments with single-stranded ends. When different DNA fragments generated by the same restriction endonuclease are mixed, their single-stranded ends can hybridize or anneal together. DNA ligase joins the two fragments to produce a recombinant DNA molecule.

The DNA fragments that contain blunt ends can also be ligated but with much less efficiency. The efficiency is increased by enzymatically adding poly(dA) tails to one species of DNA and poly(dT) tails to the second species. The fragments with complementary tails can then be annealed and ligated.

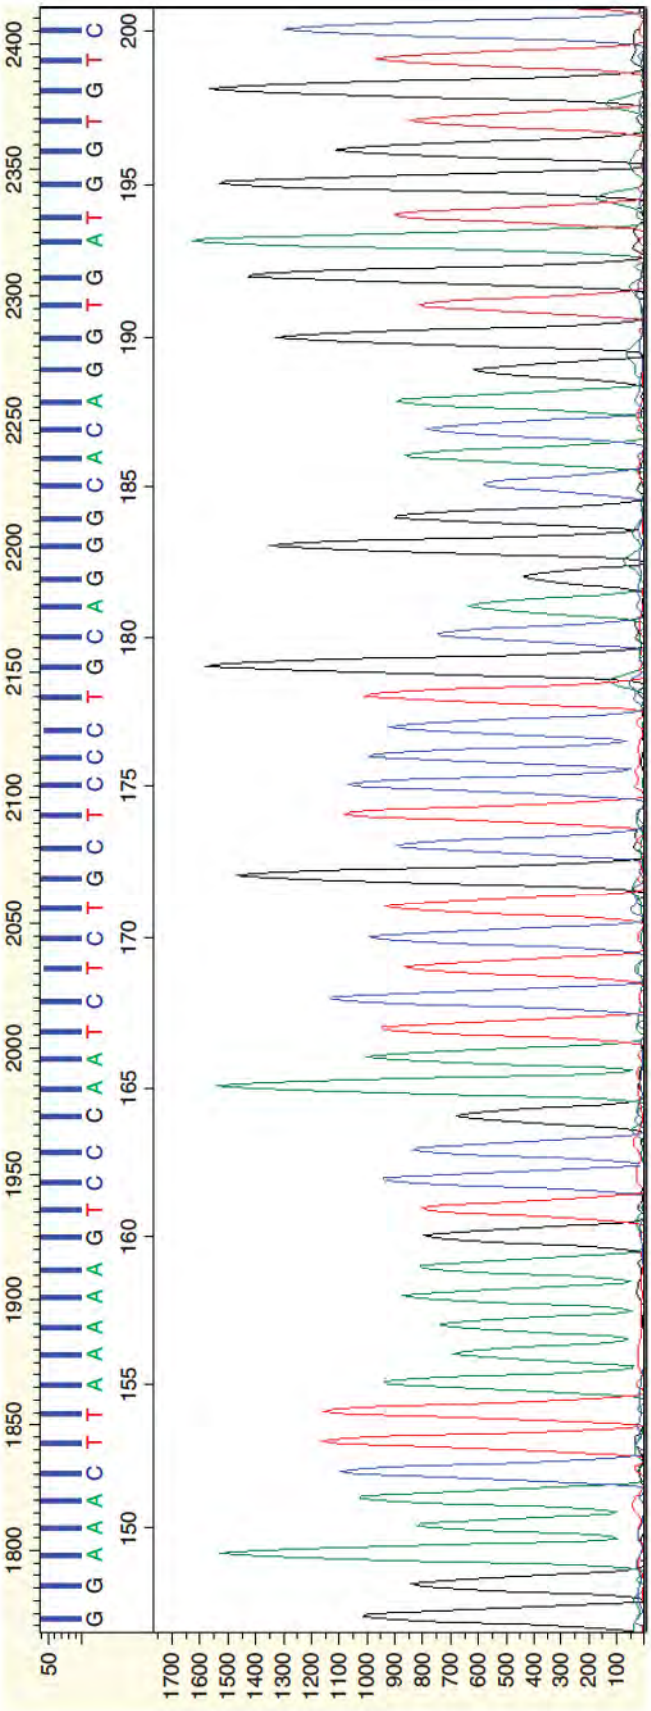

Figure 7.5 Chromatogram of DNA sequence generated by the dye-terminator sequencing method. The partial sequence of PCR amplified DNA of the human granulocyte matrix metalloproteinase 2 (MMP2) cDNA is depicted. Each ddNTP is tagged with a different colored fluor. The color of each peak corresponds to the colored nucleotide listed across the top of the figure.
Data from the laboratory of G. Soslau, Drexel Universty College of Medicine, Philadelphia, PA.

Recombinant DNA Vectors Are Produced by Cloning

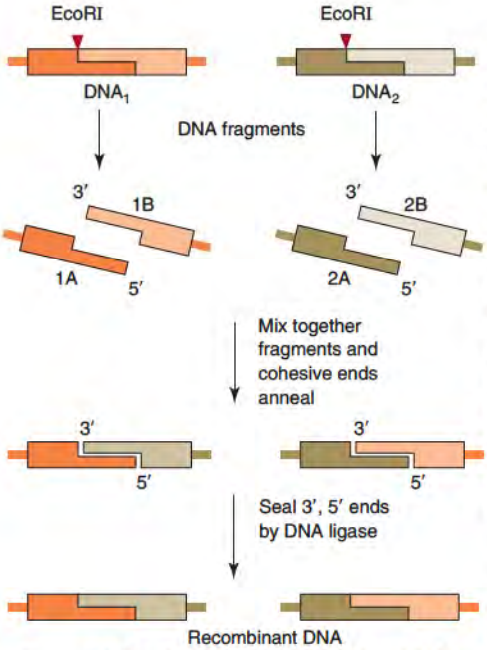

Figure 7.6 The formation of recombinant DNA from restriction endonuclease-generated fragments that contain cohesive ends. Many restriction endonucleases hydrolyze DNA in a staggered fashion yielding fragments with single-stranded regions at their 5′- and 3′-ends. DNA fragments generated from different molecules with the same restriction endonuclease have complementary single-stranded ends that can be annealed and covalently linked together with a DNA ligase. All different combinations are possible in a mixture. When two DNA fragments of different origin combine, a recombinant DNA molecule results.

By incorporating a recombinant DNA into a cell that allows replication of recombinant DNA, amplification of DNA of interest can be achieved. A carrier DNA, or cloning vector, is employed. Bacterial plasmids are ideally suited as recombinant DNA vectors.

Many bacteria contain a single circular chromosome of approximately 4×10^6 base pairs (bp) and minicircular DNA molecules called **plasmids**. Plasmids usually contain only a few thousand base pairs and are rarely associated with the larger chromosome. Genes within a plasmid include those which confer antibiotic resistance to the bacterium, an attribute useful in selecting specific colonies of the bacterium. Plasmids replicate independently of the replication of the main bacterial chromosome. One type of plasmid, the **relaxed-control** plasmids, may be present in tens to hundreds of copies per bacterium, and its replication depends solely on host enzymes that have long half-lives. Therefore, replication of "**relaxed**" **plasmids** occurs in the presence of a protein synthesis inhibitor. Bacteria accumulate several thousand plasmid copies per cell under these conditions. Because of this, the relaxed plasmid type is routinely used for production of recombinant DNA. In plasmids subject to **stringent control**, replication depends on continued synthesis of plasmid-encoded proteins. They replicate at about the same rate as the large bacterial chromosome, and only few copies occur per cell.

The first practical recombinant DNA contained foreign DNA ligated with the vector *E. coli* **plasmid pSC101**, which contains one EcoRI restriction endonuclease site and a gene that confers antibiotic resistance to the bacterium. The plasmid contains an origin of replication and associated DNA regulatory sequences that are together called a **replicon**. However, the single restriction endonuclease site limits the DNA fragments that can be cloned to those generated by EcoRI; the one antibiotic-resistance selectable marker reduces the convenience in selection, and the plasmid replicates poorly.

Plasmid vectors with broad versatility are constructed by recombinant DNA technology. The desirable features of a plasmid vector include a relatively low molecular weight (3–5 kilobases [kb]) to accommodate larger fragments, several different restriction sites useful in cloning a variety of fragments, multiple selectable markers to aid in selecting bacteria with recombinant DNA molecules, and a high rate of replication. The first plasmid constructed (Figure 7.7) to satisfy these requirements was **pBR322**, which is used to generate many vectors in use today. These contain an inserted DNA sequence termed a **polylinker**, **restriction site bank**, or **polycloning site**, which contains numerous restriction endonuclease sites unique to the plasmid.

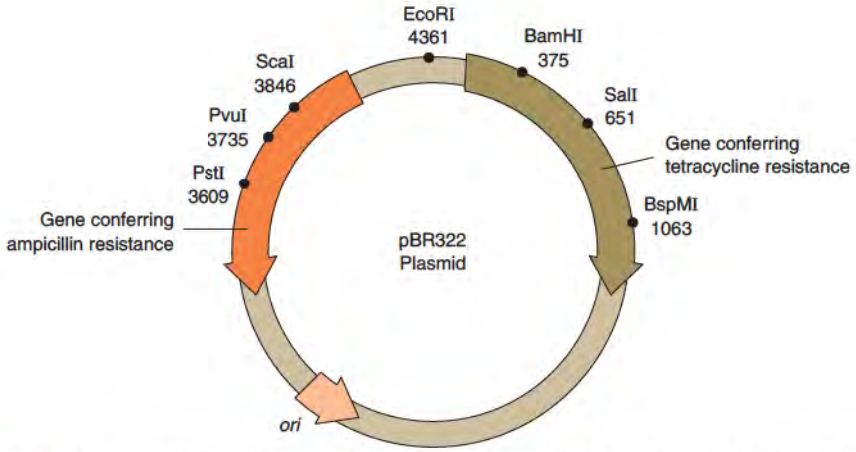

Figure 7.7 The pBR322 plasmid constructed in the laboratory to contain features that facilitate cloning of foreign DNA fragments. By convention the numbering of the nucleotides begins with the first T in the unique EcoRI recognition sequence (GAATTC) and the positions on the map refer to the 5′-base of the various restriction endonuclease-recognition sites. Only a few of these within the antibiotic resistance genes and none of the sites where an enzyme cuts more than once are shown.

Directional Cloning: DNA Inserted into Vector DNA in a Specific Direction

Directional cloning reduces the number of variable recombinants and increases the probability of selection of the desired recombinant. Insertion of foreign DNA, with a defined polarity, into a plasmid vector without the plasmid resealing itself can be accomplished by use of two restriction endonucleases (Figure 7.8); vectors with polylinkers are ideally suited for this purpose. The use of two enzymes yields DNA fragments and linearized plasmids with different sticky ends. Under these conditions the plasmid is unable to reanneal with itself. In addition, the foreign DNA is inserted into the vector in only one orientation. This is extremely important when one clones a potentially functional gene downstream from the promoter-regulatory elements in expression vectors.

Bacteria Transformed with Recombinant DNA and the Need for a Selection Process

The artificial introduction of DNA into bacteria is referred to as **transformation**. It is accomplished by briefly exposing the cells to divalent cations that make them transiently permeable to small DNA molecules. Recombinant plasmid molecules, containing foreign DNA, are then introduced into bacteria and replicate normally.

Once a plasmid has been introduced into a bacterium, both can replicate. During the transformation process, some bacteria may not take up a plasmid or may be transformed with a vector not carrying foreign DNA; in preparation some vectors may reanneal without inclusion of the foreign DNA. In some experimental conditions DNA fragments are generated that are readily purified from small, highly purified DNA species, for example, some DNA viruses. More typically, however, restriction endonuclease generates numerous DNA fragments whose number depends on the size and complexity of DNA being used, and individual fragments cannot be isolated from these samples. Restriction endonucleases

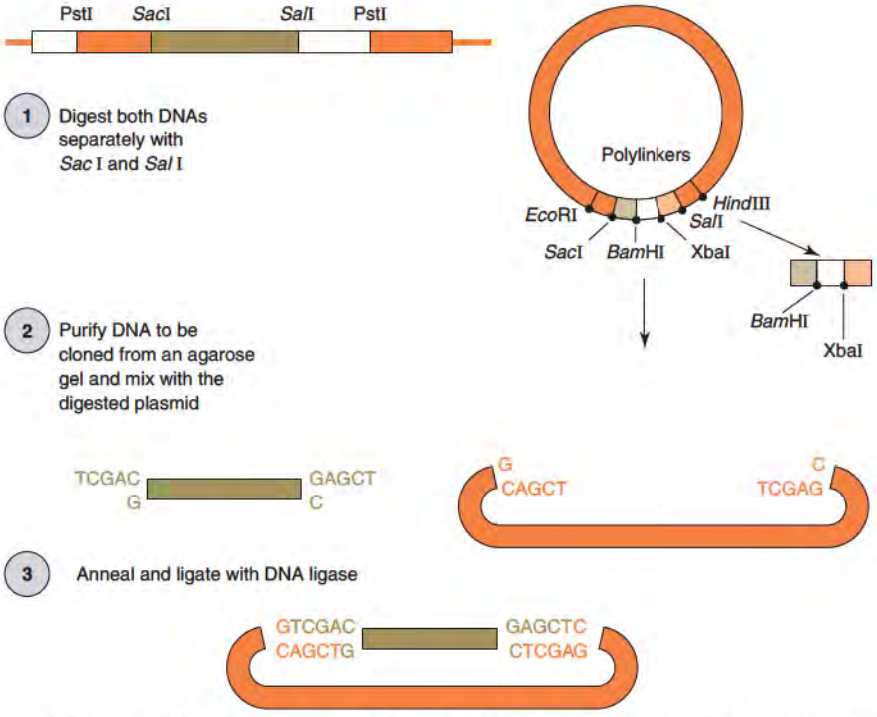

Figure 7.8 Directional cloning of foreign DNA into vectors with a specified orientation. Insertion of a foreign DNA fragment into a vector with a specified orientation requires two different annealing sequences at each end of the fragment and the corresponding complementary sequence at the two ends generated in the vector. Two different annealing sequences are generated by specific restriction endonucleases that hydrolyze both the foreign DNA fragment and vector. A polylinker with numerous unique restriction endonuclease sites within the vector facilitates directional cloning. Knowledge of the restriction map for the DNA of interest allows for the selection of appropriate restriction endonucleases.

do not necessarily produce fragments that contain intact genes. A fragment may contain an entire gene but lack the required flanking regulatory sequences, such as the promoter region. If the foreign gene is of mammalian origin, its regulatory sequences are not recognized by the bacterial synthetic machinery. The primary gene transcript (premRNA) may contain introns that cannot be processed by the bacteria. Methods have been developed to select bacteria that contain the desired DNA.

Recombinant DNA Molecules in a Gene Library

When a complex mixture of thousands of different genes, located on different chromosomes as in the human genome, is subjected to cleavage by a single restriction endonuclease, thousands of DNA fragments are generated. These DNA fragments can be annealed with a plasmid vector that has been cleaved to produce a linear molecule by the same restriction endonuclease. By adjusting the ratio of plasmid to foreign DNA, the probability of joining at least one copy of each DNA fragment within a circularized recombinant-plasmid DNA approaches 1. Usually, only one DNA fragment is inserted into each plasmid vector. Bacteria are transformed with the recombinant molecules so that one plasmid is taken up by one bacterium. Each recombinant molecule is then replicated within the bacterium; this produces progeny, each carrying multiple copies of the recombinant DNA. The resulting total bacterial population will contain fragments of DNA that may represent the entire human genome. This is termed a **gene library**. As in any library containing thousands of volumes, a selection system must be available to retrieve the book or gene of interest.

Plasmids are commonly employed to clone DNA fragments generated from DNA of limited size and complexity, such as viruses, and to subclone large DNA fragments previously cloned in other vectors. Genomic DNA fragments are usually cloned from vectors that can carry larger foreign DNA fragments than plasmids (p. 277).

Selection of Transformed Bacteria by Loss of Antibiotic Resistance

When a single transformed bacterium carrying a recombinant DNA multiplies, all of its progeny will carry copies of the same recombinant plasmid. The problem is how to identify the colony that contains the desired plasmid in a field of thousands to millions of different bacterial colonies. The plasmid construct pBR322 and its modifications carry two genes that confer antibiotic resistance and are sensitive to several restriction endonucleases. When a fragment of foreign DNA is inserted into a restriction site within one of them, the gene becomes nonfunctional and the bacteria carrying this recombinant plasmid are sensitive to the antibiotic (Figure 7.10). The second antibiotic resistance gene within the plasmid, however, remains intact, and the bacteria will be resistant to this antibiotic. This **insertional inactivation** of plasmid gene products permits selection of bacteria that carry recombinant plasmids.

pBR322 contains genes that confer resistance to **ampicillin** (amp^r) and **tetracycline** (tet^r). A gene library of cellular DNA fragments inserted within the tet^r gene can be selected and screened in two stages (Figure 7.9). First, the bacteria are grown in an ampicillin containing growth medium. Bacteria that are not transformed because they lack a normal or recombinant plasmid will not grow in the presence of the antibiotic, and this population of bacteria is eliminated. This, however, does not indicate which of the remaining viable bacteria carry a recombinant plasmid vector rather than a plasmid with no DNA insert. The second step is to identify bacteria that carry recombinant vectors with nonfunctional tet^r genes, which are, therefore, sensitive to tetracycline.

The bacteria resistant to ampicillin are plated and grown on agar plates containing ampicillin (Figure 7.9). Replica plates are made by touching the colonies on the original agar plate with a filter and then touching additional sterile plates with the filter. All the plates will contain portions of each original colony at identifiable positions on the plates. The replica plate can contain tetracycline, which will kill bacteria harboring a disrupted tet^r gene. Comparison of replica plates with and without tetracycline indicates which colonies on the original ampicillin plate contain recombinant plasmids.

Either DNA or RNA probes (pp. 268 and 270) are used to identify the DNA of interest. Ampicillin resistant bacterial colonies on agar can be plated onto a nitrocellulose filter

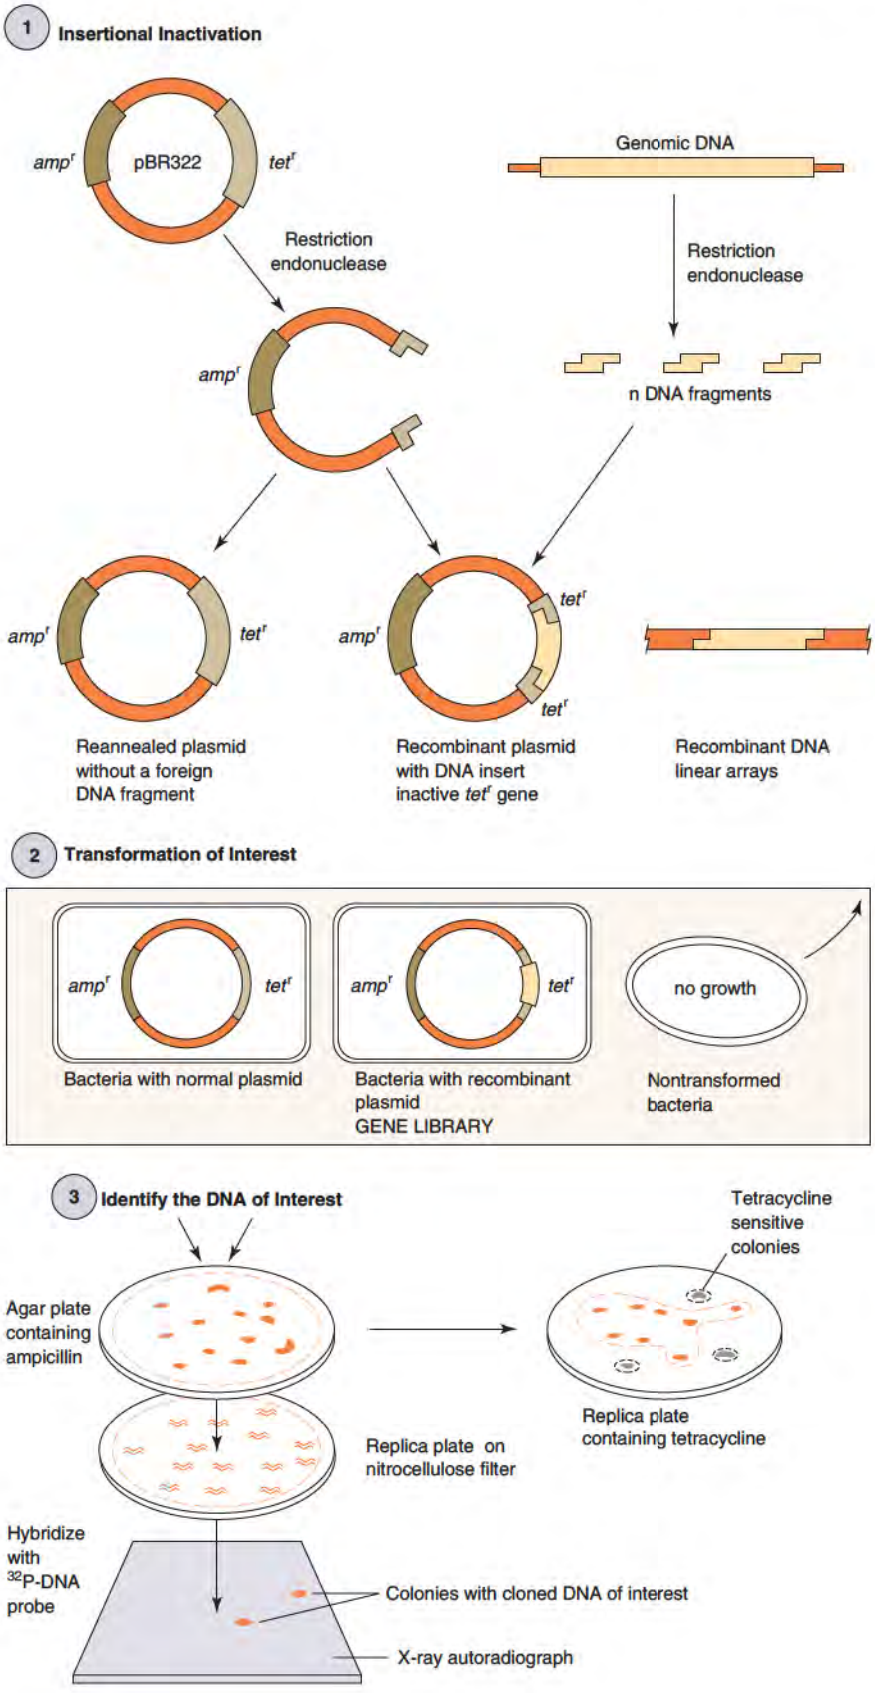

Figure 7.9 Insertional inactivation of recombinant plasmids and detection of transformed bacteria carrying a cloned DNA of interest. When the insertion of a foreign DNA fragment into a vector disrupts a functional gene sequence, the resulting recombinant DNA does not express the gene. The gene that codes for resistance to tetracycline (Tet^r) is destroyed by DNA insertion while the ampicillin resistance gene (Amp^r) remains functional. Destruction of one resistance gene and the retention of a second antibiotic resistance gene permits the detection of bacterial colonies carrying the foreign DNA of interest within the replicating recombinant vector.

CLINICAL CORRELATION 7.5

Multiplex PCR Analysis of the HGPRTase Gene Defects in the Lesch–Nyhan Syndrome

Lesch–Nyhan syndrome (OMIM 300322) results from a deficiency in hypoxanthine-guanine phosphoribosyltransferase (HGPRTase) activity (see Clin. Corr. 20.2, p. 811). Several variant forms of HGPRTase defects have been detected. Multiplex PCR amplification of the HGPRT gene locus has been employed to analyze this gene in cells derived from Lesch–Nyhan patients and results account for the variability of the HGPRTase. The gene, composed of nine exons, can be multiplex amplified using 16 different primers in a single PCR reaction. The products can be separated by agarose gel electrophoresis. Analysis of the HGPRT gene locus by multiplex amplification of DNA derived from cells of several patients detected great variations ranging from deletions of regions of exons to total absence of the exons.

Rossiter, B. J. F., et al. PCR, A Practical Approach, Vol. 1. In McPherson, M.J., et al. (Eds)., Oxford: Oxford University Press, 1994, 67.

and adhering cells lysed with NaOH (Figure 7.9). DNA within the lysed bacteria is also denatured by the NaOH and becomes firmly bound to the filter. A labeled DNA or RNA probe that is complementary to the DNA of interest will hybridize with the nitrocellulose bound DNA. The filter is then tested by X-ray autoradiography, which will detect any colony that carries the cloned DNA of interest. These spots indicate the colonies on the original agar plate that can be grown in a large-scale culture for further manipulation.

Cloned and amplified DNA fragments usually do not contain a complete gene and are not expressed. The DNA inserts, however, can readily be purified for sequencing or used as probes to detect genes within a mixture of genomic DNA, to assay transcription levels of mRNA, and to detect disease producing mutations.

α-Complementation for Selecting Bacteria Carrying Recombinant Plasmids

Vectors have been constructed (the pUC series) such that selected bacteria transformed with these vectors carrying foreign DNA inserts can be identified visually (Figure 7.11). The pUC plasmids contain the regulatory sequences and part of the 5′-coding sequence (N-terminal 146 amino acids) for the β-galactosidase gene (lac Z gene) of the lac operon (p. 305). The translated N-terminal fragment of β-galactosidase is an inactive polypeptide. Mutant *E. coli,* that code for the missing inactive carboxy-terminal portion of β-galactosidase, are transformed using the pUC plasmids. The translation of the host cell and plasmid portions of the β-galactosidase in response to an inducer, **isopropyl thio-β-D-galactoside**, complements each other to yield an active enzyme. The process is referred to as **α-complementation**. When these transformed bacteria are grown in the presence of a chromogenic substrate (5-bromo-4-chloro-3-indolyl-β-D-galactoside [X-gal]) for β-galactosidase, they form blue colonies. If, however, a foreign DNA fragment has been inserted into the sequence for the N-terminal portion of β-galactosidase, the active enzyme cannot be formed. Bacteria, transformed with these recombinant plasmids and grown on X-gal yield white colonies, can be selected visually from nontransformed blue colonies.

PCR Circumvents the Need to Clone DNA

Cloning and amplification of a DNA fragment are employed in subcloning, mutagenesis, and sequencing studies. The PCR has largely replaced the need to amplify recombinant DNA in a replicating biological system, greatly reducing the time and preparative steps required. It is not necessary to know the sequence of the DNA insert (up to 6 kb) to amplify it by the PCR since the sequence of the vector DNA flanking the insert is known.

PCR may completely circumvent the need to clone the DNA of interest. For instance, a gene of known sequence can readily be analyzed in a patient's DNA for detection of mutations by a **multiplex PCR strategy**. DNA is isolated from the patient's blood cells, and multiple pairs of oligonucleotide primers are synthesized to amplify the entire gene or selected regions within the gene (Figure 7.10). Analysis of the amplified DNA fragments by agarose gel electrophoresis reveals any deletion mutation as compared to the normal gene products. Direct sequencing of multiple PCR products detects point mutations in the patient's gene. Multiplex PCR has been used to detect defects in the HGPRTase gene in Lesch–Nyhan patients (Clin. Corr. 7.5).

7.5 • DETECTION AND IDENTIFICATION OF NUCLEIC ACIDS AND DNA-BINDING PROTEINS

Nucleic Acids as Probes for Specific DNA or RNA Sequences

DNA and RNA probes are used for selection of bacteria that harbor recombinant DNA of interest, for analysis of mRNA expressed in a cell or for identification of DNA sequences within a genome. They contain sequences complementary to the target nucleic acid and

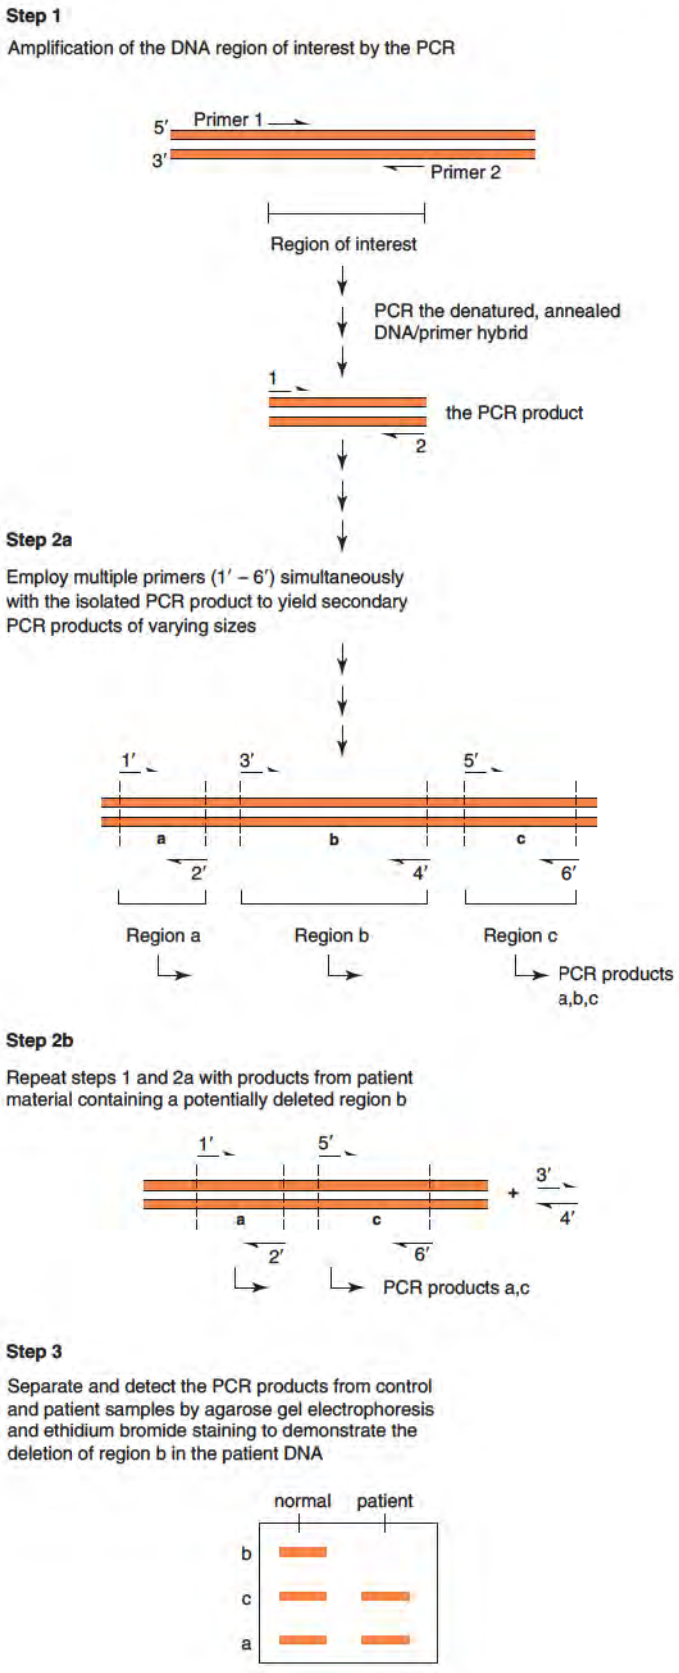

Figure 7.10 Multiplex PCR to analyze a DNA region of interest for mutations. A region of DNA within a complex DNA molecule is amplified by the PCR with primers that are complementary to sequences flanking the DNA region of interest (step 1). The PCR product is then used as a template simultaneously for multiple pairs of primers (step 2a) that are complementary throughout the DNA (here they cover three segments, *a*, *b*, and *c*). This procedure requires prior knowledge of the sequence of the normal DNA or gene. Step 2a is repeated for DNA derived from a patient with potential mutation(s) in the DNA region of interest (step 2b). The amplified DNA products from the multiplex PCR step (step 2a and b) are then analyzed by agarose gel electrophoresis to ascertain if the patient sample contains a mutation (step 3).

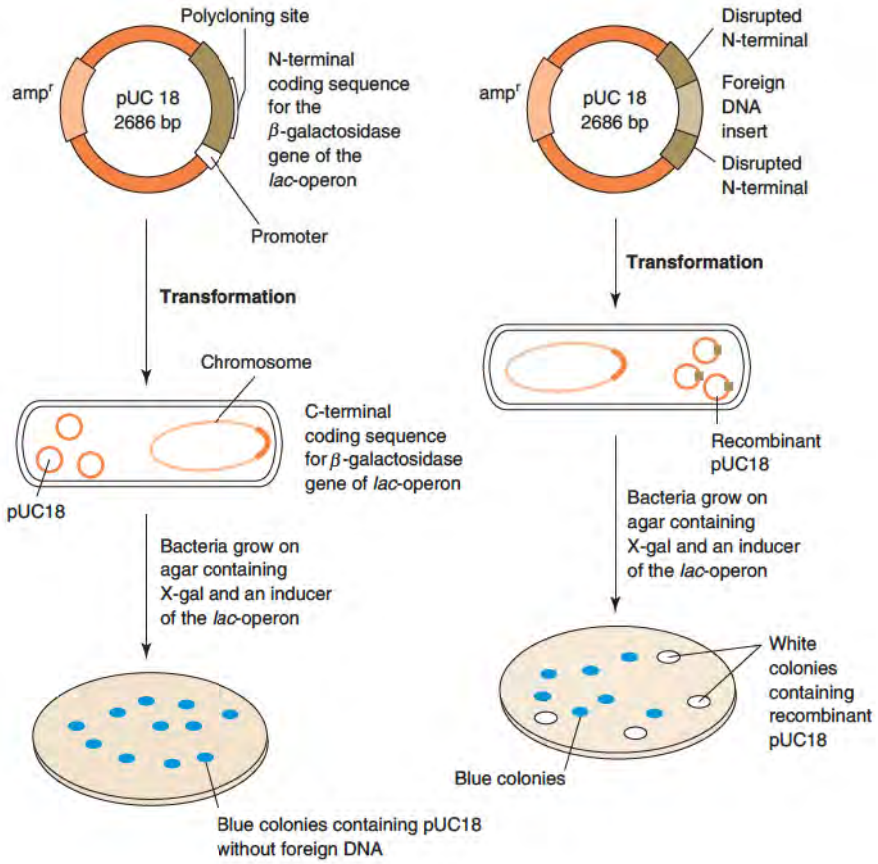

Figure 7.11 α-Complementation for detection of transformed bacteria. A constructed vector (pUC 18) expresses the N-terminal coding sequence for β-galactosidase of the lac operon. Bacterial mutants coding for the C-terminal portion of β-galactosidase are transformed with pUC 18. These transformed bacteria grown in the presence of a special substrate for the intact enzyme (X-gal) result in blue colonies because they contain the enzyme to react with substrate. The functional N-terminal and C-terminal coding sequences complement each other to yield a functional enzyme. If, however, a foreign DNA fragment insert disrupts the pUC 18 N-terminal coding sequence for β-galactosidase, bacteria transformed with this recombinant molecule will not produce a functional enzyme. Bacterial colonies carrying these recombinant vectors can then be visually detected as white colonies.

hybridize with the nucleic acid of interest. The degree of complementarity determines the tightness of binding of the probe. The probe does not need to contain the entire complementary sequence of the DNA. The probe can be labeled, usually with ^{32}P or with nonradioactive labels that depend on enzyme substrates coupled to nucleotides, which when incorporated into the nucleic acid is detected by an enzyme-catalyzed reaction.

Labeled probes are produced by **nick translation** of double-stranded DNA. Nick translation (Figure 7.12) involves the random cleavage of a phosphodiester bond in the backbone of a DNA strand by DNase I; the breaks are called nicks. *E. coli* DNA polymerase I, with its 5′ → 3′ exonucleolytic activity and its DNA polymerase activity, creates single-strand gaps by hydrolyzing nucleotides from the 5′-side of the nick and then filling in the gaps with its polymerase activity. The reaction is usually carried out in the presence of an α-^{32}P-labeled dNTP and the other three unlabeled dNTPs. The DNA employed in this method is usually purified and is derived from cloned DNA, viral DNA, or cDNA.

Random primer labeling of DNA has distinct advantages over the nick translation method. The random primer method typically requires only 25 ng of DNA as opposed to 1–2 μg of DNA for nick translation and results in labeled probes with a specific activity ($>10^9$ cmp/ug) approximately 10 times higher. This method generally produces longer labeled DNA probes. The double-stranded probe is melted and hybridized with a mixture of random hexanucleotides containing all possible sequences (ACTCGG, ACTCGA, ACTCGC, etc.). Hybridized hexanucleotides serve as primers for DNA synthesis with a DNA polymerase, such as the Klenow enzyme, in the presence of one or more radioactively labeled dNTPs.

Labeled RNA probes have advantages over DNA probes. For one, relatively large amounts of RNA can be transcribed from a template that may be available in very limited quantities. A double-stranded DNA (dsDNA) probe must be denatured prior to hybridization with the target DNA and rehybridization with itself competes for hybridization with the DNA of interest. No similar competition occurs with single-stranded RNA probes that hybridize with complementary DNA or RNA molecules. Synthesis of an RNA probe requires DNA as a template. To be transcribed the template must be covalently linked to

an upstream promoter that can be recognized by a DNA dependent RNA polymerase. Vectors have been constructed that are well suited for this technique.

A labeled DNA or RNA probe is hybridized to nitrocellulose-bound nucleic acids and identified by the detection of labeled probe. Nucleic acids of interest are transferred to nitrocellulose from bacterial colonies grown on agar or from agarose gels on which they are electrophoretically separated by size.

Southern Blot Technique for Identifying DNA Fragments

The transfer of DNA species separated by agarose gel electrophoresis to a filter for analysis was developed in the 1970s by E. M. Southern and is an indispensable tool. The method is called the **Southern blot technique** (Figure 7.13). A mixture of restriction endonuclease-generated fragments can be separated according to size by electrophoresis through an agarose gel. The DNA is denatured by soaking the gel in alkali. The gel is then placed on absorbent paper, and a nitrocellulose filter is placed directly on top of the gel. Several layers of absorbent paper are placed on top of the nitrocellulose filter. The absorbent paper under the gel is kept wet with a concentrated salt solution that is pulled up through the gel, the nitrocellulose, and into the absorbent paper layers above by capillary action. The DNA is eluted from the gel by the upward movement of the high-salt solution onto the nitrocellulose filter directly above, where it becomes bound. The position of the DNA bound to the nitrocellulose filter is the same as that present in the agarose gel. Single-stranded membrane-bound DNA can be analyzed with labeled probes.

The Southern blot technique is invaluable for detection and determination of the number of copies of particular sequences in complex genomic DNA, for confirmation of DNA cloning results, and demonstration of polymorphic DNA in the human genome that correspond to pathological states. An example of the use of Southern blots is shown in Figure 7.13. Whole human genomic DNA, isolated from three individuals, was digested separately with a restriction endonuclease generating thousands of fragments. These were distributed throughout the agarose gel according to size in an electric field. The DNA was transferred (blotted) to a nitrocellulose filter and hybridized with a ^{32}P-labeled DNA or RNA probe for a gene of interest. The probe detected two bands in all three individuals indicating that the gene of interest was cleaved at one site within its sequence. Individuals A and B presented a normal pattern while patient C had one normal band and one lower-molecular-weight band. This is an example of detecting altered restriction endonuclease-generated DNA fragments from different individuals within a single species, **restriction fragment length polymorphism (RFLP).** The detection of a reduced molecular weight fragment in patient C implies that deletion of a segment of the gene occurred and may be associated with a pathological state. The gene from this patient is cloned, sequenced, and fully analyzed to characterize the altered nature of the DNA (Clin. Corr. 7.6).

Other techniques that employ the principles of Southern blot are the transfer of RNA (Northern blots), as described below and of proteins (Western blots) to nitrocellulose filters or nylon membranes.

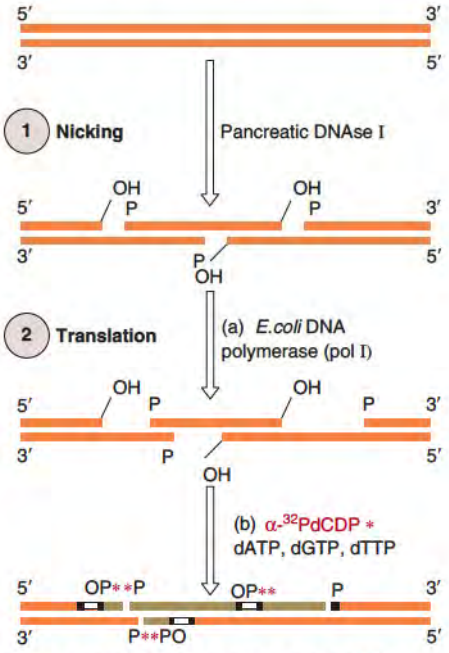

Figure 7.12 Nick translation to label DNA probes. Purified DNA molecules can be radioactively labeled and used to detect, by hybridization, the presence of complementary RNA or DNA in experimental samples. (1) Nicking step: Introduces random single-stranded breaks in DNA; (2) Translation step: *E. coli* DNA polymerase (pol I) has both 5′–3′ exonuclease activity that removes nucleotides from the 5′-end of the nick and polymerase activity that simultaneously fills in the single-stranded gap with radioactively labeled nucleotides using the 3′-end as a primer.

Single-Strand Conformation Polymorphism

Southern blot analysis and detection of base changes in DNA from different individuals by RFLP analysis is dependent on alteration of a restriction endonuclease site. A base substitution, deletion or insertion (**a single-nucleotide polymorphism [SNP]**) rarely occurs within a restriction endonuclease site. However, these modifications are detected at a specific site by **single-strand conformation polymorphism (SSCP).** This technique takes advantage of the fact that single-stranded DNA, smaller than 400 bases long, subjected to electrophoresis through a polyacrylamide gel migrates with a mobility partially dependent on its conformation. A single base alteration usually modifies the DNA conformation sufficiently to be detected as a mobility shift on electrophoresis through a non-denaturing polyacrylamide gel.

The analysis of a small region of genomic DNA or cDNA for SSCP is accomplished by PCR-amplification of the region of interest. Sense and antisense oligonucleotide primers are synthesized that flank the region of interest, and this DNA is amplified by PCR

in the presence of radiolabeled nucleotide(s). The purified radiolabeled double-stranded PCR product is then heat denatured in 80% formamide and immediately loaded onto a nondenaturing polyacrylamide gel. The mobilities of control products are compared to samples from experimental studies or patients. Detection of mutations in samples from patients identify genetic lesions. These procedures were successfully applied to the analysis of genes associated with the long-QT syndrome that has been implicated in the sudden infant death syndrome (SIDS) (Clin. Corr. 7.7). The method depends on prior knowledge of the sequence of the gene or gene fragment of interest whereas analysis by RFLP requires only restriction map analysis of DNA.

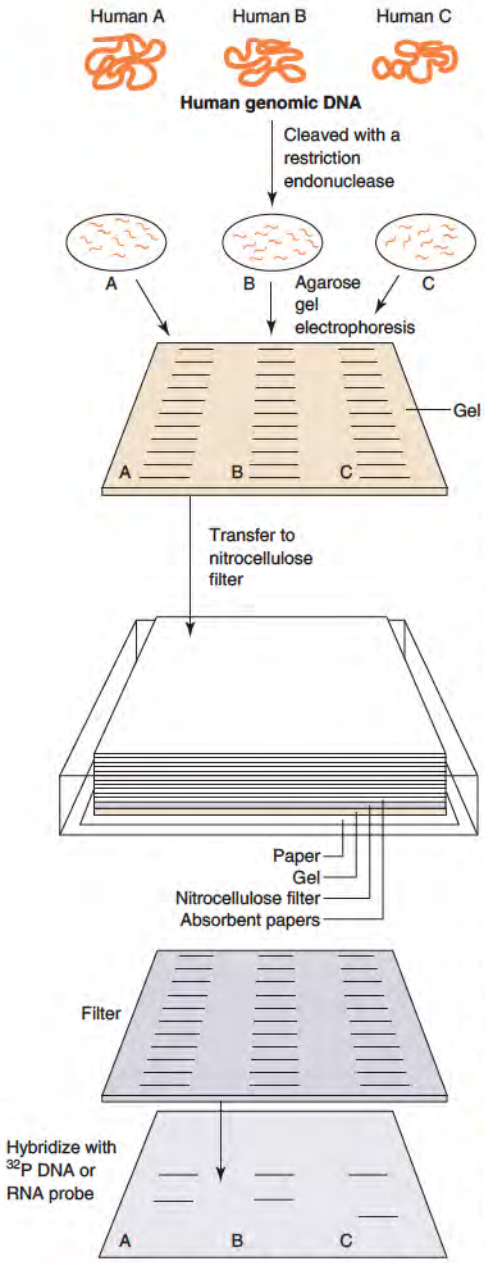

Figure 7.13 Southern blot to transfer DNA from agarose gels to nitrocellulose. Transfer of DNA to nitrocellulose, as single-stranded molecules, allows for the detection of specific DNA sequences within a complex mixture of DNA. Hybridization with nick translated labeled probes can demonstrate if a DNA sequence of interest is present in the same or different regions of the genome.

Detection of mRNA

Analysis of the amount of mRNA species in tissue or total RNA preparations is often critical for our understanding gene regulation of cell growth and tissue differentiation. We can assess timing, level, and site within a tissue of gene expression through the analysis of specific mRNA species. Several techniques are available to assay the amount of a specific mRNA species in an RNA preparation. (a) **Northern blot analysis** requires the electrophoretic separation of RNA species, by size, on an agarose gel followed by the transfer and cross-linking to a membrane as in the Southern blot technique. The fixed RNA species are then hybridized with a labeled probe specific for the mRNA species of interest. If the probe is radiolabeled, hybrids are detected by autoradiography. Nonradioactive probes are also available. Northern blot analysis allows ready determination of the size of the mRNA and identification of potential alternatively spliced transcripts and/or the presence of multigene family transcripts. (b) **RT-PCR** (Section 7.8, p. 281), unlike the Northern blot, allows us to measure the amount of an mRNA species present in an RNA sample. Measurement is based on comparison of the relative amount of the PCR product of an internal control transcript to the amount of a specific mRNA in the same sample. Typical internal control transcripts include GAPDH (glyceraldehyde 3-phosphate dehydrogenase) and β-actin. (c) The **nuclease protection assay** (NPA) does not give any information about the size of the mRNA of interest, but is ideally suited for the simultaneous analysis of multiple mRNA species. Radiolabeled or nonisotopic probe(s) are hybridized with the RNA sample in solution. Hybridization in solution is more efficient than hybridization to membrane-fixed RNA, as used in Northern blots. Any remaining unhybridized probe and RNA are then hydrolyzed with nucleases. The mixture of hybridized species is then separated through a low percentage (6%) acrylamide gel. The size of each hybridized species is determined by the size of the probe employed. NPA is commonly used to detect mRNA transcripts in different tissues (Figure 7.14). (d) ***In situ* hybridization** is the only method described in this section to define which cells in a sample of formalin-fixed tissue express a specific gene. In this method, RNA is not isolated or subjected to electrophoretic separations. Rather tissues of interest are fixed, thin sectioned, and mounted onto microscope slides. Proteins are digested with protease K to increase accessibility of the labeled probe to hybridize with the cellular mRNA of interest. This method supports findings of the nuclease protection assays and also defines which cell types within the tissues are expressing the mRNA of interest.

Detection of Sequence-Specific DNA-Binding Proteins

Regulatory proteins bind to specific DNA sequences that flank genes that up- or down- regulate gene expression. The **electrophoretic mobility shift assay** (**EMSA**), or gel retardation, method has been employed extensively to analyze sequence-specific DNA-binding proteins along with the DNA sequence required for binding. Proteins with potential DNA-binding characteristics are prepared from whole cell extracts, nuclear extracts, purified protein preparations, or recombinant proteins from genetically engineered expression systems. The DNA probe is radio-labeled. The DNA employed may be DNA fragments, double-stranded synthetic oligonucleotides, or cloned DNA containing a known protein-binding site(s) or potential protein-binding site(s). The DNA must be double stranded since single-stranded DNA would bind nonspecifc single-strand binding proteins (with cell or nuclear extracts) that would interfere with the interpretation of the results. The purified labeled DNA probe

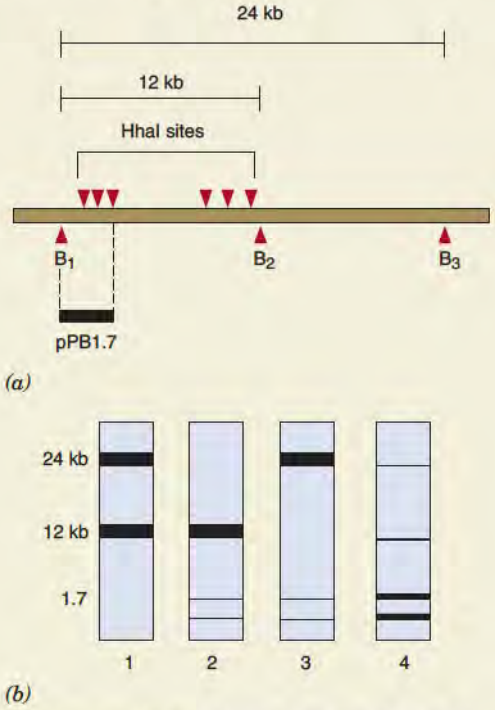
CLINICAL CORRELATION 7.6

Restriction Fragment Length Polymorphisms Determine the Clonal Origin of Tumors

It is generally assumed that most tumors are monoclonal in origin; that is, a rare event alters a single somatic cell genome such that the cells grow abnormally into a tumor mass with all-daughter cells carrying the identically altered genome. Proof that a tumor is monoclonal versus polyclonal can help to distinguish hyperplasia (increased production and growth of normal cells) from neoplasia (growth of new or tumor cells). The detection of restriction fragment length polymorphisms (RFLPs) in Southern blotted DNA samples allows one to define the clonal origin of human tumors. If tumor cells were collectively derived from different parental cells, they should contain a mixture of DNA markers characteristic of each cell of origin. However, an identical DNA marker in all tumor cells would indicate a monoclonal origin. The analysis is limited to females to take advantage of the fact that each cell carries only one active X chromosome of either paternal or maternal origin with the second X chromosome being inactivated. Activation occurs randomly during embryogenesis and is faithfully maintained in all daughter cells with one-half the cells carrying an activated maternal X chromosome and the other one-half an activated paternal X chromosome.

Analysis of the clonal nature of a human tumor depends on the fact that activation of an X chromosome involves changes in the methylation of selected cytosine (C) residues within the DNA molecule. Several restriction endonucleases, such as Hha I which cleaves DNA at GCGC sites, do not cleave DNA at their recognition sequences if a C is methylated within this site. Therefore, the methylated state (activated versus inactivated) of the X chromosome can be probed with restriction endonucleases. Also, the paternal X chromosome can be distinguished from the maternal X chromosome in a significant number of individuals by differences in the electrophoretic migration of restriction endonuclease generated fragments derived from selected regions of the chromosome. These fragments are identified on a Southern blot by hybridization with a DNA probe that is complementary to this region of the X chromosome. An X-linked gene that is amenable to these studies is the hypoxanthine guanine phosphoribosyltransferase (HGPRTase) gene. The HGPRTase gene consistently has two Bam HI restriction endonuclease sites (B1 and B3 in figure), but in some individuals a third site (B2) is also present.

The presence of site B2 in only one parental X chromosome HGPRT permits detection of RFLPs. Therefore, a female cell may carry one X chromosome with the HGPRT gene possessing 2Bam HI sites (results in one DNA fragment of 24 kb) or 3Bam HI sites (results in a single detectable DNA fragment of 12 kb). This figure depicts the expected results for the analysis of tumor cell DNA to determine its monoclonal or polyclonal origin. As expected, three human tumors examined by this method were shown to be of monoclonal origin.



Analysis of genomic DNA to determine the clonal origin of tumors. (*a*) The X chromosome-linked hypoxanthine guanine phosphoribosyltransferase (HGPRTase) gene contains two invariant Bam HI restriction endonuclease sites (B1 and B3) whereas in some individuals a third site, B2, is also present. The gene also contains several Hha I sites; however, all of these sites, except H1, are usually methylated in the active X chromosome. Therefore, only the H1 site would be available for cleavage by Hha I in the active X chromosome. A cloned, labeled probe, pPB1.7, is used to determine which form of the HGPRTase gene is present in a tumor and if it is present on an active X chromosome. (*b*) Restriction endonuclease patterns predicted for monoclonal versus polyclonal tumors are as follows: (1) Cleaved with Bam HI alone. 24-kb fragment derived from a gene containing only B1 and B3 sites and 12-kb fragment derived from a gene containing extra B2 site. Pattern is characteristic for heterozygous individual. (2) Cleaved with Bam HI plus Hha I, monoclonal tumor with the 12 kb derived from an active X chromosome (methylated). (3) Cleaved with Bam HI plus Hha I; monoclonal tumor with the 24-kb fragment derived from an active X chromosome (methylated). (4) Cleaved with Bam HI plus Hha I, polyclonal tumor. All tumors studied displayed patterns as in Lane 2 or Lane 3.

Vogelstein, B., Fearon, E. R., Hamilton, S. R., and Feinberg, A. B. Use of restriction fragment length polymorphism to determine the clonal origin of tumors. *Science* 227:642, 1985.

and protein sample are preincubated to form a stable protein-DNA complex prior to the electrophoretic analysis of the sample.

Figure 7.15 schematically depicts the expected results where the radio-labeled DNA complexes with a protein resulting in its retarded movement through the gel relative to the unreacted DNA. If an antibody to the DNA-binding protein of interest is added to the preincubation tube, one of two possible reactions occurs. If the antibody binds to an epitope that does not impede protein binding to the DNA, the complex size is increased resulting in a **supershift** (greater retardation) in the gel migration. Conversely, if the antibody blocks

CLINICAL CORRELATION 7.7

Single-Strand Conformational Polymorphism for Detection of Spontaneous Mutations that May Lead to SIDS

The sudden infant death syndrome (SIDS) is a major cause of death during the first year of life in the United States. Prospective study of more then 34,000 newborns that were monitored by electrocardiography indicated a strong correlation between increased risk of SIDS and prolonged QT interval in their heart EKG. On the basis of this study, it was decided to look for a mutation in one or more of the genes known to be related to the Long QT syndrome in a 44-day-old infant that presented cyanotic, apneic, and pulseless to a hospital emergency room. The child's arrhythmia with a prolonged QT interval was stabilized with multiple electrical DC shocks followed by drug treatment. Genomic DNA was prepared from peripheral blood lymphocytes from the infant and his parents. One gene associated with the Long QT syndrome contained the substitution of AAC for TCC at position 2971 to 2972 (protein associated with the sodium channel) child's but not the parents' DNA sample. The mutation replaced a serine residue with an asparagine in a highly conserved region of the protein that is presumed to participate in the function of the sodium channel. The mutation was not detected in 200 control subjects. The conclusion was that the child had a spontaneous mutation in a gene that was associated with a prolonged QT interval and that this contributed to a SIDS-like event. After treatment, the child was symptom free at nearly 5 years of age. This study points to the potential value of neonatal electrocardiographic screening to reduce infant mortality due to SIDS.

Schwartz, P. J., Priori, S. G., Dumaine, R., Napolitano, C., et al. A molecular link between the sudden infant death syndrome and the Long-QT syndrome. *N. Engl. J. Med.* 343: 262, 2000.

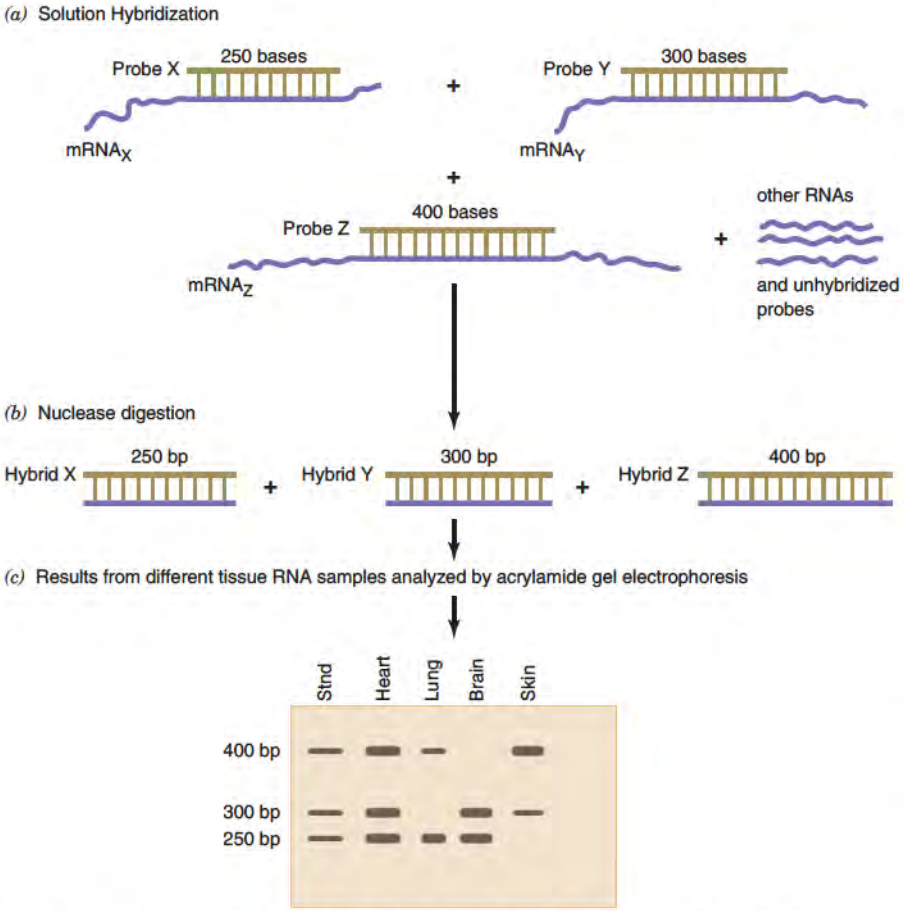


Figure 7.14 Nuclease protection assay. Total cellular mRNA can be isolated from different tissues. Single-stranded DNA probes that are complementary to known sequences of different gene transcripts (mRNAx, mRNAy, mRNAz) are hybridized with the RNA mixture. Nuclease digestion with a ribonuclease will hydrolyze single-stranded RNA regions of mRNA not hybridized with the DNA probe and all nonhybridized RNA species. Only the DNA–RNA hybrids protected against nuclease will remain for analysis by acrylamide gel electrophoresis. Differential expression of genes in specific tissues is then readily observed.

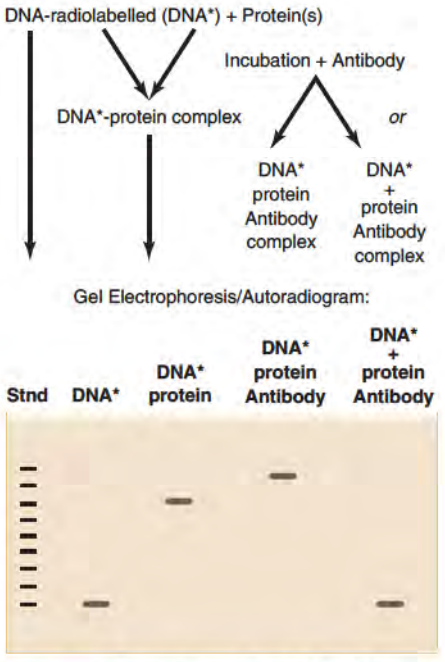

Figure 7.15 Electrophoretic mobility shift assay. Purified DNA migrates through a gel when subjected to an electric field based on its charge and molecular mass. If a protein(s) is(are) added to this, purified DNA that complexes with the DNA the total apparent molecular mass of the DNA is increased. This would slow its migration through the gel—a mobility shift. The addition of an antibody that reacts with the protein complexed with the DNA, but does not interfere with the DNA–protein interaction, will further increase the size of the DNA–protein complex and slow its migration. If the antibody reacts with the DNA-binding region of the protein a DNA–protein complex will not form. In both cases the antibody helps to identify the DNA-binding protein.

the protein's DNA-binding site, a protein–antibody complex will form and the labeled DNA probe will be unmodified in its migration through the gel. In either case the result with the antibody would confirm the identity of the DNA-binding protein.

7.6 • COMPLEMENTARY DNA AND COMPLEMENTARY DNA LIBRARIES

Insertion of specific functional eukaryotic genes into vectors that can be expressed in a prokaryotic cell could produce large amounts of genetically engineered proteins with significant medical, agricultural, and experimental potential. Hormones and enzymes, including insulin, erythropoietin, thrombopoietin, interleukins, interferons, and tissue plasminogen activator, are currently produced by these methods. It is not possible to clone functional genes from genomic DNA, except in rare instances. One reason is that most genes within the mammalian genome yield transcripts that contain introns that must be spliced out of the primary mRNA transcript. Prokaryotic systems cannot splice out the introns to yield functional mRNA transcripts. This problem is circumvented by synthesizing **complementary DNA (cDNA)** from functional eukaryotic mRNA.

mRNA as Template for DNA Synthesis Using Reverse Transcriptase

Messenger RNA can be reverse-transcribed to cDNA, and the cDNA inserted into a vector for amplification, identification, and expression. Mammalian cells normally contain 10,000–30,000 different species of mRNA molecules at any time during the cell cycle. In some cases, however, a specific mRNA species may approach 90% of the total mRNA, such as mRNA for globin in reticulocytes. Many mRNAs are normally present at only a few (1–14) copies per cell. A cDNA library can be constructed from the total cellular mRNA, but if only a few copies per cell of mRNA of interest are present, the cDNA may be very difficult to identify. Methods that enrich the population of mRNAs or their corresponding cDNAs permit reduction in number of different cDNA species within a cDNA library and greatly enhance the probability of identifying the clone of interest.

Desired mRNA Is Enriched by Separation Techniques

Messenger RNA can be separated by size by gel electrophoresis or centrifugation. Isolation of mRNA in a specific molecular size range enriches severalfold an mRNA of interest. Knowledge of the molecular weight of the protein encoded by the gene of interest gives a clue to the approximate size of the mRNA transcript or its cDNA; variability in the predicted size, however, arises from differences in the length of the untranslated regions of the mRNAs.

Enrichment of a specific mRNA molecule is also accomplished by immunological procedures, but it requires the availability of antibodies against the encoded protein by the gene of interest. Antibodies added to an *in vitro* protein synthesis mixture react with the growing polypeptide chain associated with polysomes and precipitate it. The mRNA is then purified from the immunoprecipitated polysomal fraction.

Complementary DNA Synthesis

An mRNA mixture is used as a template to synthesize complementary strands of DNA using RNA-dependent DNA polymerase, reverse transcriptase (Figure 7.16). A primer is required; advantage is taken of the poly(A) tail at the 3′-terminus of eukaryotic mRNA. An oligo(dT) with 12–18 bases is employed as the primer that hybridizes with the poly(A) sequence. After cDNA synthesis, the hybrid is denatured or the mRNA hydrolyzed in alkali to obtain the single-stranded cDNA. The 3′-termini of single-stranded cDNAs form a hairpin loop that serves as a primer for the synthesis of the second strand of the cDNA by the Klenow fragment or a reverse transcriptase. The resulting double-stranded cDNA contains a single-stranded loop that is recognized and digested by S1 nuclease. The ends of the cDNA must be modified prior to cloning in a vector. One method involves incubating

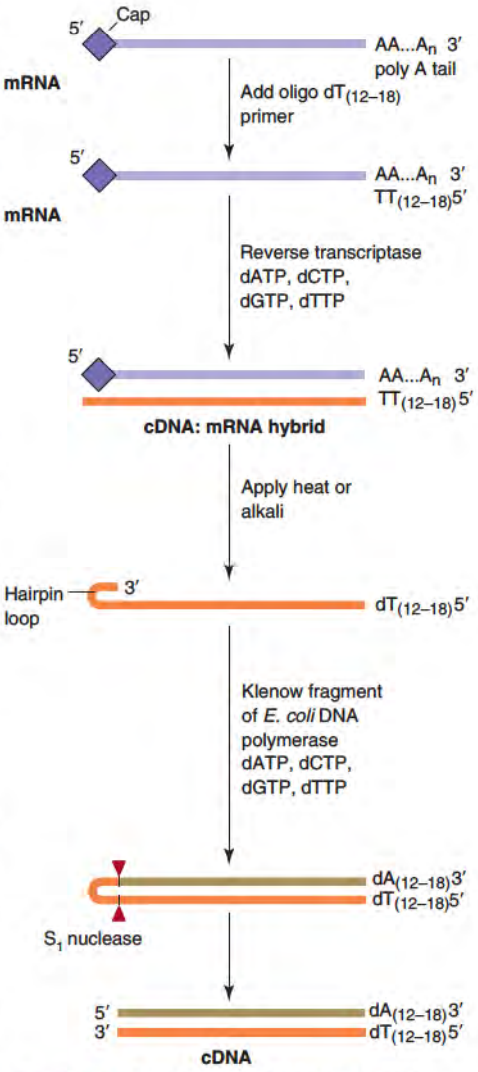

Figure 7.16 Synthesis of cDNA from mRNA. The 3′ poly(A) tail of mRNA is hybridized with an oligomer of dT (oligo$[dT]_{12\text{-}18}$) that serves as a primer for reverse transcriptase which catalyzes the synthesis of the complementary DNA (cDNA) strand in the presence of all four deoxynucleotide triphosphates (dNTPs). The resulting cDNA:mRNA hybrid is separated into single-stranded cDNA by melting with heat or hydrolyzing the mRNA with alkali. The 3′-end of the cDNA molecule forms a hairpin loop that serves as a primer for the synthesis of the second DNA strand catalyzed by the Klenow fragment of *E. coli* DNA polymerase. The single-stranded unpaired DNA loop is hydrolyzed by S_1 nuclease to yield a double-stranded DNA molecule.

blunt-ended cDNA molecules with linker molecules and a bacteriophage T4 DNA ligase that catalyzes the ligation of blunt-ended molecules (Figure 7.17). The synthetic linker molecules contain restriction endonuclease sites that are now cleaved with the appropriate enzyme for insertion of the cDNA into a vector cleaved with the same endonuclease.

Bacteriophage DNA (p. 281) is the most convenient and efficient vector to create cDNA libraries because they can readily be amplified and stored indefinitely. Two bacteriophage vectors, **λgt10** and **λgt11,** and their newer constructs are employed to produce cDNA libraries. The cDNA libraries in λgt10 are screened only with labeled nucleic acid probes when the sequence of the DNA is unknown, whereas, those in λgt11, an **expression vector,** can also be screened with antibody for the production of the protein or antigen of interest. If the sequence of the desired cDNA is known, then PCR is used to screen the recombinant bacteriophage.

Total Cellular RNA as Template for DNA Synthesis Using RT–PCR

Alternative methods to construct cDNA libraries employ a **reverse transcriptase-PCR (RT–PCR)** technique and obviate the need to purify mRNA. One such strategy is depicted in Figure 7.18 and begins with the reverse transcriptase production of a DNA-mRNA hybrid. The method uses terminal transferase to add a dG homopolymer tail to the 3′-end followed by hydrolysis of the mRNA. PCR primers are synthesized to hybridize with the dG and dA tails and terminate with two different restriction endonuclease sequences. The resulting PCR-amplified cDNA is then hydrolyzed with two different restriction endonucleases for directional cloning (p. 265) into an appropriate vector.

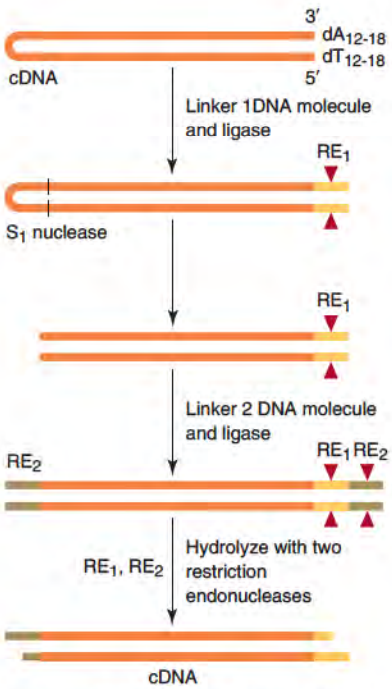

Figure 7.17 Modification of cDNA for cloning. The procedure begins with double-stranded DNA that contains a hairpin loop. A linker DNA that contains a restriction endonuclease site (RE_1) is added to the free end of the cDNA by blunt end ligation. The single-stranded hairpin loop is next hydrolyzed with S_1 nuclease. A second linker with a different restriction endonuclease site within (RE_2) is blunt end ligated to the newly created free cDNA. The second linker will probably bind to both ends but will not interfere with the first restriction endonuclease site. The modified DNA is hydrolyzed with the two restriction endonucleases and can be inserted into a plasmid or bacteriophage DNA by directional cloning.

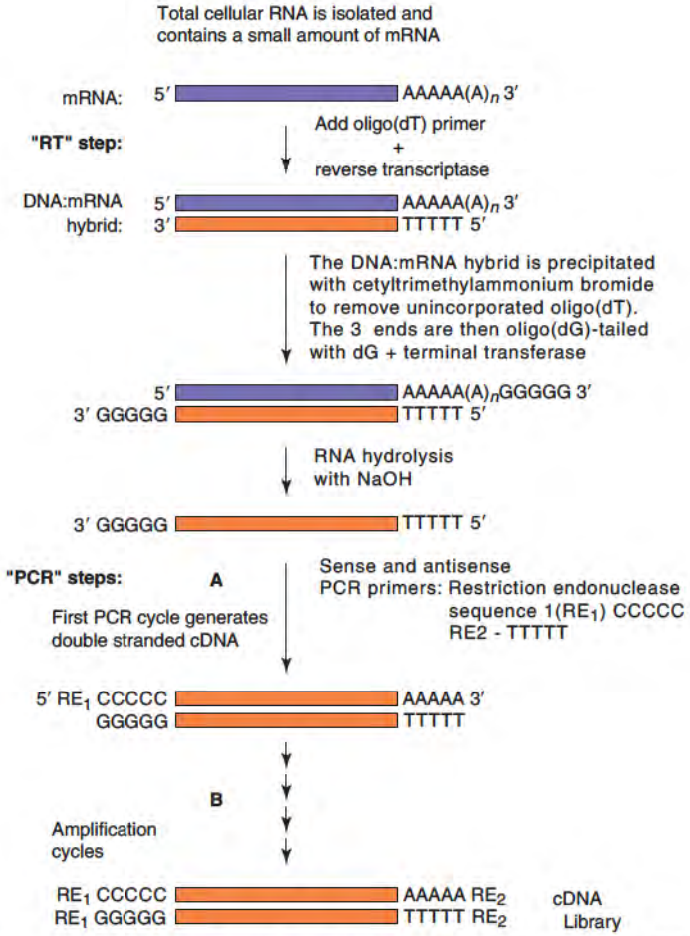

Figure 7.18 Generation of cDNA by reverse transcriptase–PCR (RT–PCR). Total cellular RNA or mRNA can be used to generate cDNA by RT–PCR. The mRNA with an oligo rA tail is reverse transcribed with an oligo dT primer. An oligo dG tail is added to the 3′-ends of the RNA and DNA strands, and the RNA strand is subsequently hydrolyzed with NaOH. Sense and antisense primers, modified with restriction site sequences, are then employed to amplify the cDNA by the PCR. The products can be hydrolyzed with the specific restriction endonucleases (RE and RE_2) for cloning and subsequent studies.

7.7 • BACTERIOPHAGE, COSMID, AND YEAST CLONING VECTORS AND ANALYSIS OF LONG STRETCHES OF DNA

Detection of noncoding sequences (i.e., introns) in most eukaryotic genes and distant regulatory regions that flank the genes necessitated cloning strategies to package larger DNA fragments than can be cloned in plasmids. Plasmids accommodate foreign DNA inserts 5–10 kb long. Recombinant DNA fragments larger than this are randomly deleted during replication of the plasmid within the bacterium. Thus, alternate vectors have been developed.

Bacteriophage as Cloning Vectors

Bacteriophage λ (λ phage), a virus that infects and replicates in bacteria, is an ideal vector for DNA inserts about 15 kb long. The λ phage selectively infects bacteria and replicates by a lytic or nonlytic (lysogenic) pathway. The λ phage contains a self-complementary 12-base single-stranded tail (cohesive termini) at both ends of its 50-kb double-stranded DNA. On infection of the bacteria, the cohesive termini (cos sites) of a single λ phage DNA self-anneal and the ends are covalently linked by the host cell DNA ligase. The circular DNA serves as a template for transcription and replication. λ phage, with restriction endonuclease-generated fragments representing a cell's whole genomic DNA inserted into it, are used to infect bacteria. Recombinant bacteriophage, released from the lysed cells, are collected and constitute a genomic library in λ phage. The phage library can be screened more rapidly than a plasmid library because of the increased size of the DNA inserts.

Numerous λ phage vectors have been constructed for different cloning strategies. Only a generic λ phage vector will be described. A 15- to 25-kb segment of the phage DNA can be replaced without impairing its replication in *E. coli* (Figure 7.19). The length

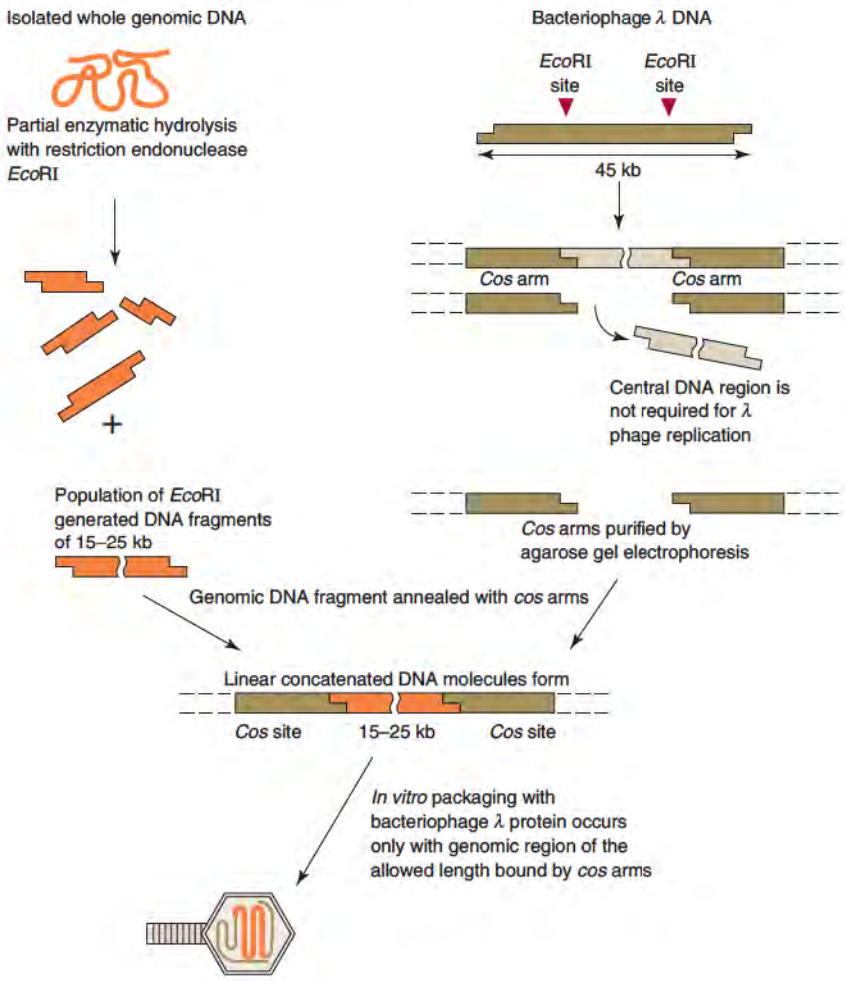

Figure 7.19 Cloning genomic DNA in bacteriophage λ. Whole genomic DNA is incompletely digested with a restriction endonuclease (e.g., EcoR1). This results in DNA of random size fragments with single-stranded sticky ends. DNA fragments called Cos arms, are generated with the same restriction endonuclease from bacteriophage DNA. The purified Cos arms carry sequence signals required for packaging DNA into a bacteriophage virion. The genomic fragments are mixed with the Cos arms, annealed and ligated, forming linear concatenated DNA arrays. The *in vitro* packaging with bacteriophage λ proteins occurs only with genomic DNA fragments of allowed lengths (15–25 kb) bounded by Cos arms.

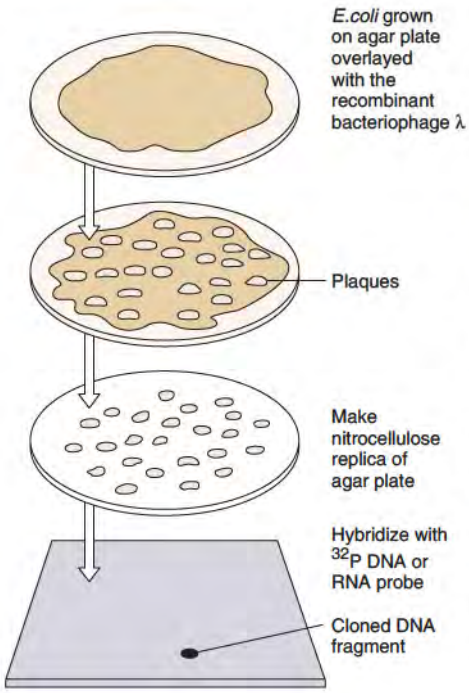

Figure 7.20 Screening genomic libraries in bacteriophage λ. Competent *E. coli* are grown to confluence on an agar plate and then overlaid with the recombinant bacteriophage. Plaques develop where bacteria are infected and subsequently lysed by the phage λ. Replicas of the plate can be made by touching the plate with a nitrocellulose filter. The DNA is denatured and fixed to the nitrocellulose with NaOH. The fixed DNA is hybridized with a ^{32}P-labeled probe and exposed to X-ray film. The autoradiograph identifies the plaque(s) with recombinant DNA of interest.

of phage DNA to be packaged into the virus particle must be about 50 kb long. The linear λ phage DNA is digested with a specific restriction endonuclease that generates small terminal fragments with their cos sites (arms). These are then separated from larger intervening fragments. Cellular genomic DNA is partially digested by appropriate restriction enzymes to permit annealing and ligation with the phage arms. DNA fragments smaller or larger than 15–25 kb hybridize with the cos arms but are excluded from being packaged into infectious bacteriophage particles. All the information required for phage infection and replication in bacteria is carried within the cos arms. The recombinant phage DNA is mixed with λ phage proteins *in vitro,* which assemble into infectious virions. These are then propagated in an appropriate *E. coli* strain to yield a λ phage library. Many *E. coli* strains have been genetically altered to sustain replication of specific recombinant virions.

Screening Bacteriophage Libraries

A bacteriophage library can be screened by plating the virus on a continuous layer of bacteria (a bacterial lawn) grown on agar plates (Figure 7.20). Individual phage will infect, replicate, and lyse one cell. The progeny virions will then infect and subsequently lyse bacteria immediately adjacent to the site of the first infected cell creating a clear region or plaque in the opaque bacterial lawn. Phage, within each plaque, is picked up on a nitrocellulose filter (as for replica plating) and the DNA fixed to the filter with NaOH. The location of cloned DNA fragments of interest are located by hybridizing the filter-bound DNA with a labeled DNA or RNA probe followed by autoradiography. The bacteriophage in the plaque corresponding to the labeled filter-bound hybrid are picked up and amplified in bacteria for further analysis. PCR is also employed if the full or partial sequence is known of the desired cDNA. Here one takes portions of several plaques, and if the DNA of interest is present in one or more, a region can be amplified with an appropriate primer pair by PCR. The PCR product is then detected by gel electrophoresis. Complementary DNA libraries in bacteriophage are also constructed that contain the phage cos arms. If the cDNA is recombined with phage DNA that permits expression of the gene, such as λgt 11, plaques can be screened immunologically with antibodies specific for the antigen of interest.

Cloning DNA Fragments into Cosmid and Artificial Chromosome Vectors

Even though λ phage is the most commonly used vector to construct genomic DNA libraries, the length of many genes exceeds the maximum size of DNA that can be inserted between the phage arms. A **cosmid vector** can accommodate foreign DNA inserts of about 45 kb. **Bacterial artificial chromosomes (BACs)** and **yeast artificial chromosomes (YACs)** have been developed to clone DNA fragments 100–200 and 200–500 kb long, respectively. Although cosmid and YAC vectors are difficult to work with, their libraries permit the cloning of large genes with their flanking regulatory sequences, as well as families of genes or contiguous genes.

Cosmid vectors are a cross between plasmid and bacteriophage vectors. Cosmids contain an antibiotic resistance gene for selection of recombinant DNA molecules, an origin of replication for propagation in bacteria, and a cos site for packaging of recombinant molecules in bacteriophage particles. The bacteriophage with recombinant cosmid DNA can infect *E. coli* and inject its DNA into the cell. Cosmid vectors contain only approximately 5 kb of the 50-kb bacteriophage DNA and, therefore, cannot direct its replication and assembly of new infectious phage particles. Instead, the recombinant cosmid DNA circularizes and replicates as a large plasmid. Bacterial colonies with recombinants of interest are selected and amplified by methods similar to those described for plasmids.

Standard cloning procedures and some novel methods are employed to construct YACs. Very large foreign DNA fragments are joined to yeast DNA sequences, one that functions as telomeres (distal extremities of chromosome arms) and another that functions as a centromere and as an origin of replication. The recombinant YAC DNA is introduced into the yeast by transformation. The YAC constructs are designed so that yeast transformed with

CLINICAL CORRELATION 7.8

The Use of Yeast Artificial Chromosome (YAC) Transgenic Mice to Study Huntington Disease

It is often difficult or impossible to study the role of a mutant protein's role in the genesis of the diseased state in human disorders. The development of animal models is an invaluable tool to study human diseases such as the adult onset neurodegenerative disorder, Huntington disease (HD) (OMIM 143100). HD is caused by the expansion of the CAG trinucleotide in exon1 of the HD gene resulting in polyglutamine stretchs in the coded Huntington (htt) protein. The resulting polyglutamine tracts appear to be toxic to selected regions of the brain. A transgenic mouse model was generated with a YAC transgene that contained the full-length human HD gene plus 25-kb upstream and 120-kb downstream sequences to ensure the inclusion of endogenous regulatory regions. YAC mice containing 46, 72, and 128 CAG repeats were created. The YAC 128 transgenic model most mirrored the human disease. These mice presented with motor and cognitive deficits that were similar to what was observed in humans. The wild-type htt protein is mainly found in the cytoplasm while the mutant protein localizes to the nucleus. Anti-htt antibody evaluation of brain tissues from wild-type (WT) mice and Y128 mice at 1 mon and 2 mon of age demonstrated that the normal and mutant htt proteins were not present in the nuclei of WT mice or 1-month-old Y128 mice; the mutant htt protein was detected in the nucleus only in the striatum of the 2-month-old Y128 mice; and as the Y128 mice aged further, although some mutant htt was detected in nuclei in other brain regions, it increased and remained greatest in the striatum. The striatum is the predominant region affected in both human HD and 2-month-old Y128 mice, and the accumulation of htt also corresponded with the age when motor and cognitive defects were first observed in these mice. It appears that the onset of the nuclear localization of the mutant htt protein in the striatum is the major contributor to the selective degeneration observed in HD. The mechanism of how the mutant htt protein exerts its toxic effects when localized to the nucleus is unknown but is thought to involve modification of gene expression and possibly activation of apoptosis.

Van Raamsdonk, J. M., Warby, S. C., and Hayden, M. R. Selective degeneration in YAC mouse models of Huntington Disease. *Brain Res. Bull.* 72: 124, 2007.

recombinant chromosomes grow as visually distinguishable colonies. This facilitates the selection and analysis of cloned DNA fragments. **Transgenic animals** can also be generated by the introduction of recombinant YAC DNA into their genome. If these animals express a defective human gene, they can be used as a model to study the corresponding human disease (Clin. Corr. 7.8).

Subcloning Permits Definition of Large Segments of DNA

Complete analysis of functional elements in a cloned DNA fragment requires sequencing of the entire molecule. Current techniques can sequence 200–400 bases, yet cloned DNA inserts are frequently much larger. Restriction maps of the initial DNA clone are essential for cleaving the DNA into smaller pieces to be **subcloned** for further analysis. The sequence of each subcloned DNA fragment can be determined. Overlapping regions of the subcloned DNA properly align and confirm the entire sequence of the original DNA clone.

Sequencing is often accomplished without subcloning. Antisense primers are used that are complementary to the initially sequenced 3′-ends of the cloned DNA. This process is repeated until all of the cloned DNA has been sequenced. This method obviates the need to prepare subclones but requires synthesis or purchase of numerous primers. On the other hand, the subcloned DNA is always inserted back into the same region of the plasmid. Therefore, one set of primers complementary to the plasmid DNA sequences flanking the inserted DNA is used for all of the sequencing reactions with subcloned DNA.

Chromosome Walking Defines Gene Arrangement in Long Stretches of DNA

Knowledge of how genes and their regulatory elements are arranged in a chromosome should lead to an understanding of how sets of genes may be coordinately regulated. It is difficult to clone DNA fragments large enough to identify contiguous genes. The combination of several techniques allows for analysis of stretches of DNA 50–100 kb long. The method, **chromosome walking**, is possible because λ phage or cosmid libraries contain partially cleaved genomic DNA cut at specific restriction endonuclease sites. The cloned fragments will contain overlapping sequences with other cloned fragments. Overlapping

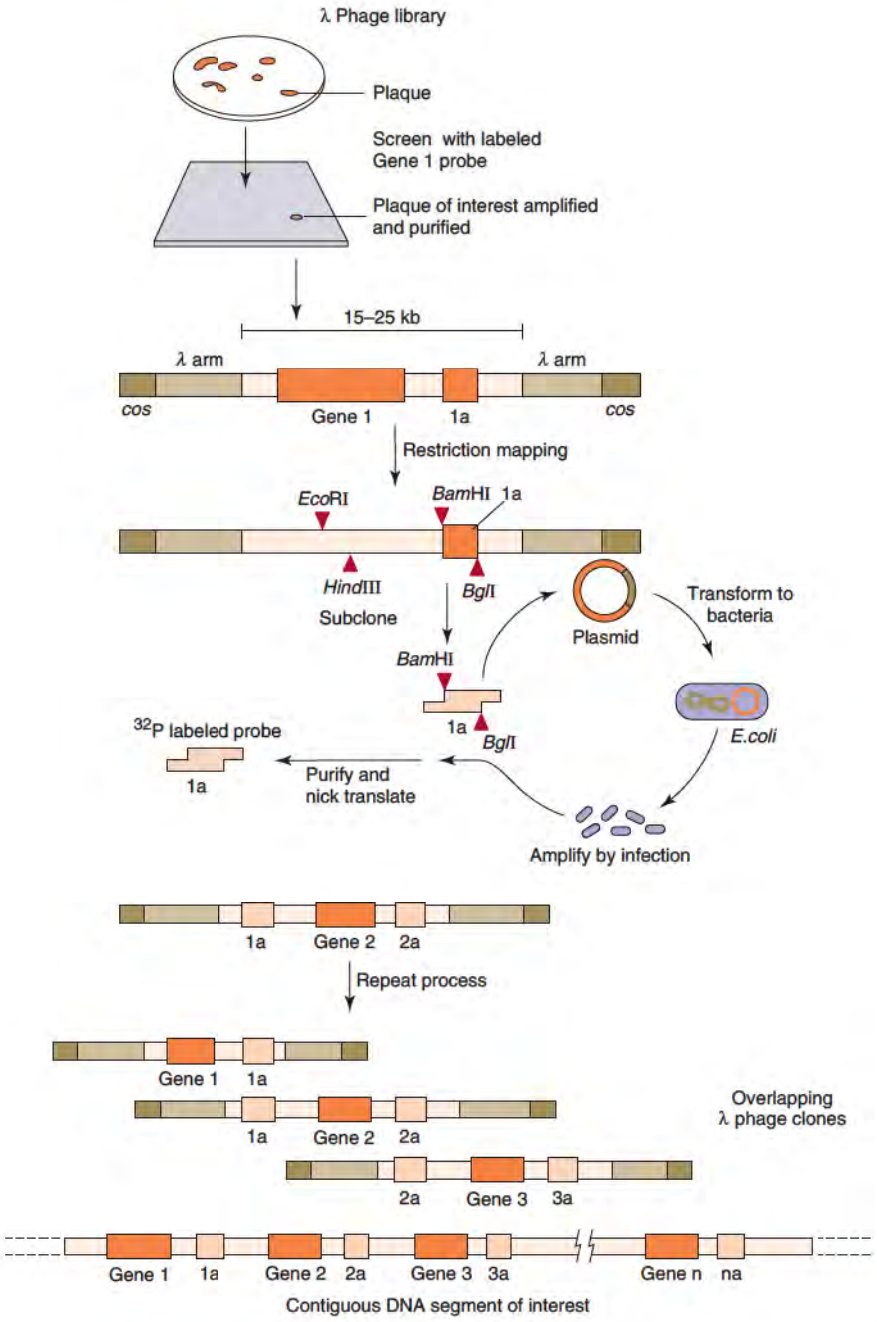

Figure 7.21 Chromosome walking to analyze contiguous DNA segments in a genome. Initially, a DNA fragment is labeled by nick translation to screen a library for recombinant λ phage carrying a gene of interest. The amplified DNA is mapped with several restriction endonucleases to select a new region (1a) within the original cloned DNA that can be recloned (subcloned). The subcloned DNA (1a) is used to identify other DNA fragments within the original library that would overlap the initially amplified DNA region. The process can be repeated many times to identify contiguous DNA regions upstream and downstream of the initial DNA (gene 1) of interest.

regions are identified by restriction mapping, subcloning, screening λ phage or cosmid libraries, and sequencing procedures.

The procedure of chromosome walking is shown in Figure 7.21. A λ phage library is screened with a DNA or RNA probe for a sequence of interest. The selected DNA is cloned and restriction mapped, and a small segment is subcloned in a plasmid, amplified, purified, and labeled by nick translation. This labeled probe is used to rescreen the λ phage library for complementary sequences and these are then cloned. The newly identified overlapping cloned DNA is then treated in the same fashion as the initial DNA clone to search for other overlapping sequences. In higher eukaryotic genomes caution must be taken so that subcloned DNA does not contain one of the large numbers of repeating DNA sequences. If a subcloned DNA probe contains a repeat sequence, it hybridizes to numerous bacteriophage plaques and prevents identification of a specific overlapping clone. These procedures in conjunction with chromosome jumping were employed to identify the human Cystic Fibrosis gene (Clin. Corr. 7.9).

CLINICAL CORRELATION 7.9

The Use of Chromosome Walking and Jumping to Identify the Cystic Fibrosis Gene

Cystic fibrosis (CF) (OMIM 602421) is a commonly encountered severe autosomal recessive disorder (1 in 2000 births) resulting from mutations in the CF transmembrane conductance regulator (CFTR). These mutations result in defective transport in the conducting pulmonary and exocrine glands. The primary clinical symptom associated with CF is chronic pulmonary disease. The determination of the CF locus was determined by linkage analysis of numerous polymorphic DNA markers to the long arm of chromosome 7, band q31. Approximately a 500-kb region of chromosome 7 was further analyzed by chromosome walking and jumping to identify the CF gene. Chromosome jumping allowed the researchers to initiate a new bidirectional walk from the end point of each jump. A restriction map was constructed from the phage and cosmid clones derived from chromosome walking and jumping and ultimately led to the identification of the CF gene (CFTR gene), which spans about 250 kb. The identification of the CFTR gene and its major mutation has allowed for the accurate prenatal and clinical diagnosis of the disease. In the ensuing years since the identification of the CFTR gene many studies have been directed toward the correction of the disease and the technological aspects required for the delivery of genes to target cells. However, success has been elusive. It has been recently reported that a new BAC vector has been constructed with a 250.3-kb insert that contains both the whole genomic CFTR gene and its upstream and downstream regulatory sites. The human CFTR gene was correctly expressed in a cultured mouse cell line from integrated copies of the BAC vector. These results point to the potential application for gene therapy of CF.

7.8 • EXPRESSION VECTORS AND FUSION PROTEINS

The recombinant DNA methodology described to this point has dealt primarily with screening, amplification, and purification of cloned DNA species. An important goal of recombinant DNA studies is to have a foreign gene expressed in bacteria with the product in a biologically active form. Sequencing of many bacterial genes and their flanking regions has identified the spatial arrangement of regulatory sequences required for expression of genes. A promoter and other regulatory elements upstream of the gene are required to transcribe a gene (p. 305). The mRNA transcript of a recombinant eukaryotic gene, however, is not translated in a bacterial system because it lacks the bacterial recognition sequence, the Shine–Dalgarno sequence, required to orient it properly with a functional bacterial ribosome. **Expression vectors** facilitate the functional transcription of DNA inserts. A foreign gene can be inserted into such a vector downstream of a regulated promoter but within a bacterial gene, commonly the lacZ gene. The mRNA transcript of the recombinant DNA contains the lacZ Shine–Dalgarno sequence, codons for a portion of the 5′-end of the lacZ protein, followed by the codons of the complete foreign gene of interest. The protein product is a **fusion protein** that contains a few N-terminal amino acids of the lacZ protein and the complete sequence of the foreign protein product.

Foreign Genes Expressed in Bacteria Allow Synthesis of Their Encoded Proteins

Many plasmid and bacteriophage vectors permit the expression of eukaryotic genes in bacterial cells. Rapidly replicating bacteria become a biological factory to produce large amounts of specific proteins, which have research, clinical, and commercial value. As an example, recombinant technologies have produced human protein hormones for treatment of patients with aberrant or missing hormone production. Figure 7.22 depicts a generalized plasmid vector for the expression of a mammalian gene. Recall that the inserted gene must be in the form of cDNA from its corresponding mRNA since the bacterial system cannot remove the introns in the pre- mRNA transcript. The DNA must be inserted in register with the codons of the 3′-terminal region of the bacterial protein when creating a fusion protein. That is, insertion must occur after a triplet codon of the bacterial protein and at the beginning of one for the eukaryotic protein to ensure proper translation. Finally, to yield a

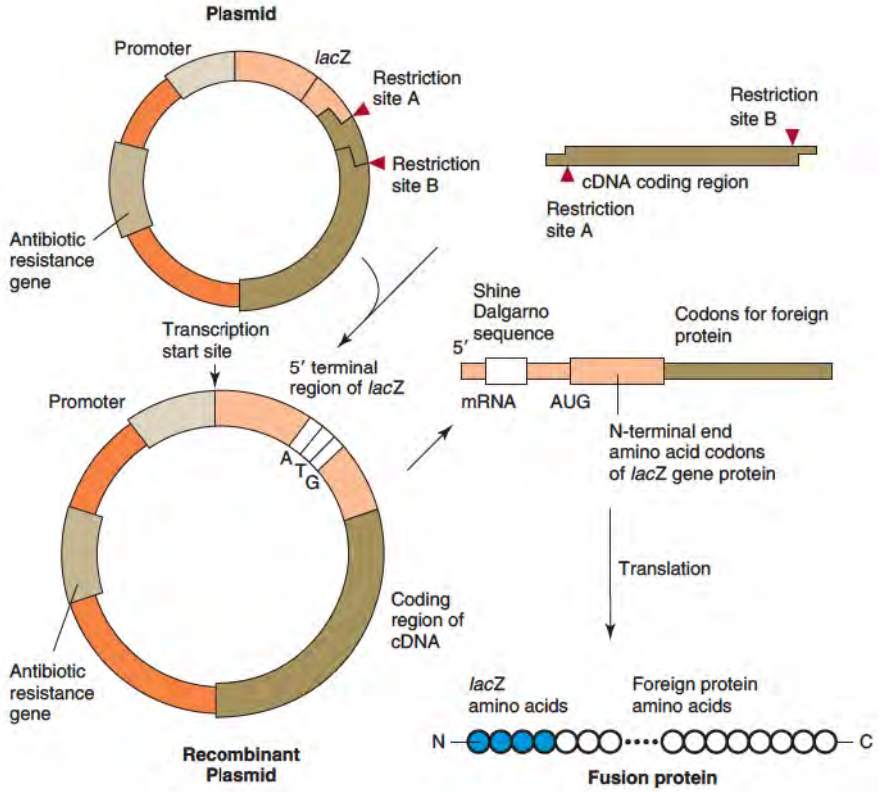

Figure 7.22 Construction of a bacterial expression vector. A cDNA for a protein of interest is inserted downstream of bacterial regulatory sequences (promoter [P]) for the lacZ gene, the coding sequence for the mRNA Shine–Dalgarno sequence, the AUG codon, and a few codons for the N-terminal amino acids of the LacZ protein. The mRNA produced from this expression vector directs synthesis in the bacterium of a fusion protein with a few of its N-terminal residues identical to those of the LacZ protein.

functional transcript, the foreign gene must be inserted in the proper orientation relative to the promoter. This is achieved by directional cloning.

Eukaryotic proteins synthesized within bacteria are often unstable and are degraded by intracellular proteases. Fusion protein products, however, are usually stable. The amino acids encoded by the prokaryotic genome may be cleaved from the purified fusion protein by enzymatic or chemical procedures. A strategy to circumvent the intracellular instability of some proteins is to produce a foreign protein that is secreted. This requires cloning the foreign gene in a vector so that the fusion protein synthesized contains a signal peptide that is recognized by the bacterial signal peptidase that properly processes the protein for secretion.

Expression Vectors in Eukaryotic Cells

Genetic diseases in mammals result from missing or defective intracellular proteins. To use recombinant techniques to treat these diseases, vectors have to be incorporated into mammalian cells. They also require some targeting mechanism such that the vectors are selective for the affected tissue or cells containing the aberrant protein. Numerous vectors permit the expression of foreign DNA genes in mammalian cells grown in tissue culture. They are used extensively for elucidation of the posttranslational processing and synthesis of proteins in cultured eukaryotic cells. The targeting of foreign genes to specific tissues or at specific developmental stages has met with very limited success.

Expression vectors have been developed that allow replication, transcription, and translation of foreign genes in cultured eukaryotic cells. They include both RNA and DNA viral vectors. Shuttle vectors contain both bacterial and eukaryotic replication signals thus permitting replication of the vector in both bacteria and mammalian cells. Shuttle vectors allow a gene to be cloned and purified in large quantities from a bacterial system and then transferred for expression in mammalian cells. Some expression vectors become integrated into the host cell genome and are stably expressed in the daughter cells. Other expression vectors remain as extrachromosonal or episomal DNA and permit only transient expression of their foreign gene prior to cell death.

Introduction of foreign DNA, such as viral expression vectors, into cultured eukaryotic cells is called **transfection**, a process that is analogous to transformation of DNA into bacterial cells. Two common methods involve the formation of a complex of DNA with

calcium phosphate or diethylaminoethyl (DEAE)-dextran, which is then endocytosed and transferred to the nucleus, where it is replicated and expressed. Both methods are employed to establish transiently expressed vectors while the calcium phosphate procedure is also used for permanent expression of foreign genes. Typically, 10%–20% of the cells in culture are transfected by these procedures.

DNA Elements Required for Expression of Vectors in Mammalian Cells

Expression of recombinant genes in mammalian cells requires the presence of appropriate controlling elements within the vector. To be expressed, the cloned gene is inserted in the vector in the proper orientation relative to control elements which include a promoter, polyadenylation signals, and an enhancer. Expression may be improved by the inclusion of an intron. Some or all of these DNA elements may be present in the recombinant gene if whole genomic DNA is used for cloning. A particular cloned fragment generated by restriction endonuclease cleavage, however, may not contain these elements. A cDNA would not contain these required DNA elements. It is, therefore, necessary that the expression vector to be used in mammalian cells be constructed so that it contains all of the required controlling elements.

The controlling elements can be inserted into the vector by recombinant technologies. Enhancer and promoter elements should be recognized by a broad spectrum of cells in culture for the greatest applicability of the vector. Controlling elements derived from viruses with a broad host range, for example, **papovavirus**, **simian virus 40 (SV40)**, **Rous sarcoma virus**, and **human cytomegalovirus** are used. The vector must contain a viral origin of replication (ori) sequence. Specific protein factors, encoded by genes inserted in the vector or previously introduced into the host genome, recognize and interact with the ori sequence to initiate DNA replication.

Selection of Transfected Eukaryotic Cells by Utilizing Mutant Cells with Specific Nutrient Requirements

It is important to grow the transfected cells selectively since they often represent only 10%–20% of the cell population. A gene can be incorporated into a cell that confers resistance to a drug or confers selective growth capability. This is achieved by **cotransfection** in which two different vectors are efficiently taken up by cells, one that carries the selectable marker and the other that carries the gene of interest. In most cases, more than 90% of transfected cells carry both vectors. Two commonly used selectable markers are the thymidine kinase (tk) and the dihydrofolate reductase (dhfr) genes. Thymidine kinase is expressed in most mammalian cells where it participates in the salvage pathway of thymidine. Several mutant cell lines are available that lack a functional thymidine kinase gene (tk–) and do not survive in growth medium that contains hypoxanthine, aminopterin, and thymidine. Only those tk–mutant cells cotransfected with a vector carrying a tk gene, usually from herpes simplex virus, will grow in the medium. In most instances, these cells have been cotransfected with the gene of interest.

Dihydrofolate reductase maintains cellular concentrations of tetrahydrofolate for nucleotide biosynthesis (p. 813). Cells lacking this enzyme survive only in media that contains thymidine, glycine, and purines. Mutant cells (dhfr–), transfected with the dhfr gene, are, therefore, selectively grown in a medium that lacks these supplements. Expression of foreign genes in mutant cells, cotransfected with selectable markers, is limited to cell types with the required gene defect that can be isolated.

Normal cells, transfected with a vector that carries the dhfr gene, are resistant to methotrexate, an inhibitor of dihydrofolate reductase and are selected for by growth in methotrexate. Similarly, normal cells transfected with a bacterial gene coding for aminoglycoside 3′-phosphotransferase (APH) are resistant to aminoglycoside antibiotics such as neomycin and kanamycin; this inhibits protein synthesis in both prokaryotes and eukaryotes. Vectors that carry an APH gene are used as a selectable marker in both bacterial and mammalian cells.

Foreign Genes Expressed in Virus-Transformed Eukaryotic Cells

Figure 7.23 depicts the transient expression of a transfected gene in COS cells, a commonly used system to express foreign eukaryotic genes. COS cells are cultured simian cells, which were transformed with a SV40 genome with a defective origin. The defective viral genome has become integrated into the host cell genome and constantly expresses viral proteins. Infectious

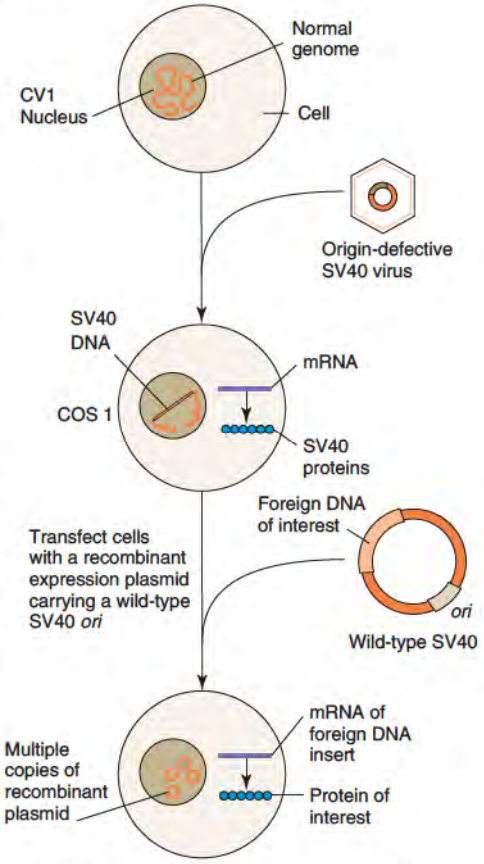

Figure 7.23 Expression of foreign genes in eukaryotic COS cells. CV1, an established tissue culture cell line of simian origin, can be infected and supports the lytic replication of the simian DNA virus, SV40. Cells are infected with an origin(ori)-defective mutant of SV40 whose DNA permanently integrates into the host CV-1 cell genome. The defective viral DNA continuously codes for proteins that can associate with a normal SV40 ori to regulate replication. Due to its defective ori, the integrated viral DNA will not produce viruses. The SV40 proteins synthesized in the permanently altered CV-1 cell line, COS-1, can, however, induce the replication of recombinant plasmids carrying a wild-type SV40 ori to a high copy number (as high as 10^5 molecules per cell). The foreign protein synthesized in the transfected cells may be detected immunologically or enzymatically.

viruses that are normally lytic to infected cells are not produced because the viral origin of replication is defective. The SV40 proteins expressed by the transformed COS cell interact with a normal SV40 ori carried in a transfected vector and therefore, promote the repeated replication of the vector that may reach a copy number in excess of 10^5 molecules per cell. Transfected COS cells die after 3–4 days probably from toxic overload of the episomal vector DNA.

7.9 • SITE-DIRECTED MUTAGENESIS

By mutating selected regions or single nucleotides within cloned DNA, it is possible to define the role of DNA sequences in gene regulation and amino acid sequences in protein function. **Site-directed mutagenesis** is the controlled alteration of selected regions of a DNA molecule. It may involve insertion or deletion of selected DNA sequences or replacement of a specific nucleotide with a different base. A variety of chemical methods mutate DNA usually at random sites within the molecule.

Role of DNA Flanking Regions Evaluated by Deletion and Insertion Mutations

Site-directed mutagenesis is carried out in various regions of a DNA sequence including the gene itself or the flanking regions. Figure 7.24 depicts a simple deletion mutation strategy where the sequence of interest is selectively cleaved with restriction endonuclease, the specific sequences removed, and the altered recombinant vector recircularized with DNA ligase. The role of the deleted sequence can be determined by comparing the level of expression (translation) of the gene product, measured immunologically or enzymatically, to the unaltered recombinant expression vector. A similar technique is used to insert new sequences at the site of cleavage. Deletion of a DNA sequence within the flanking region of a cloned gene can indicate its regulatory role in gene expression. The spatial arrangement of regulatory elements relative to one another, to the gene, and to its promoter may also be important in the regulation of gene expression (p. 307).

Analysis of a potential regulatory sequence involves inserting the sequence upstream of a reporter gene in an expression vector. A reporter gene, usually of prokaryotic origin, encodes a protein that can be distinguished from proteins which are normally present in the nontransfected cell and which can be conveniently and rapidly assayed. A commonly used reporter gene is the chloramphenicol acetyltransferase (CAT) gene of bacteria. This enzyme acetylates and inactivates chloramphenicol, an inhibitor of protein synthesis in prokaryotic cells. The effect of a regulatory element on expression of the CAT gene then can be determined. The regulatory element can be mutated prior to insertion into the vector carrying the reporter gene to determine the element's spatial and sequence requirements.

Regulatory elements may lack restriction endonuclease sites. In such a case deletion mutations are made by linearizing cloned DNA by restriction endonuclease cleavage downstream of the regulatory sequence. The DNA is then systematically truncated with an exonuclease that removes nucleotides from the free end of both strands of the linearized DNA. Longer digestion generates smaller DNA fragments. Figure 7.25 demonstrates how larger deletion mutations (yielding smaller fragments) can be tested for functional activity. Hydrolysis of the DNA occurs at both ends of the linearized vector and destroys the original restriction endonuclease site (RE2). A unique restriction endonuclease site is reestablished to recircularize the truncated DNA molecule for further manipulations to evaluate the function of the deleted sequence. This is accomplished by ligating the blunt ends with a linker DNA, a synthetic oligonucleotide containing one or more restriction endonuclease sites. The ligated linkers are cut with the appropriate enzyme permitting recircularization and ligation of the DNA.

Site-Directed Mutagenesis of a Single Nucleotide

The procedures discussed previously can elucidate the functional roles of DNA sequences. Frequently, however, one wants to evaluate the role of one nucleotide at a selected site within the DNA so as to evaluate the role of specific amino acids in a protein (Clin. Corr. 7.10).

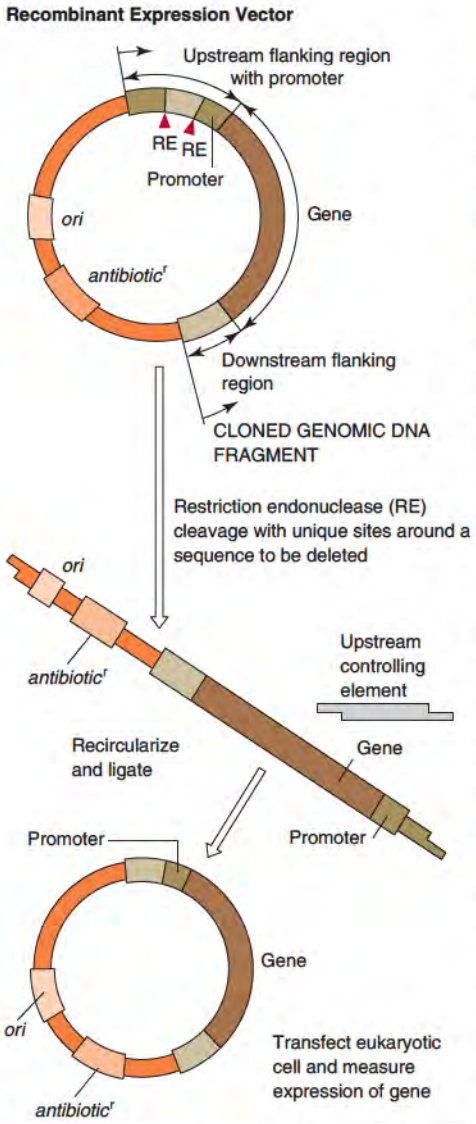

Figure 7.24 Use of expression vectors to study DNA regulatory sequences. The gene of interest with upstream and/or downstream DNA flanking regions is inserted and cloned in an expression vector, and the base-line gene expression is determined in an appropriate cell. Defined regions of potential regulatory sequences can be removed by restriction endonuclease cleavage, and the truncated recombinant DNA vector can be recircularized, ligated, and transfected into an appropriate host cell. The level of gene expression in the absence of the potential regulator is determined and compared to controls to ascertain the regulatory role of the deleted flanking DNA sequence.

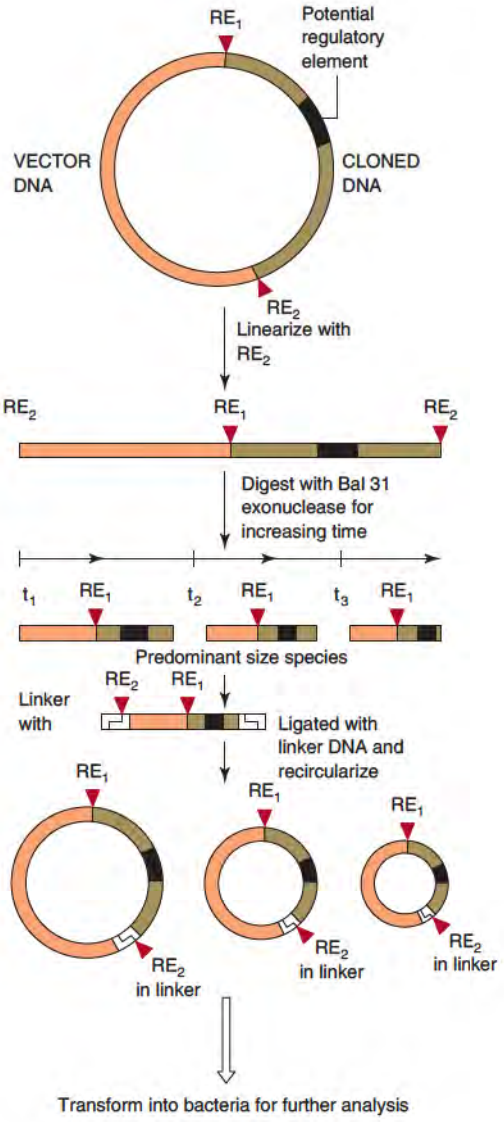

Figure 7.25 Enzymatic modification of potential DNA regulatory sequences. A purified recombinant DNA molecule with a suspected gene regulatory element within flanking DNA regions is cleaved with a restriction endonuclease (RE_2). The linearized recombinant DNA is digested for varying periods with the exonuclease, Bal31, reducing the size of the DNA flanking the potential regulatory element. The resulting recombinant DNA molecules of varying reduced sizes have small DNA oligomers (linkers) containing a restriction endonuclease sequence for RE_2 ligated to their ends. The linker modified DNA is hydrolyzed with RE_2 to create complementary single-stranded sticky ends that permit recircularization. The potential regulatory element, bounded by various reduced-sized flanking DNA sequences, can be amplified, purified, sequenced, and inserted upstream of a competent gene in an expression vector. Modification of the expression of the gene in an appropriate transfected cell can then be monitored to evaluate the role of the potential regulatory element placed at varying distances from the gene.

This method also permits the creation or destruction of a restriction endonuclease site at specific locations. Site-directed mutagenesis of a specific nucleotide is a multistep process that begins with cloning the normal gene in a bacteriophage (Figure 7.26). The M13 series of recombinant bacteriophage vectors are commonly employed. This filamentous bacteriophage specifically infects male *E. coli* that express sex pili (F factor) coded on a plasmid. The M13 bacteriophage contains DNA in a single-stranded or replicative form, which is replicated to double-stranded DNA within an infected cell. The double-stranded form is isolated from infected cells and used for cloning the gene to be mutated. The plaques of interest are visually identified by α-complementation (p. 268).

The recombinant M13 is used to infect susceptible *E. coli*. The progeny bacteriophage released into the growth medium contains single-stranded DNA. In **oligonucleotide-directed mutagenesis** an oligonucleotide (18–30 nucleotides long) is synthesized that is complementary to a region of interest except for the nucleotide to be mutated. This oligomer, with one mismatched base, hybridizes to the single-stranded gene and serves as a primer. Primer extension by bacteriophage T4 DNA polymerase results in double-stranded DNA that is transferred into susceptible *E. coli* where the mutated DNA strand serves as a template for new (+) strands that carry the mutated nucleotide.

The bacteriophage plaques, that contain mutated DNA, are screened by hybridization with a labeled probe of the original oligonucleotide carrying the altered nucleotide. By adjusting the wash temperature of the hybridized probe, only the perfectly matched hybrid remains complexed with the mutated DNA whereas the oligomer with mismatched

CLINICAL CORRELATION 7.10

Site-Directed Mutagenesis of Type VII Collagen (C7)

Dystrophic epidermolysis bullosa (DEB) (OMIM 226600) is a genetic disease resulting from a mutation in the COL7A1 gene that encodes for type VII collagen (C7). The C7 homotrimer molecule is an important component of the anchoring fibrils that link the basement membrane of the skin to the underlying papillary dermis. Mutated COL7A1 proteins result in diminutive or reduced numbers of anchoring fibrils. More than 300 distinct mutations have been identified within the COL7A1 gene with little correlation of genotype with the diseased phenotype. Patients with DEB present with mild to severe intensities of the diseased state depending on which mutation they have. All patients present with some degree of blistering, scarring, and skin involvement. Site-directed mutagenesis was used to generate four different single amino acid mutations. The purified recombinant C7 mutant proteins were then employed to analyze functional properties of the proteins *in vitro* that appeared to correspond to clinical phenotypes of the DEB patients.

Woodley, D. T., Hou, Y., Martin, S., Li, W., and Chen, M. Characterization of molecular mechanisms in underlying mutations in dystrophic epidermolysis bullosa using site-directed mutagenesis. *J. Biol. Chem.* 283:17838, 2008.

nucleotide will dissociate from the wild-type DNA. The M13 that carries the mutated gene is then replicated in bacteria, the DNA purified, and the mutated region of the gene sequenced to confirm the identity of the mutation. A modified method to selectively replicate the mutated strand has been developed to improve the efficiency of site-directed mutagenesis. The M13 bacteriophage, replicated in a mutant *E. coli*, incorporates some uracil residues in place of thymine because of a metabolic defect in synthesis of dTTP from dUTP and lack of an enzyme that normally removes uracil from DNA. The purified

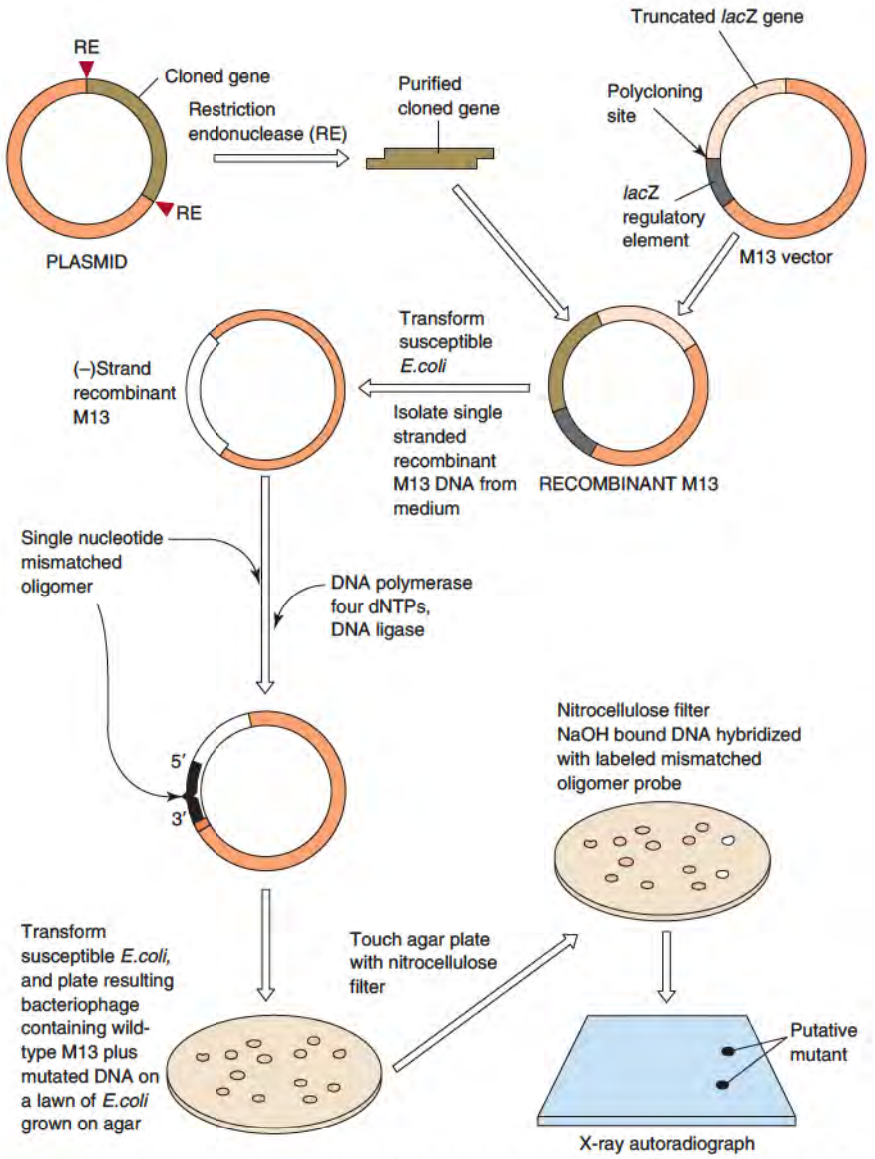

Figure 7.26 Site-directed mutagenesis of a single nucleotide and detection of the mutated DNA. The figure is a simplified overview of the method. This process involves the insertion of an amplified pure DNA fragment into a modified bacteriophage vector, M13. Susceptible *E. coli*, transformed with the recombinant M13 DNA, synthesize the (+) strand DNA packaged within the virion bacteriophage proteins. The bacteriophage are isolated from the growth medium and the single-stranded recombinant M13 DNA is purified. The recombinant M13 DNA serves as a template for DNA replication by DNA polymerase, deoxynucleoside triphosphates (dNTPs), DNA ligase, and a special primer. The DNA primer (mismatched oligomer) is synthesized to be exactly complementary to a region of the DNA (gene) of interest except for the one base intended to be altered (mutated). The newly synthesized M13 DNA, therefore, contains a specifically mutated base which when reintroduced into susceptible *E. coli* will be faithfully replicated. The transformed *E. coli* are grown on agar plates with replicas of the resulting colonies picked up on a nitrocellulose filter. DNA associated with each colony is denatured and fixed to the filter with NaOH and the filter-bound DNA is hybridized with a ^{32}P-labeled mismatched DNA oligomer probe. The putative mutants are then identified by exposing the filter to X-ray film.

single-stranded M13 uracil-containing DNA is hybridized with a complementary oligomer containing a mismatched base at the nucleotide to be mutated. The oligomer serves as the primer for DNA replication *in vitro* with the template (+) strand containing uracils and the new (–) strand containing thymines. When the double-stranded M13 DNA is transformed into a wild-type *E. coli* the uracil-containing strand is destroyed and the mutated (−) strand serves as the template for the progeny bacteriophage, most of which will carry the mutation of interest.

The PCR is also employed for site-directed mutagenesis. Strategies have been developed to incorporate a mismatched base into one of the oligonucleotides that primes the PCR. Some of these procedures employ M13 bacteriophage and follow the principles described in Figure 7.27. A variation of these PCR methods, **inverse PCR mutagenesis,** has been applied to small recombinant plasmids (4–5 kb). The method is very rapid with 50%–100% of the generated colonies containing the mutant sequence. The two primers are synthesized so that they anneal back-to-back with one primer carrying the mismatched base.

A method for site-directed mutagenesis that obviates the need for ss DNA and laborious selection steps has been commercially developed by Stratagene. The process employs oligonucleotide-directed mutagensis and PCR with any plasmid DNA vector isolated from

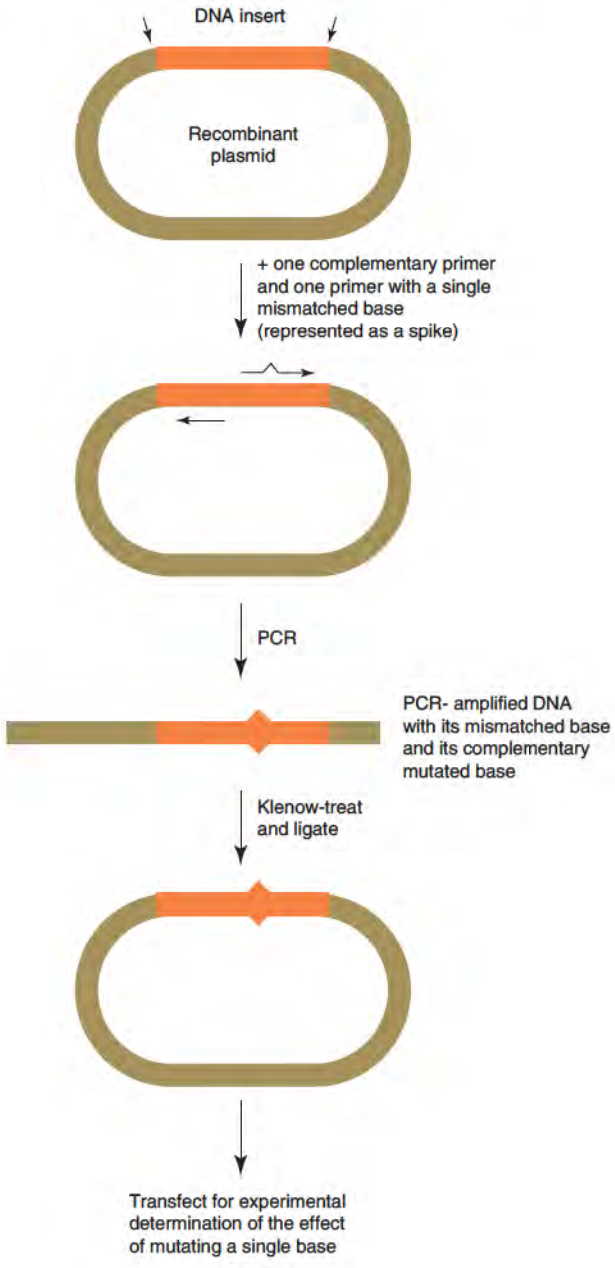

Figure 7.27 Inverse PCR mutagenesis. A single base can be mutated in recombinant DNA plasmids by inverse PCR. Two primers are synthesized with their antiparallel 5′-ends complementary to adjacent bases on the two strands of DNA. One of the two primers carries a specific mismatched base that is faithfully copied during the PCR amplification steps yielding ultimately a recombinant plasmid with a single mutated base.

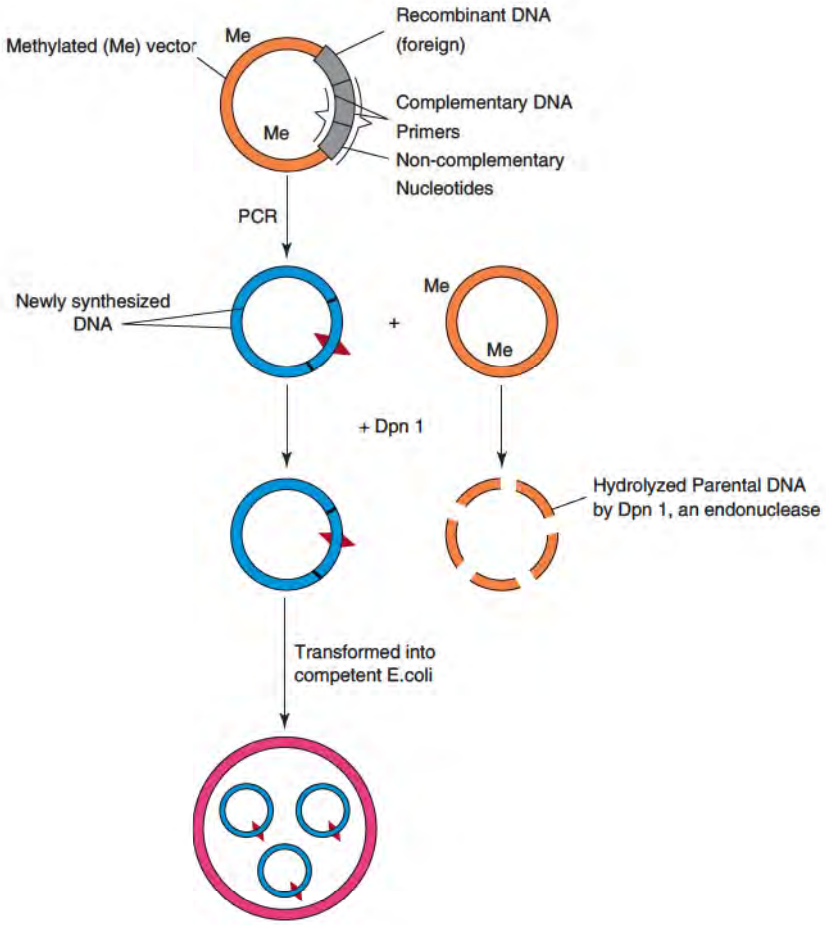

Figure 7.28 Site-directed mutagenesis of double-stranded DNA. A recombinant DNA molecule can be mutated at a selected site by synthesizing complementary primers that each contains a nucleotide that is not complementary to the parental DNA strand but are complementary to each other. The primers are extended by PCR leaving nicks (X) in each strand which is ligated upon transformation into competent E. coli. The methylated (Me) parental DNA is removed by hydrolysis with the endonuclease, Dpn I, prior to transformation.

DNA methylating competent *E. coli* strains. As depicted in Figure 7.28 one anneals two complementary oligonucleotides, carrying the desired altered nucleotide, to a region of a cloned DNA inserted within the vector. The oglionucleotides are then PCR extended with a Phusion-type DNA polymerase without primer displacement, generating a mutated recombinant plasmid molecule with nicks in both strands. The reaction mixture is then treated with an endonuclease, *Dpn*-I, which selectively digests the methylated parental (nonmutated) DNA. The remaining nicked mutated DNA plasmids (nonmethylated) are transformed into competent cells that ligate the nick and replicate the mutated recombinant plasmids.

7.10 • APPLICATIONS OF RECOMBINANT DNA TECHNOLOGIES

Recombinant DNA methods are applicable to numerous biological disciplines including agriculture, studies of evolution, forensic biology, and clinical medicine. Genetic engineering can introduce new or altered proteins into crops (e.g., corn), so that they contain amino acids essential to humans but often lacking in plant proteins. Toxins lethal to specific insects but harmless to humans can be introduced into crops to protect plants thus avoiding the use of environmentally destructive pesticides. The DNA from cells in the amniotic fluid of a pregnant woman can be analyzed for genetic defects in the fetus. Minuscule quantities of DNA from biological samples preserved in ancient tar pits or frozen tundra have been amplified and sequenced for evolutionary studies. DNA from a single hair, a drop of blood, or sperm from a rape victim can be isolated, amplified, and mapped for forensic purposes. Improvement in current technologies should permit selective introduction of genes into defective cells and of nucleic acids into specific cells to inhibit selectively the expression of detrimental genes.

Antisense Nucleic Acids in Research and Therapy

Antisense nucleic acids (RNA or DNA) are used to study the intracellular expression and function of specific proteins. Natural and synthetic antisense nucleic acids that are complementary to mRNA inactivate it and block translation. There are hundreds, perhaps thousands, of different micro RNAs (antisense RNA) encoded by the human genome. Each cell type expresses different combinations of these **microRNA**s that selectively regulate gene expression at the RNA level. Both natural and synthetic antisense RNAs are processed to or associated with a protein complex, RISC (RNA-induced silencing complex), that presents the approximately 21 oligomer (21 mer) antisense RNA to the sense RNA (usually mRNA) and the complementary strands hybridize. The sense/antisense RNA is then recognized for destruction/inhibition **(RNA interference [RNAi])**. Natural or synthetic antisense RNAs that are larger than the 21 mer must be hydrolyzed to the appropriate size by an enzyme called Dicer resulting in the **small-interfering RNA (siRNA)**. The stable introduction of siRNA into cells can permanently reduce or knockdown the expression of selected genes. RNAi technologies are currently being used in numerous laboratories as a research tool to elucidate specific gene function and by many pharmaceutical and biotechnology companies to develop RNAi-based therapeutics. The introduction of antisense nucleic acids into cells has opened new avenues to explore how selectively repressed proteins function within that cell. This method also holds great promise in control of viral infections. Antisense technology and site-directed mutagenesis are part of reverse genetics (from gene to phenotype), which selectively modifies a gene to evaluate its function, while classical genetics depends on the isolation and analysis of cells carrying random mutations that can be identified. A second use of the term **reverse genetics** refers to the mapping and ultimate cloning of a human gene associated with a disease for which the molecular agents are still unknown.

Antisense RNA is introduced into cells by common cloning techniques. Figure 7.29 demonstrates a gene cloned in an expression vector downstream of a promoter but in the opposite direction to normal. This places the complementary or antisense strand of the DNA under the control of the promoter with expression- or transcription-yielding antisense RNA. Transfection of cells with the antisense expression vector introduces antisense RNA that hybridizes with normal mRNA. The mRNA–antisense RNA complex is not translated due to a number of reasons such as its inability to bind to ribosomes, blockage of normal processing, and rapid enzymatic degradation.

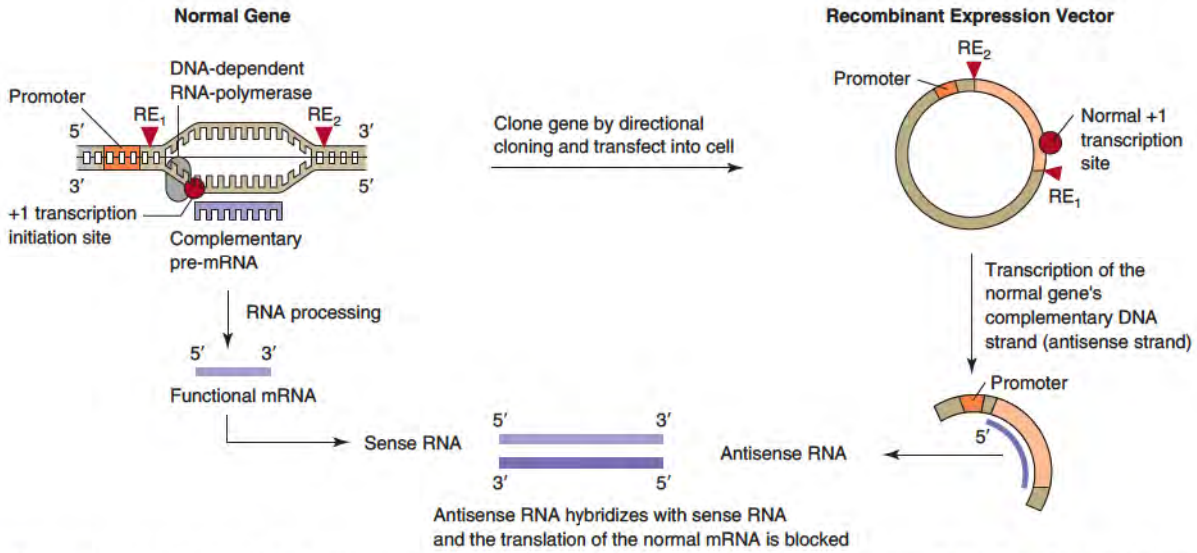

Figure 7.29 Production of antisense RNA. A gene, or a portion of it, is inserted into a vector downstream of a promoter by directional cloning and in the reverse orientation to that normally found. Transfection of this recombinant DNA into the parental cell that carries the normal gene results in the transcription of RNA (antisense RNA) from the cloned reversed-polarity DNA along with a normal cellular mRNA (sense RNA) transcript. The two antiparallel complementary RNAs hybridize within the cell resulting in blocked expression (translation) of the normal mRNA transcript.

Synthetic antisense DNA oligonucleotides have been produced that inhibit viral infection including that by the human immunodeficiency virus (HIV). It is conceivable that antisense HIV nucleic acids will be introduced into bone marrow cells removed from AIDS patients. These protected cells will then be reintroduced into the patient and replace those cells normally destroyed by the virus. Progress is being made with antisense nucleic acids that regulate the expression of oncogenes, genes involved in cancer formation. Harnessing antisense technologies holds great promise for the treatment of human diseases (Clin. Corr. 7.11). Although many studies have been conducted with siRNA that are 21 bases long to trigger RNAi, it has been recently demonstrated that the use of slightly longer double-stranded antisense RNAs, which are then substrates for Dicer, are more effective inhibitors of gene expression. This is thought to result from the participation of Dicer with the formation of the RISC complex (Clin. Corr. 7.11B).

Molecular Techniques Applied to the Whole Animal

As described, many *in vitro* and intracellular systems facilitate the purification, sequencing, and modification of genes or their cDNAs and DNA flanking regions of genes with potential regulatory functions. Introduction of foreign genes into a whole animal, deletion of a gene from the whole animal genome, and cloning of a whole animal has been achieved. While clear bioethical issues and hurdles must be addressed when using some of these methodologies, the methods themselves hold great promise for future gene therapy.

Gene Therapy: Normal Genes Can Be Introduced into Cells with a Defective Gene

Individuals who possess a defective gene resulting in a debilitating or fatal condition can theoretically be treated by supplying their cells with a normal gene. **Gene therapy**, the transfer of a normal gene to humans, has been accomplished using retroviral vectors (Clin. Corr. 7.12). The success of gene transfer depends, in part, on the integration of the gene into the host

CLINICAL CORRELATION 7.11

siRNA-Mediated Regulation of Gene Expression

A. Aptamer–siRNA for HIV-1 Therapy

The use of short-interfering RNA, siRNA, (antisense RNA) to regulate gene expression of HIV-1 proteins in diseased cells requires the efficient delivery of siRNA to target cells. An aptamer has been engineered to recognize and selectively bind to gp120 (glycoprotein 120). The gp120 is a HIV-1 protein that is expressed on the membrane of infected cells. An aptamer is a nuleic acid molecule capable of selective binding of target molecules such as specific proteins. Chimeric molecules of the anti-gp120 aptamer and anti-tat/rev siRNA were produced by covalently linking the two species. The siRNA was a 27-mer that serves as a Dicer substrate. The aptamer-siRNA was selectively taken up by HIV-1 infected cells expressing gp120. The 27-mer siRNA was then processed intracellularly by Dicer yielding an inhibitory 21-mer anti-tat/rev siRNA. The knockdown of expression of the HIV-1 tat/rev genes along with the antiviral effect of the anti-gp120 aptamer had a combined inhibitory effect on HIV-1 replication. The use of aptamer–siRNA chimeras holds great promise for the systemic treatment of HIV infections and other diseases that present potential surface target markers.

B. Use of Dicer-Substrate siRNA for Pain Research

The majority of drugs sold today that act on the Central Nervous System (CNS) are directed at the treatment of pain. The two main classes of analgesic drugs are opioids and nonsteroidal anti-inflammatory drugs. All too often, these drugs are ineffective, or lose their potency in the treatment of chronic pain. It has been shown in a model that G-protein-coupled receptor, NTS2, in the CNS is involved in the transmission of pain. RNAi (RNA interference) was employed to knock down the expression of the NTS2 gene in mice. It was found that use of a 27-mer (antisense RNA to the NTS2 mRNA) that would serve as a Dicer-substrate siRNA (DsiRNA) efficiently suppressed the expression of NTS2. The DsiRNA was suspended in a cationic lipid, i-Fect, and administered into the rat spinal cord by intrathecal injection. The administration of a low dose of DsiRNA ameliorated pain for up to 3–4 days which corresponded to a knockdown of the NTS2 receptor protein over the same time period. This type of treatment with DsiRNA may ultimately help reduce intractable chronic pain in humans.

CLINICAL CORRELATION 7.12

Gene Therapy: Normal Genes Can Be Introduced into Cells with Defective Genes

A. Gene therapy to treat severe combined immune deficiency disease (SCID) (OMIM 102700)

More than 4000 genetic diseases are known, many of which are debilitating or fatal. Most are currently incurable. With the advent of new technologies in molecular biology, the clinical application of gene transfer and gene therapy is becoming a reality. Diseases that result from a deficiency in adenosine deaminase (ADA) or a mutation in the gene that encodes a subunit of several cytokine receptors, γc, are but two of many genetic diseases that may be readily cured by gene therapy.

ADA is important in purine salvage, catalyzing the conversion of adenosine to inosine or deoxyadenosine to deoxyinosine. It contains 363 amino acids and has highest activity in thymus and other lymphoid tissues. Over 30 mutations in the ADA gene are associated with severe combined immune deficiency disease (SCID), an autosomal recessive disorder. These immune-compromised children usually die in the first few years of life from overwhelming infections. The first authorized gene therapy in humans began on September 14, 1990, with the treatment of a 4-year-old girl with ADA deficiency. The patient's peripheral blood T cells were cultured with appropriate growth factors. The ADA gene was introduced within these cells by retroviral-mediated gene transfer. A modified retrovirus was constructed to contain the human ADA gene such that it would be expressed in human cells without virus replication. The modified T cells carrying a normal ADA gene were then reintroduced to the patient by autologous transfusion. Levels of ADA as low as 10% of normal are sufficient to normalize the patient. The patient, 10 years later at age 13, was alive and well and maintained circulating gene-corrected T cells at a level of 20%–25% of total T cells.

The X-linked inherited disorder, SCID-X1, results in the blocked differentiation of T and natural killer (NK) lymphocytes. SCID-X1 results from a mutation in the cytokine receptor subunit, γc, common to interleukin-2, -4, -7, -9, and -15 receptors. The methodology of treatment for an 8- and an 11-month-old patient was similar to that employed for the ADA-deficient SCID patients; this tends to be a less severe disease than the SCID-X1. The SCID-X1 studies transduced CD34+ stem cells with a retroviral vector carrying the normal γc cDNA. This resulted in a much higher level of gene transduction than observed in earlier studies. Both infants had their immune systems normalized sufficiently after 3 months to leave the protective isolation of the hospital.

A moratorium on gene therapy for SCID-X1 was triggered in 2003 by the induction of a leukemia-like syndrome in 2 of 14 European children treated for this disease. The T-cell leukemia was caused by retroviral insertion and up regulation of the LMO2 gene that encodes a transcription factor required for hematopoiesis. It is anticipated that future modifications in the vector used for gene therapy should prevent the apparent insertional preference of the retrovirus near active genes.

B. Gene Therapy to Treat Leber Congenital Amaurosis

An exciting use of genetic therapy has recently been reported to correct visual function in Leber congenital amaurosis which represents multiple forms of severe, recessively inherited infantile-onset rod-cone dystrophies. A 65-kD protein is a key component of the visual cycle and is encoded for by the RPE65 gene in the retinal pigment epithelium. A nonfunctional RPE65 gene causes a loss of 11-cis retinal, which is required for red photoreceptor cells to respond to light. It appears that children possess an alternate pathway for the availability of 11-cis retinal which disappears as they age. Children with this disease have visual function that diminishes with age with the progressive degeneration of cone photoreceptor cells. Three patients (ages 17–23) had a recombinant adeno-associated virus vector containing the human RPE65 coding sequence surgically administered to the subretinal space of one eye. At the time of surgery each patient retained some visual function in good lighting but limited, or no vision in low lighting. The results of this study indicate that patients with advanced degeneration of the cone photoreceptor cells achieved modest improvement in visual function with RPE65 gene therapy. It is postulated that such gene therapy given to younger patients would be more beneficial than with adults.

genome, which is directed by the retroviral integration system. Integration, however, is normally a random event that could have deleterious consequences. Studies indicate that the viral integration machinery is selectively tethered to specific target sequences within the host DNA by protein–protein interactions to obviate these potential problems.

Transgenic Animals

In order to investigate the role of a selected gene product in growth and development of a whole animal, the gene must be introduced into the fertilized egg. Foreign genes can be inserted into the genome of a fertilized egg. Animals that develop from such a fertilized egg carry the inserted gene in every cell and are referred to as **transgenic animals**.

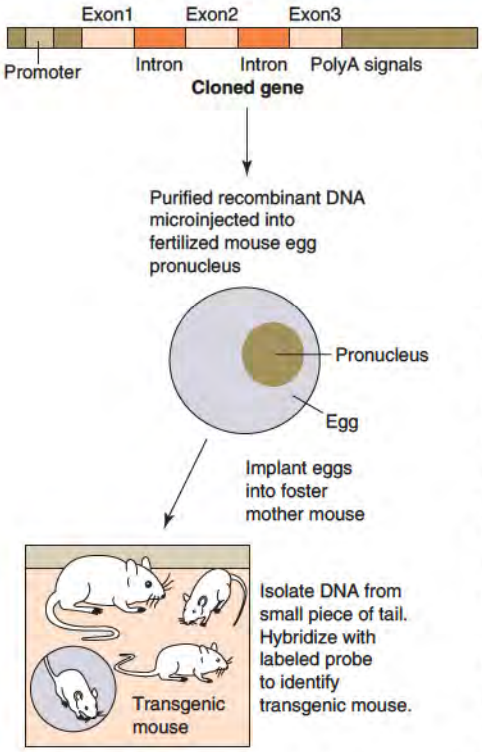

Figure 7.30 Production of transgenic animals. Cloned, amplified, and purified functional genes are microinjected into several fertilized mouse egg pronuclei *in vitro*. The eggs are implanted into a foster mother. DNA is isolated from a small piece of each offspring pup's tail and hybridized with a labeled probe to identify animals carrying the foreign gene (transgenic mouse). The transgenic mice can be mated to establish a new strain of mice. Cell lines can also be established from tissues of transgenic mice to study gene regulation and the structure or function of the foreign gene product.

Figure 7.30 outlines a popular method to create transgenic animals. The gene of interest is usually a cloned recombinant DNA molecule with its own promoter or is cloned with a different promoter that can be selectively regulated. Multiple copies of the gene are microinjected into the pronucleus of the fertilized egg. The foreign DNA inserts randomly within the chromosomal DNA. If an insert disrupts a critical cellular gene, the embryo will die. Usually, nonlethal mutagenic events result from the insertion of foreign DNA into the chromosome.

Transgenic animals are currently being used to study DNA regulatory elements, expression of proteins during differentiation, tissue specificity, and the role of oncogene products on growth, differentiation, and induction of tumorigenesis. Such technologies should permit replacing defective genes in the developing embryo (Clin. Corr. 7.13).

Knockout Mice

The creation of an animal with a selected gene destroyed in every cell allows researchers to define the biological role of the gene if its loss is nonlethal. The basic principles behind creating a **null**, or **knockout**, **mouse** involves inactivating a recombinant purified gene, introducing this altered gene into an embryonic stem (ES) cell such that it replaces the normal gene, injecting the modified ES cell into a developing blastocyst, implanting the blastocyst into a foster mother, and selecting offspring lacking a normal gene. A common approach to inactivate a selected gene is to insert an antibiotic resistance gene, known as neo, into the cloned gene of interest. This both inactivates the gene of interest and allows identification of ES cells that have been successfully transfected. The normal gene in a very low percentage of ES cells may be replaced by the neo-disrupted recombinant gene by **homologous recombination**. The nucleotide sequences of the altered or disrupted gene align with the homologous sequence of the normal gene and swap places, or may insert within the normal gene. In either case the net result is to destroy or knockout the normal ES cellular gene. Selection of altered ES cells, microinjection into a mouse blastocyst, birth of chimeric offspring, and breeding of offspring homozygous for the altered gene (Figure 7.31) is an extremely labor-intensive process. The process has been applied in numerous experiments to evaluate the role of selected genes (Clin. Corr. 7.14).

Dolly, a Lamb Cloned from an Adult Cell

The cloning of animals raises numerous ethical questions such as: Is it man's purview to select the genetic composition of animals and to propagate these animals? Clearly, there are many experimental advantages to developing animals with identical genetic information. However, the application of whole animal cloning techniques to humans raises ethical issues that most consider unacceptable.

Cloning viable offspring from adult mammalian cells is: very labor intensive. The method that produced Dolly, the cloned lamb, began with the culturing of mammary gland cells from a 6-year-old Finn Dorset ewe. Cells were arrested in G_0 by being maintained in

CLINICAL CORRELATION 7.13

Transgenic Animal Models

Transgenic animal models hold promise to correct genetic diseases early in fetal development. They are used to study the regulation of expression and the function of specific gene products in an animal and may lead to creation of new breeds of commercially valuable animals. Transgenic mice have been produced from fertilized mouse eggs with rat growth hormone (GH) genes microinjected into their male pronuclei (p. 292). Approximately 600 copies of the gene, fused to the mouse metallothionein-I (MT-I) promoter region were introduced into each egg, which was then inserted into the reproductive tract of a foster mother mouse. The resulting transgenic mouse carried the rat GH gene within its genome. The diet of the animals was supplemented with $ZnSO_4$ at 33 days postparturition to activate the mouse MT-I promoter and initiate transcription of the rat GH gene. Continuous overexpression of rat GH in some transgenic animals produced mice nearly twice the size of littermates that did not carry the rat GH gene. A transgenic mouse transmitted the rat GH gene to one-half of its offspring, indicating that it had stably integrated into the germ cell genome and that new breeds of animals can be created.

Palmiter, R. D., Brinster, R. L., Hammer, R. E., Trumbauer, M. E., et al. Dramatic growth of mice that develop from eggs microinjected with metallothionein-growth hormone fusion genes. *Nature* 300:611, 1982.

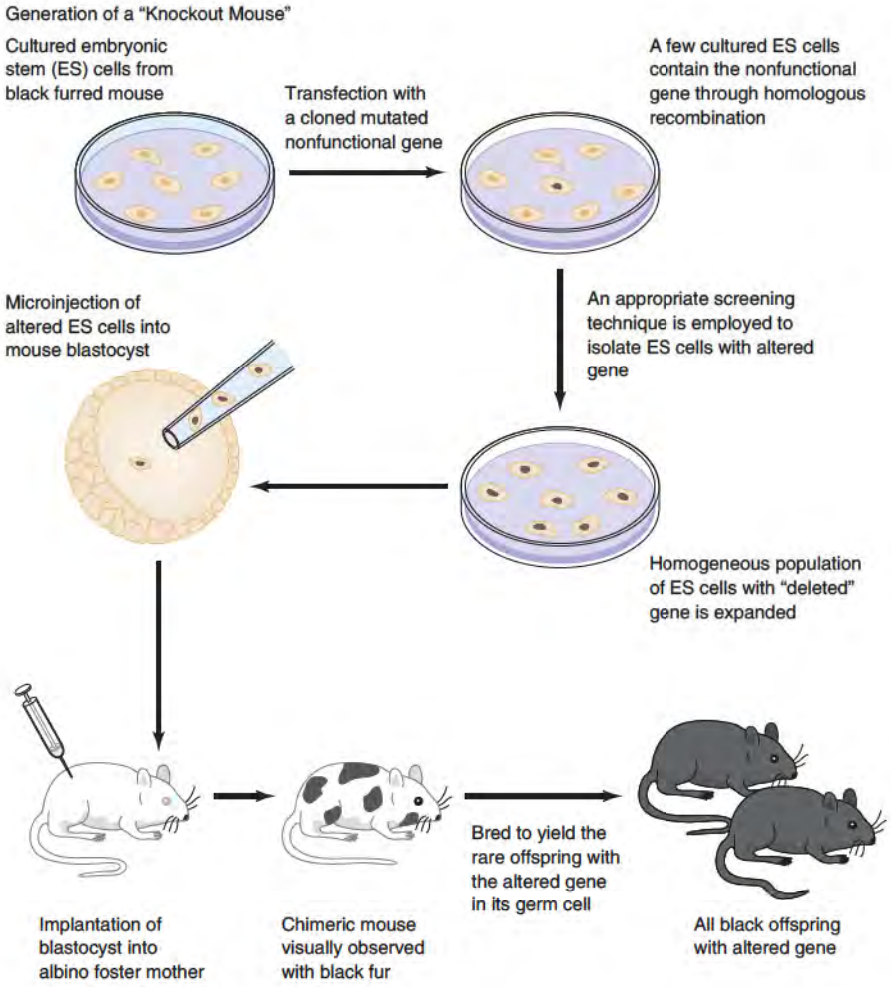

Figure 7.31 Generation of a knockout mouse. Cultured embryonic cells can be manipulated through recombinant technology to carry a defective or "deleted" gene. The altered cells can be introduced into a blastocyst that is then implanted into a foster mother. Offspring can then be selected that have the nonfunctional "deleted" gene in all of their cells—the knockout animal.

CLINICAL CORRELATION 7.14

Knockout Mice to Define a Role for the $P2Y_1$ Purinoceptor

Platelets play a central role in hemostasis and thrombosis. An important physiologic agonist that induces platelet aggregation is ADP. Studies in the 1970s established the dogma that ADP, bound to a G protein-coupled receptor, induced aggregation while extracellular ATP, acting at the same receptor site, competitively inhibits aggregation. Sometimes rules, based on limited evidence, become firmly entrenched and take years to be reworked. In the 1990s it became clear that platelets possess at least three different purinoceptors with different binding specificities for ATP versus ADP. An understanding of how these potentially interactive receptors function is very important clinically. ATP and ADP are released into the cardiovascular system/blood under a variety of normal and pathological conditions. The balance between the agonist action of ADP and the antagonist action of ATP may play a significant role in the regulation of platelet responses. Defining the mechanisms of action may lead to the production of new drugs to combat thrombosis. The recent development of a knockout (null) mouse model allowed for the assessment of the role of the purine receptor, $P2Y_1$.

Although the $P2Y_1$ receptor is found in many tissues other than platelets, the knockout mouse had no apparent abnormalities. However, normal levels of ADP failed to induce their platelets to aggregate, whereas high concentrations of ADP did. Aggregated platelets did not show the usual change in shape. The $P2Y_1$-null mice were resistant to thromboembolism, and thus this receptor may be a good target for antithrombotic drugs.

Soslau, G., and Youngprapakorn, D. A possible dual physiological role of extracellular ATP in the modulation of platelet aggregation. *Biochim. Biophys. Acta* 1355:131, 1997; and Leon, C., Hechler, G., Freund, M., Eckly, A., et al. Defective platelet aggregation and increased resistance to thrombosis in purinergic $P2Y_1$ receptor-null mice. *J. Clin. Invest.* 104:1731, 1999.

culture medium with a low serum content. The nuclei from quiescent diploid donor cells were then transferred to anucleated oocytes derived from a Scottish Blackface ewe. The artificially fertilized eggs developed to the morula or blastocyst stage in culture and then transferred to a recipient ewe that carried the fetus to term. Only a small percentage of implanted embryos survive to term. However, the methodology to clone offspring from adult somatic cells has been successfully extended to cattle, mice, and monkeys.

Dolly was euthanized in 2004 due to a progressive lung disease associated with what appeared to be a premature aging process. It is not clear if these defects were a result of the cloning process and/or environmental factors. However, cloning techniques continue to be explored with the intent that cloning will have great therapeutic value. Recently a female mouse was created from two female eggs by bypassing a process called **imprinting**. Imprinting dictates that some active genes must be contributed by the mother and others from the father. Normally mammalian embryos engineered with two sets of female or male chromosomes will not develop. The female mouse created from two mothers lived to adulthood and bore her own litter of pups.

With the success of creating Dolly and the isolation of **human embryonic stem cells (hESC)**, scientists began their quest to combine the two techniques to create embryonic stem cells genetically tailored for a particular patient, **therapeutic cloning**. A major step in this direction has been accomplished by the Herculean effort that created a single hESC line derived from a cloned blastula. The cloned blastula was created by inserting the nucleus of a human cumulus cell (cells surrounding an egg in an ovary) into an anucleated human egg and subjecting it to the appropriate chemical environment to induce replication. The hESC line grows normally in culture and should be able to differentiate into all cell types of the body. These cells could be induced to form normal cells of any tissues to replace defective tissues in patients.

Embryonic stem cells are **pluripotential cells** that can develop into any cell type within an organism given the correct environment and signaling molecules. Much hope and ethical concerns have swirled around the development and use of embryonic stem cells for the treatment of many human diseases. Recent studies demonstrate that human somatic cells can be reprogrammed to pluripotential, embryonic-like stem cells. The stable introduction of four transcription factors, Oct 4, Sox2, Klf4, and Myc, into mouse or human somatic cells by viral vectors resulted in the formation of **induced-pluripotent stem (iPS) cells**. Although much work remains to demonstrate the safety of using these iPS cells for clinical treatment of diseases, their potential is enormous. Furthermore, iPS cells can be patient specific to obviate any immune response.

Recombinant DNA in Agriculture Has Commercial Impact

Perhaps the greatest gain to humanity would be the practical use of recombinant technology to improve agricultural crops. Genes must be identified and isolated that code for properties such as higher crop yield, rapid plant growth, resistance to adverse conditions such as arid or cold periods, and plant size. New genes, not common to plants, may be engineered into plants so as to confer resistance to insects, fungi, or bacteria. Finally, genes for structural proteins can be modified to contain essential amino acids not normally present, without modifying the function of the protein. Production of plants with new genetic properties requires introduction of genes into plant cells that can differentiate into whole plants.

New genetic information carried in crown gall plasmids can be introduced into plants infected with soil bacteria known as agrobacteria. Agrobacteria naturally contain a crown gall or Ti (tumor-inducing) plasmid whose genes integrate into an infected cell's chromosome. The plasmid genes direct the host plant cell to produce new amino acid species called opines (such as the amino acid derivatives of arginine and pyruvate, octopine, or arginine and α-ketoglutarate, nopaline) that are required for bacterial growth. A crown gall, or tumor mass, of undifferentiated plant cells develops at the site of bacterial infection. New genes engineered into the Ti plasmid can be introduced into plant cells on infection with the Agrobacteria. The cells can then be grown in culture and induced to redifferentiate into

whole plants. Every cell would contain the new genetic information and would represent a transgenic plant.

Some limitations in producing plants with improved genetic properties must be overcome before significant advances in our world food supply can be realized. Clearly, genes for desired characteristics must be identified and isolated. Also, important crops such as corn and wheat cannot be transformed by Ti plasmids; therefore, other vectors must be identified. Significant success has been achieved in designing crop plants resistant to insects and viruses. Recently genetic engineering inserted a foreign gene into pea plants to produce a protein that inhibits the feeding of weevil larvae on the pea seeds. This will permit storage of peas and other legume seeds without the need of protective chemical fumigants (currently Brazilian farmers lose 20%–40% of their stored beans to pests).

7.11 • GENOMICS, PROTEOMICS, AND MICROARRAY ANALYSIS

Genomics is the study of the molecular characteristics of the whole genome. This includes the sequence of the genome, the identification of genes and their regulatory sequences, and the pattern of gene expression. Dozens of prokaryotic and eukaryotic genomes, as well as over one thousand viruses, have been sequenced (Table 7.1). The sequencing of numerous genomes of marine microbes has recently added approximately one million new genes to the 180,000 documented genes. It is estimated that there are more than 10 billion genes in the Earth's repertoire. A singe gene may give rise to multiple protein species due to splice choice of RNA transcript and variable posttranslational processing of the protein product. The complement of proteins within a cell is referred to as its **proteome**. Proteomics is the study of proteins expressed in tissues under various conditions, protein interactions, and protein modifications. Clin. Corr. 7.15 describes how proteomics has been used to diagnose early stages of cancer by identifying tumor-associated biomarkers.

TABLE 7.1 • A Partial Listing of Prokaryotic and Eukaryotic Species Whose Genomes Have Been Sequenced

	Species	*Genome Size*
Prokaryotes (over 100 microbes)	*Hemophilus influenzae*	1.83 Mb
	Chlamydia pneumoniae	1.23 Mb
	Neisseria meningitides	2.27 Mb
	Vibrio cholerae	4.0 Mb
		Number of Chromosomes
Simple Eukaryotes	*Saccharomyces cerevisiae* (yeast)	16
	Plasmodium falciparum (malarial protozoan)	14
	Anopheles gambiae (mosquito)	3
	Drosophila melanogaster (fruit fly)	5
Plants	*Avena sativa* (oat)	7
	Hordeum vulgare (barley)	7
	Oryza sativa (rice)	12
	Zea mays (corn)	10
Vertebrates	*Danio rerio* (zebra fish)	25
	Gallus gallus (chicken)	39
	Mus musulus (mouse)	21
	Rattus norvegicus (rat)	22
	Homo sapiens (human)	24

CLINICAL CORRELATION 7.15

Microarray Techniques to Detect and Treat Diseases

A. Nucleic Acid Microarray Analysis of Breast Cancer

The treatment modality of human breast cancer patients depends, in large part, on the estrogen receptor (ER) status of the tumor cells. Estrogen receptor-positive tumors generally respond well to adjuvant hormone or drug therapy whereas ER-negative tumors usually do not. Patients with ER-negative tumors have variable responses to chemotherapy, and there are no known indicators to predict postoperative prognoses. The amplified cellular RNA derived from 10 ER-negative patients who died within 5 years of breast cancer and 10 ER-negative patients who were alive, disease free, was analyzed on a cDNA microarray consisting of 25,344 genes. The analysis detected 71 genes with higher expression in the group that died than those who lived and 15 genes expressed at higher levels in the survivors versus those who died. A scoring system was developed based on gene markers to classify ER-negative breast cancer patients into a poor prognosis versus a good prognosis group. The scoring system appears to have a high degree of accuracy and may help direct treatment protocols and define new gene targets for drug treatment.

B. Antibody Microarray Technology for Treatment of Brain Tumors

Glioblastoma multiforme (GBM) is the most common central nervous system tumor found in human adults and, unfortunately, one of the most lethal cancers. Abnormal activation of phosphatidylinositol-3-kinase (PI3K) pathway components is a hallmark for GBM, as well as other cancers. Receptor tyrosine kinases (RTKs) activate PI3K. Some examples of RTKs include the growth factor receptors EGFR, PDGFR, and VEGFR. It was found that multiple RTKs activated PI3K in GBM by analyzing tumor cell extracts incubated with RTK antibody arrays. Here antibodies, specific to numerous RTKs, are fixed to a solid support and will bind the cellular RTKs. The activated RTK present in the cell extract is phosphorylated at tyrosine residues which are readily detected in the RTK–antibody complex by a second horseradish peroxidase (HRP) conjugated antibody against phospho-tyrosines. A substrate (fluorescent or colored) for HRP is then used to identify which active RTKs were present in a tumor cell extract. On the identification of which RTKs were involved in the activation of PI3K in a particular tumor cell line, specific RTK inhibitors were tested for their ability to reduce colony formation and cell viability. A single RTK inhibitor had little effect, and dual RTK inhibitors were more effective. However, use of three RTK inhibitors was most effective. Assays of untreated primary human GBM tumors all contained multiple phosphorylated RTKs while tissue from normal brain specimens had no detectable RTK activation. These studies demonstrate the ability to rapidly profile the complement of activated RTKs present in GBM samples from patients such that clinicians can personalize their drug treatment.

Microarray Analysis

Analysis of genomes and proteomes has been greatly facilitated by the development of microarray technologies developed first for analyzing nucleic acids. Nucleic acid hybridization and antigen–antibody complex formation are employed extensively in techniques described in preceding sections for the analysis of one or a few macromolecular species. However, techniques with a very high throughput are required to analyze simultaneously the hundreds to thousands of genes expressed in a cell. Microarray techniques depend on these same macromolecular interactions described previously such as in Southern, Northern, and Western blots. The fixation of DNA probes to solid impermeable surfaces reduces the solution volumes and times required for hybridization. DNA microarrays are produced by computer-controlled additions of microdrops of cloned or PCR synthesized DNA sequences to a glass slide with a poly-L-lysine substrate to which these DNA probes are covalently cross-linked. DNA or RNA to be analyzed is isotopically or fluorescently labeled and then hybridized with the fixed probes on a glass slide (Figure 7.32). Positive reactions are detected and quantified by high-resolution imaging and computer analysis. Many DNA microarrays are available that focus on selected genes involved in discreet processes or pathways such as signal transduction and apoptosis. A specific example of altered gene expression in malaria-infected cells is depicted in Figure 7.33.

DNA oligonucleotides (usually 20 or more bases) are also synthesized on micromatrices fixed to a glass slide. The size of the micromatrix varies from $1 \times 10 \times 5$ μm to $100 \times 100 \times 20$ μm. Thousands of different oligonucleotides, each complementary to a specific gene, are immobilized on what is termed a **DNA chip**. A single–chip microarray for the human genome, which will be commercially available, contains 1 million oligonucleotide

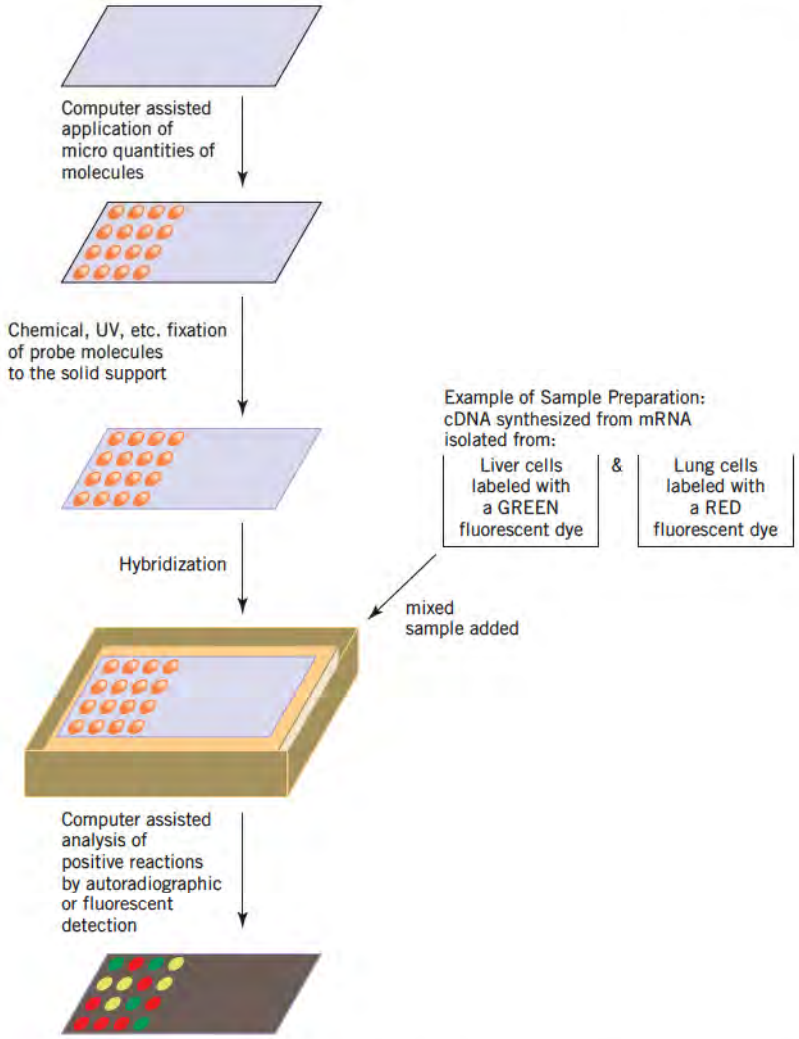

Figure 7.32 DNA microarray analysis. The surface of an impermeable support, typically glass or polypropylene, is prepared to apply multiple samples of DNA or oligonucleotides. Slide with oligonucleotides or nucleic acids representing 100s to 1,000s of genes is incubated in a chamber under appropriate conditions for hybridization followed by appropriate washes to remove nonhybridized cDNA. Green fluorescent spots would indicate genes expressed in liver cells, red fluorescent spots for genes expressed in lung cells, and yellow fluorescent spots for genes expressed in both tissues.

probes. This DNA chip will detect about 50,000 RNA transcripts from approximately 30,000 human genes. These biological microchips are compared to electronic microchips since both are capable of performing multiple reactions in parallel in a high-throughput fashion.

Microarrays allow for the analysis of expression of the whole genome or genes in a selected pathway. Genes expressed in a specific tissue or under a selected metabolic or diseased state could give clues as to which genes are active in the specific condition. Unfortunately, a single microarray plate gives a static snapshot of genomic genes expressed under a particular condition. Regulatory genes involved in the final altered expression cannot be readily deduced from this single picture since many genes may be turned on or off by downstream pathways during the transition to the final cellular state. Coregulatory genes involved in the switch between different metabolic or disease states could be determined by microarray analysis at multiple time points between the initial and final stage of altered gene expression. Computer analysis of microarrays generated over the time course can cluster genes that appear to be coordinately expressed. **Cluster analysis** allows identification of potential genes that coregulate the alteration of the cell from one state to another.

Protein microarrays are produced with antibodies or nonantibody proteins fixed to slides or filters that can capture target proteins in a sample in a fashion similar to those used for DNA microarrays. Other protein probes are being developed for protein microarrays such as short stretches of synthesized DNA or RNA (**aptamers**) that selectively bind specific proteins. Protein arrays are generally produced with recombinant proteins that may be generated from tissue-specific cDNA expression libraries. These microarrays are readily analyzed with specific antibodies that are fluorescently labeled. This approach has been

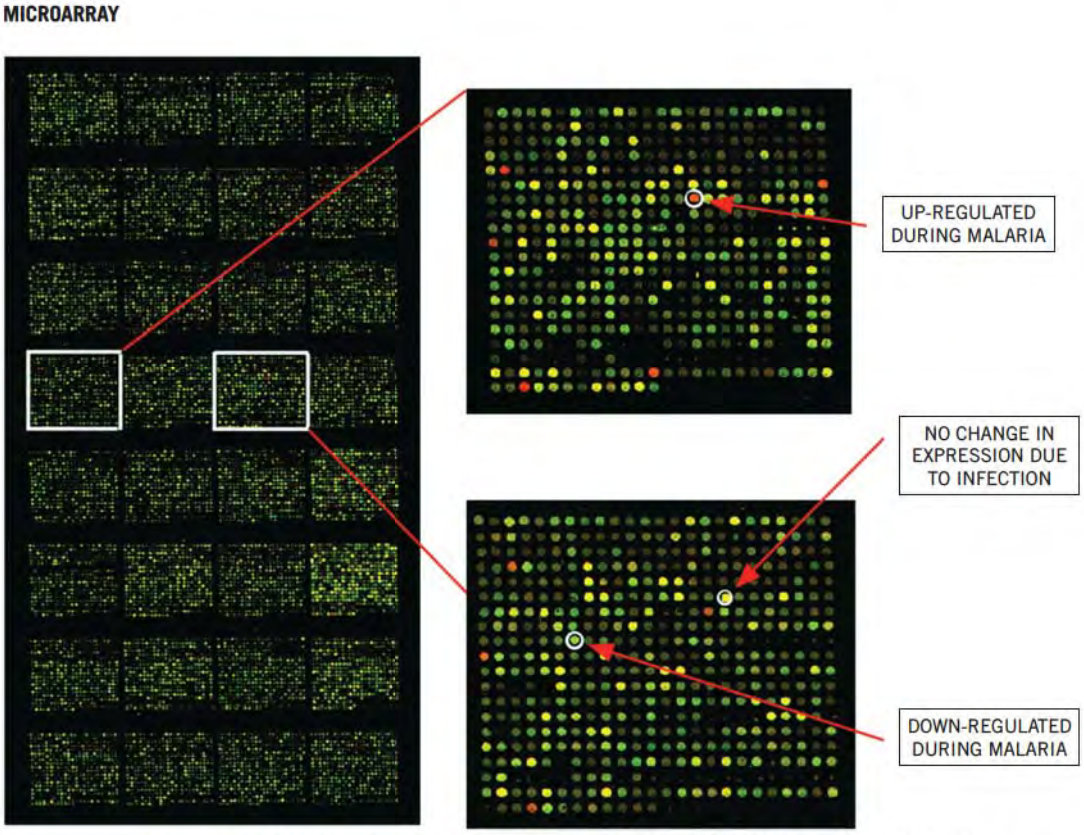

Figure 7.33 Microarray analysis of gene expression in mice infected with a rodent malaria parasite. DNA, RNA, or oligonucleotides, representing part or all of the cellular genome, or proteins or antibodies, representing part of the cellular proteome, are fixed on an impermeable support. The fixed probes are reacted with appropriately labeled cellular components that will form a stable complex through hybridization or protein–protein interactions. Identification of nucleic acids or proteins that associate with the fixed samples in the microarrays allows for the analysis of cellular gene expression in cells maintained under a variety of conditions.
Mouse DNA microarrays were produced for the mouse genome which contains 13,443 synthetic oligonucleotides representing well- characterized mouse genes. Each oligonucleotide is 70 bases in length derived from the 3′-end of each gene, optimized to minimize cross-hybridization to all known mouse genes. The array includes a comprehensive set of immune system related genes encoding a lymphocyte subset and activation markers, cytokines, chemokines, their receptors, adhesion molecules, costimulatory molecules, immunoregulatory factors, transcription factors and signal transduction proteins, and others. Samples: Splenocyte RNA from uninfected mice was used to synthesize cDNA fluorescently labeled with Cy3 (green). Splenocyte RNA from mice on day 8 of infection with a rodent malaria parasite was used to synthesize cDNA fluorescently labeled with Cy5 (red). The mixed fluorescently labeled cDNA probes are hybridized with the target oligonucleotide array. Genes that are up-regulated in mice infected with malaria are red and those that are down-regulated in these animals are green. Genes that are unaffected by the malarial parasite are yellow.
Data are unpublished work from the laboratory of Dr. James Burns, Department of Microbiology, Drexel University College of Medicine.

successfully employed to detect the antibody repertoire in human plasmas associated with some autoimmune diseases.

Microarray techniques are critical for the analysis of genomic expression and the proteomic state of cells in normal cells as compared to the patterns in cells that are altered due to changes such as a modified metabolic environment, differentiation, response to drugs, response to growth factors, or a diseased state.

Human Genome

By 1996 the genome of yeast, a eukaryote, consisting of approximately 14×10^6 bps distributed among 16 chromosomes, was sequenced. The genome of the nematode, *C. elegans,* sequenced by 1998, contains approximately 18,000 genes as compared to the 6,000 genes

of yeast. In 2000, a **shotgun sequencing** approach was employed to sequence essentially the whole 180-× 10^6-bps genome of the fruit fly *Drosophila melanogaster*. This method involves the breakage of the whole genome into small pieces, sequencing the pieces by a rapid automated procedure, and assembling the sequenced fragments into the proper order assisted by overlapping sequences and a super computer. The availability of previously cloned sequences facilitated the sequencing.

The shotgun sequencing approach was employed to speed up the sequencing of the human genome. Several human chromosomes had already been mapped and thousands of cDNA clones had been sequenced or were ready to be sequenced, which would ultimately provide landmarks of the huge human genetic map. In 2000, J. C. Venter and F. S. Collins jointly announced that their groups had sequenced 97% of the human genome.

The determination of a genomic sequence is only a part of the genome puzzle. The start and stop site of each gene must be determined along with what the gene codes for a process referred to as **annotation**. Eukaryotic genomes usually contain permanently condensed or heterochromatic regions around the centromeres. These regions contain repetitive DNA that is not cloned and sequenced by any of the current sequencing methods. It may be decades or more before the complete determination of all the genes and regulatory elements are resolved.

The completion of the human genome project generated enormous amounts of data. The achievement of the project is only the beginning of our understanding of the molecular underpinnings of how a single cell functions, let alone an organism. It is now considered that the human genome encodes about 30,000 genes, far fewer genes than anticipated, and only about 20% more than a plant genome and about 40% more than *C. elegans* (roundworm). However, the RNA transcripts of the "static" genome are relatively "dynamic" as are their translated protein products. Splice choice of the primary RNA transcript results in different protein products from the same gene (p. 295). Protein products may also undergo numerous chemical modifications and association with other peptide subunits or proteins. It is estimated that the 30,000 genes ultimately give rise to 200,000 to 2 million protein products whose expression is dependent, in part, on tissue specificity, stage of development, and metabolic conditions. The task before us now is to be able to analyze transcripts and their final translation products at the structure or function level.

The delineation of all of the human genes and their regulatory sequences should greatly enhance our understanding of many genetic diseases. Technological advances to manipulate genes and gene expression should open new avenues to regulate or cure many diseases. Genetic diseases should eventually be curable by gene replacement therapy; limited clinical trials in gene therapy have been initiated. Considering the enormous advances made in molecular biology in just the past three decades, it is reasonable to believe the when will not be that far off. The old challenge confronting scientists was how to sequence the human genome; the new challenge is how to manipulate effectively that knowledge to benefit humankind.

Key Terms

polymerase chain reaction (PCR)
nested PCR
quantitative real time PCR
restriction endonuclease
restriction maps
dideoxynucleoside triphosphate
direct sequencing
dye-terminator sequencing
recombinant DNA
plasmids
polycloning site
multiplex PCR
insertional inactivation
α complementation
complementary DNA (cDNA)
Northern blot
restriction fragment length polymorphism (RFLP)
Southern blot
single-strand conformation polymorphism (SSCP)
in situ hybridization
nuclease protection assay
electrophoretic mobility shift assay (EMSA)
bacteriophage libraries
cosmid vector
bacterial artificial chromosomes (BACS)
yeast artificial chromosomes (YACS)
chromosome walking
transgenic animals
expression vectors
fusion protein
transfection
site-directed mutagenesis
inverse PCR mutagenesis
antisense nucleic acids
microRNAs
RNA interference, RNAi
small-interfering RNA (siRNA)
gene therapy
knockout mice
pluripotential cells
genomics
microarray analysis
proteomics
shotgun sequencing

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. Construction of a restriction map of DNA requires all of the following except
   A. partial hydrolysis of DNA.
   B. complete hydrolysis of DNA.
   C. electrophoretic separation of fragments on a gel.
   D. staining of an electrophoretic gel to locate DNA.
   E. cyclic heating and cooling of the reaction mixture.
2. Preparation of recombinant DNA requires
   A. restriction endonucleases that cut in a staggered fashion.
   B. restriction endonucleases that cleave to yield blunt-ended fragments.
   C. poly(dT).
   D. DNA ligase.
   E. cDNA.

3. In the selection of bacterial colonies that carry cloned DNA in plasmids, such as pBR322, that contain two antibiotic resistance genes,
   A. one antibiotic resistance gene is nonfunctional in the desired bacterial colonies.
   B. untransformed bacteria are antibiotic resistant.
   C. both antibiotic resistance genes are functional in the desired bacterial colonies.
   D. radiolabeled DNA or RNA probes play a role.
   E. none of the above.

4. Complementary DNA (cDNA)
   A. cannot be expressed by prokaryotic systems.
   B. is reverse transcribed from functional eukaryotic mRNA.
   C. has all of the elements of the original gene for the mRNA of interest.
   D. synthesis requires the prior formation of an RNA primer.
   E. remains as a single-stranded molecule.

5. The best vector to use to carry a segment of DNA that is 350 kb in size would be
   A. bacteriophage.
   B. bacterial artificial chromosome (BAC).
   C. cosmid.
   D. plasmid.
   E. yeast artificial chromosome (YAC).

6. Antisense nucleic acids
   A. complementary to mRNA would enhance translation.
   B. could result if a gene is inserted downstream of a promoter but in opposite direction to normal.
   C. can have no clinical uses.
   D. react only with DNA.
   E. are necessary for recombinant DNA technology.

Questions 7 and 8: In the United States, a major cause of death of babies during the first year is sudden infant death syndrome (SIDS). One study showed a strong correlation for an increased risk of SIDS with a prolonged QT interval in their electrocardiograms. In one child, a gene associated with the Long QT syndrome had a substitution of AAC for TCC. This gene codes for a protein associated with the sodium channel. The mutation was detected by single-strand conformation polymorphism (SSCP).

7. Which of the following statement(s) about SSCP is/are correct?
   A. The electrophoretic mobility on polyacrylamide gel of small, single-stranded DNA during the SSCP technique depends partly on the secondary conformation.
   B. There must be a restriction endonuclease site in the region studied for SSCP to work.
   C. Radiolabeling is not used in this technique.
   D. It is not necessary to know the sequence of the DNA to be studied.
   E. All of the above.

8. In order to get enough DNA to analyze, DNA is amplified by a polymerase chain reaction (PCR). In a PCR,
   A. the nucleotide sequence of the DNA to be amplified must be known.
   B. the sample is protected from heat which would denature the DNA.
   C. the role of oligonucleotides in the reaction mixture is to act as primers for the synthesis of new DNA.
   D. the final product is single-stranded DNA.
   E. the original DNA can be amplified only about 10-fold.

Questions 9 and 10: Recombinant DNA technology has uses of interest in the medical field. One is gene therapy to introduce a normal gene into cells containing a defective gene. The first authorized human gene therapy was given to a 4-year-old girl with severe combined immune deficiency (SCID) who had a defective gene for adenosine deaminase (ADA). A modified retrovirus was constructed to contain the human ADA gene which could be expressed in human cells without replication of the virus. Another clinical use for recombinant DNA technology is to have rapidly replicating bacteria produce large amounts of specific proteins, for example, human proteins such as hormones.

9. Expression of recombinant genes in mammalian cells
   A. will not occur if the gene contains an intron.
   B. occurs most efficiently if cDNA is used in the vector.
   C. does not require directional insertion of the gene into the vector.
   D. requires that the vector have enhancer and promoter elements engineered into the vector.
   E. does not require that the vector have an origin of replication (ori).

10. Expression of a eukaryotic gene in prokaryotes involves
    A. a Shine–Delgarno (SD) sequence in mRNA.
    B. absence of introns.
    C. regulatory elements upstream of the gene.
    D. a fusion protein.
    E. all of the above.

Questions 11 and 12: Whole genomic DNA was isolated from three individuals, digested separately with a restriction endonuclease to fragments and the fragments separated on agarose gel in an electric field. The gene of interest was isolated and analyzed using Southern blot technique. Each individual sample showed two bands. The bands were identical for two of the individuals. For the third, one band was identical to one band of the other two but the second band was of lower molecular weight than the others. This is an example of restriction fragment length polymorphism (RFLP).

11. A reasonable explanation for this RFLP is that the gene in the third individual
    A. lacked the recognition sequence for the restriction endonuclease.
    B. had a mutation at the cleavage site.
    C. had an additional recognition site for the endonuclease.
    D. had a deletion of a segment of the gene.
    E. underwent a random cleavage.

12. The Southern blot technique
    A. transfers DNA fragments from agarose gel to a nitrocellulose filter.
    B. requires that the DNA fragments remain double stranded.
    C. requires that the DNA is radiolabeled prior to addition to the agarose gel.
    D. alters the position of the DNA fragments during the process.
    E. amplifies the amount of DNA material.

Problems

13. The X-ray autoradiogram of one strand of a fragment of DNA sequenced by the Sanger method was obtained. The 5′-end of the nucleotide was labeled with ^{32}P. Numbering from bottom to top of the autoradiogram, the lane from the ddG tube showed bands at positions 4 and 11; ddC tube had bands at 1, 2, 7, 8, 9, and 13; ddA at 5, 10, and 15; and ddT at 3, 6, 12, and 14. What is the sequence of the fragment? Construct the autoradiogram pattern of the complementary sequence.

14. What makes the Taq DNA polymerase frequently used for a polymerase chain reaction (PCR) different from other DNA polymerases, and why is it preferable?

Answers

1. **E** Cyclic heating and cooling is part of the PCR process, not of restriction mapping. A and B: Restriction mapping involves all degrees of hydrolysis. Partial hydrolysis gives fragments of varying sizes, and complete hydrolysis gives the smallest possible fragments. C and D: Fragments are electrophoretically separated by size on agarose gel, which is stained to reveal the DNA.
2. **D** DNA ligase covalently connects fragments held together by interaction of cohesive ends. A: This is the most desirable type of restriction endonuclease to use, but it is not essential. B: Restriction nucleases that make blunt cuts can also be used if necessary. C: This is used in conjunction with poly(dA) if restriction endonucleases that make blunt cuts are employed, but it is not essential to all of recombinant DNA preparation. E: cDNA is only one type that can be used.
3. **A** The foreign DNA is inserted into one antibiotic resistance gene, thus destroying it. B: Resistance is due to the plasmids. C: See the comment for A above. D: Radiolabeling detects the DNA of interest, not the colonies that contain cloned DNA.
4. **B** This uses an RNA-dependent DNA polymerase (reverse transcriptase). A and C: Prokaryotic systems cannot splice out introns to yield functional mRNA transcripts—thus cDNA which does not contain the sequences for these elements. D. The poly(A) tail at the 3′-end of mRNA is used as the primer to make the strand complementary to the mRNA template. E. Once the first strand is synthesized, it becomes the template for the complementary strand. cDNA is double stranded.
5. **E** It can accept DNA from 200–500 kb. A: Bacteriophage is very good for DNA inserts about 15 kb long. B: BAC can accept DNA from about 100–200 kb. C: Cosmids accept inserts of about 45 kb. D: Plasmid vectors can be very useful but can accept only small pieces of DNA.
6. **B** This would put the antisense strand of DNA under control of the promoter with subsequent transcription of antisense mRNA. A: Antisense nucleic acid binds mRNA blocking translation. C: If not now, in the future. Antisense DNA nucleotides have been produced that inhibit viral infection. D: React with both DNA and RNA.
7. **A** A single base substitution usually modifies the conformation enough to shift the mobility as detected by SSCP. B: SSCP is the method of choice if there is no restriction endonuclease site. C: DNA is amplified by PCR in the presence of radiolabeled nucleotides. There has to be a detection method for the bands. D: SSCP requires prior knowledge of the sequence.
8. **C** The oligonucleotides hybridize with the single-stranded templates in the region of interest so that replication can begin. A: DNA of unknown sequence can be used but must be inserted into a vector with known flanking regions. B: The sample must be heated to 90° to separate the DNA strands. D: PCR produces a double-stranded DNA (dsDNA). E: With automation, amplification can be a millionfold.
9. **D** Eukaryotic systems require controlling elements, which are not necessary in bacterial systems. A: Expression may be improved if an intron is present. B: cDNA does not possess the required controlling elements. C: The gene must be inserted in the proper orientation relative to the control elements. E: The vector must replicate so it needs the sequence to promote replication.
10. **E** A: The SD sequence is necessary for the bacterial ribosome to recognize the mRNA. B: Bacteria do not have the intracellular machinery to remove introns from mRNA. C: Appropriate regulatory elements are necessary to allow the DNA to be transcribed. D: A fusion protein may be a product of the reaction.
11. **D** This would account for one band being of lower molecular weight. A, B, and F: The cleavage site has a specific recognition sequence. C: This would yield more than two bands.
12. **A** This occurs by elution from the gel by a high-salt solution. B: DNA is hydrolyzed by alkali and single-strand DNA binds to the filter. C: The probe to identify the bands on the filter is radiolabeled. D: The positions on the filter are identical to the gel. E: Doesn't happen.
13. The sequence is C C T G A T C C C A G T C T A reading 5′ to 3′. The autoradiograph of the complementary strand should have bands for ddG at 1, 2, 7, 8, 9, and 13; ddC at 4 and 11; ddA at 3, 6, 12, and 14; and ddT at 5, 10, and 15.
14. PCR requires cycling between low temperatures, where hybridization of template DNA and oligomeric primers occurs, and high temperatures, where DNA melts. The Taq DNA polymerase, isolated from a thermophilic organism discovered in a hot spring, is stable at high temperatures and makes the cycling possible with no addition of fresh polymerase after each cycle. Phusion™ High-Fidelity DNA polymerase, which has been commercially developed, has even more desirable properties.

Key Concepts

- Transcription of genes provides the link between the DNA reservoir of genetic information and the expression of RNA and ultimately protein.
- Genes generally include a nontranscribed promoter that is "upstream" of the protein-encoding portion of the gene.
- The transcripts encoded by prokaryotic organisms are often polycistronic, grouping genes encoding proteins with interrelated functions together under common control. In eukaryotic organisms most genes are monocistronic.
- Transcription can be activated or repressed in response to nutritional, environmental, or other cellular signals. Regulatory responses aim to provide appropriate gene expression for existing conditions, often by incorporating small molecules indicative of cellular conditions as coregulators.
- Control of transcription often depends on sequence-specific binding proteins. The amino acid motifs of sequence-specific binding proteins have been identified, allowing transcription factors to be grouped by structural similarities.
- The identification of DNA sequences that bind to transcription factors may help identify genes that are coordinately regulated. Eukaryotic promoters often have multiple transcription factor–binding sites and utilize combinations of transcription factors to regulate gene expression.

- Modifications of DNA and chromatin play a significant role in eukaryotic gene regulation. DNA methylation and histone methylation, acetylation, and phosphorylation influence the ability to transcribe a gene.
- Transcription factors are often modular, with DNA-binding domains, protein interaction domains, activation domains, and regulatory domains.
- Transcription factors may affect the assembly of the RNA polymerase complex, the recruitment of other transcription factors, or the recruitment of modification factors.

8.1 • INTRODUCTION

To survive, a living cell must respond to changes in its environment. One way cells adjust to these changes is to alter expression of specific genes; this affects the number of the corresponding protein molecules in the cell. This chapter focuses on some of the molecular mechanisms that determine when a given gene is expressed and to what extent. Understanding how expression of genes is regulated is one of the most active areas of biochemical research today.

E. coli cells contain genes for about 4300 different proteins, but *E. coli* does not need to synthesize all of them at the same time. The classic illustration of bacterial gene regulation is that of the gene for **β-galactosidase**, which converts the disaccharide lactose to glucose and galactose. When *E. coli* grows in a medium containing glucose as the carbon source, only about five molecules of the enzyme are present in a cell. When lactose is the sole carbon source, however, there are 5000 or more molecules. Thus, when bacteria need to metabolize lactose, they increase synthesis of β-galactosidase. If lactose is removed from the medium, synthesis of this enzyme stops as rapidly as it began.

Eukaryotic cells have more extensive mechanisms of gene regulation than prokaryotic cells. Differentiated cells of higher organisms have a highly complicated structure and often a specialized biological function that is determined by expression of their genes. For example, **preproinsulin** is synthesized in β-cells of the pancreas but not in kidney cells even though the nuclei of all cells of the body contain the gene for preproinsulin. During development of the organism, the presence of proteins in specific cell types is tightly controlled with respect to timing and order of developmental events.

Much more is understood about gene regulation in prokaryotes than in eukaryotes. Furthermore, studies on prokaryotes often provide exciting new ideas that can be tested in eukaryotic cells and are important for developing rational therapies for diseases caused by bacteria.

Several well-studied examples of gene regulation in bacteria will be discussed, followed by examples of the many protein transcription factors regulating expression of genes in the human genome.

8.2 • UNIT OF TRANSCRIPTION IN BACTERIA: THE OPERON

The *E. coli* chromosome is a circular double-stranded DNA molecule of 4.6 million base pairs whose entire sequence has been determined. Most of its approximately 4300 genes are not distributed randomly; instead, genes encoding enzymes of a specific metabolic pathway are clustered in one region of the DNA. Similarly, genes for associated structural proteins, such as the 70 or so proteins that compose the **ribosome**, are frequently adjacent to one another. A set of clustered genes is usually coordinately regulated; that is, the genes are transcribed together into a *polycistronic* mRNA species that contains the coding sequences for the various proteins. The term **operon** describes the complete regulatory unit of a set of clustered genes. It includes the adjacent **structural genes** for the related enzymes or associated proteins, a **regulatory gene** or genes encoding regulator protein(s), and **control elements** or sites on the DNA near the structural genes at which regulator proteins act. Figure 8.1 shows a partial genetic map of the *E. coli* genome that gives locations of structural genes of some *E. coli* operons.

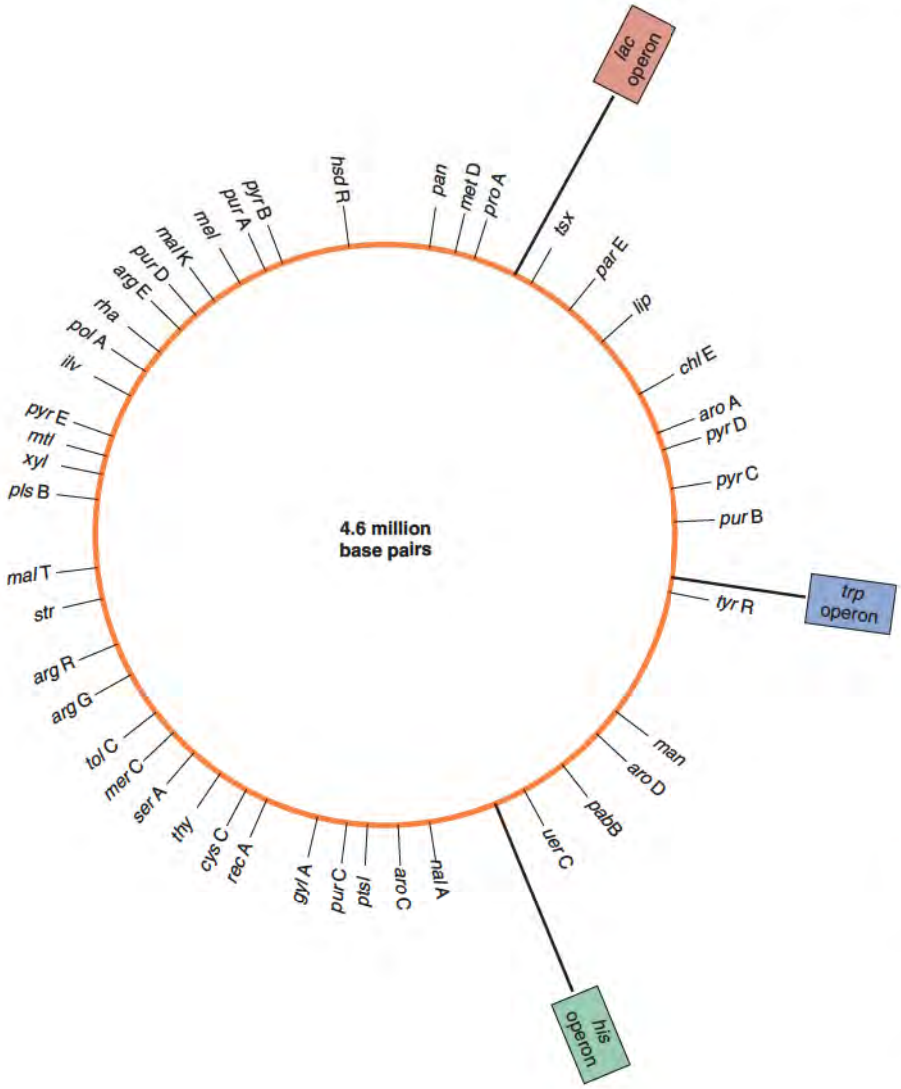

Figure 8.1 Partial genetic map of E. *coli*. Locations of a few of the 4300 genes in the circular *E. coli* genome are shown. Three operons discussed in this chapter are indicated.
Reproduced with permission from Stent, G. S., and Calendar, R. *Molecular Genetics: An Introductory Narrative.* San Francisco: Freeman, 1978, 289; modified from Bachmann, B. J., Low, K. B., and Taylor, A. L. *Bacteriol. Rev.*40:116, 1976.

When transcription of the structural genes of an operon increases in response to a specific substrate in the medium, the effect is known as **induction**. An example is the increase in transcription of the β-galactosidase gene when lactose is the sole carbon source. Bacteria also respond to nutritional changes by quickly turning off synthesis of enzymes no longer needed. For example, *E. coli* synthesizes tryptophan as the end product of a specific biosynthetic pathway. However, if tryptophan is present in the medium, synthesis of enzymes for this pathway stops. The process is called **repression**, and it prevents bacteria from using their energy to make unnecessary proteins.

Induction and repression are manifestations of the same phenomenon. The signal for each is the small molecule that is a substrate for the metabolic pathway or a product of the pathway, respectively. These small molecules are called **inducers** when they stimulate induction and **corepressors** when they cause repression.

8.3 • LACTOSE OPERON OF *E. COLI*

The lactose operon contains three adjacent structural genes (Figure 8.2). *Lac*Z codes for β-galactosidase, which is composed of four identical subunits of 1021 amino acids each. *Lac*Y codes for a permease, a 275-amino acid protein of the cell membrane that participates in the transport of sugars including lactose, across the membrane. *Lac*A codes for thiogalactoside transacetylase, a 275-amino acid enzyme that transfers an acetyl group from

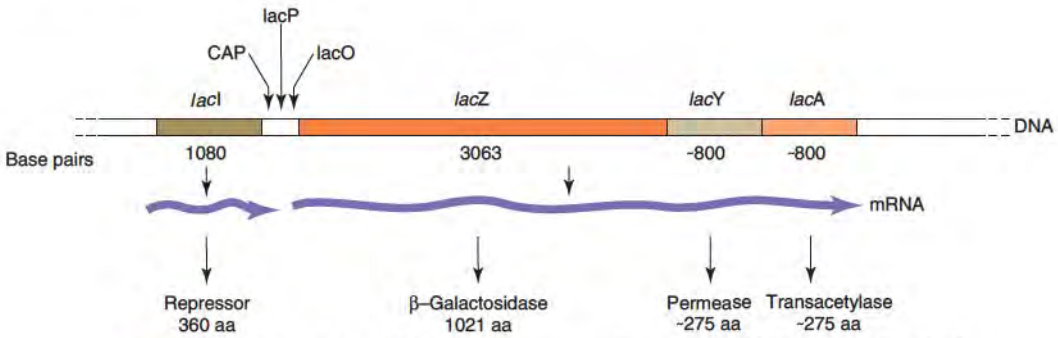

Figure 8.2 Lactose operon of *E. coli*. Lactose operon is composed of *lac*I gene, which codes for a repressor; control elements of CAP, *lac*P, and *lac*O; and three structural genes, *lacZ*, *lacY*, and *lacA*, which code for β-galactosidase, a permease, and a transacetylase, respectively. The *lac*I gene is transcribed from its own promoter. The three structural genes are transcribed from the promoter, *lac*P, to form a polycistronic mRNA from which the three proteins are translated.

acetyl CoA to β-galactosides. Of the three proteins, only β-galactosidase participates in a known metabolic pathway. The permease helps lactose move across the cell membrane. The transacetylase may be associated with detoxification and excretion reactions of nonmetabolized analogs of β-galactosides.

Mutations in *lacZ* or *lacY* that inactivate β-galactosidase or permease prevent cells from cleaving lactose or acquiring it from the medium, respectively. Mutations in *lac*A that inactivate transacetylase do not seem to affect cell growth and division.

A single mRNA species containing the coding sequences of all three structural genes is transcribed from a **promoter**, called *lac*P, located just upstream from *lacZ*. Induction of these genes occurs during initiation of their transcription. Without the inducer, transcription occurs at a very low level. In presence of inducer, transcription begins at *lac*P and proceeds through all three genes to a transcription terminator located slightly beyond *lac*A. Thus, the genes are **coordinately expressed**; all are transcribed in unison or none is transcribed.

The presence of three coding sequences on the same mRNA molecule suggests that the relative amount of the three proteins is always the same under varying conditions of induction. The inducer is a molecular switch that influences synthesis of one mRNA species for all three genes. However, the amount of each of the three proteins is often different because of differences in rates of translation or of degradation of the proteins themselves.

The mRNA induced by lactose has a half-life of about 3 min. Therefore, expression of the operon can be altered very quickly. Transcription ceases as soon as inducer is no longer present, existing mRNA molecules disappear within minutes, and cells stop making the proteins.

Repressor of Lactose Operon Is a Diffusible Protein

The regulatory gene of the lactose operon, *lac*I, codes for the lactose **repressor** whose only function is to control initiation of transcription of the *lac* structural genes. *Lac*I is located just upstream of the controlling elements for the *lac*ZYA cluster. However, a regulatory gene need not be close to the gene cluster it regulates. Transcription of *lac*I is not regulated; this gene is transcribed from its own promoter at a low rate that is relatively independent of the cell's status.

Lactose repressor is synthesized as a monomer of 360 amino acids, which forms an active homotetramer. Usually there are about 10 tetramers per cell. It has strong affinity for its main DNA-binding site, called the **operator** or *lac*O, which lies between *lac*P and *lacZ*. *lac*O partly overlaps *lac*P so bound repressor prevents **RNA polymerase** from binding to *lac*P and initiating transcription.

Besides recognizing and binding to *lac*O, the repressor has strong affinity for inducer molecules of the lactose operon. Each monomer binds to an inducer molecule, which causes a **conformational change** that greatly lowers the repressor's affinity for *lac*O (Figure 8.3). Thus, when inducer is present, the repressor no longer binds to *lac*O and RNA polymerase begins transcription from the promoter.

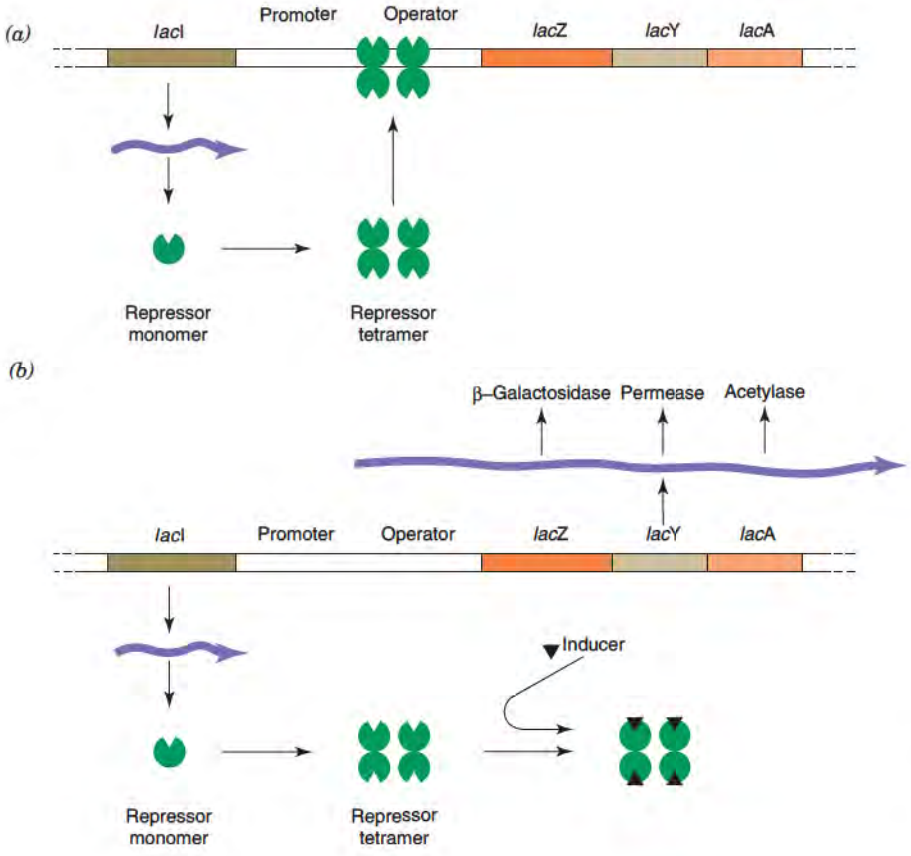

Figure 8.3 Control of lactose operon. (*a*) Repressor tetramer binds to operator and prevents transcription of structural genes. (*b*) Inducer binds to repressor tetramer, which prevents repressor from binding to operator. Transcription of the three structural genes can occur from the promoter.

Study of the lactose operon was greatly facilitated by the discovery that some small molecules, such as isopropylthiogalactoside (**IPTG**), fortuitously serve as inducers but are not metabolized by β-galactosidase. These **gratuitous inducers** bind like inducers to the repressor molecule.

The repressor protein acts in trans; that is, it can diffuse to its site of action. Some *lacI* mutations change or delete amino acids of the repressor that are part of the binding site for the inducer. These changes do not affect the affinity of repressor for the operator, so that the repressor is always bound to the operator, even in the presence of inducer, and the *lacZYA* genes are never transcribed above a very low basal level. Other *lacI* mutations change the amino acids in the operator-binding site and lessen the affinity of repressor for operator. Thus, the repressor does not bind the operator and the *lacZYA* genes are continuously transcribed. Such mutations are **repressor-constitutive mutations** because the *lac* genes are permanently expressed. A few rare *lacI* mutants increase the affinity of repressor for operator. In these cases inducer molecules can bind to repressor, but they are less effective in releasing repressor from the operator.

Repressor-constitutive mutants illustrate the features of a negative control system. An active repressor, in the absence of an inducer, shuts off expression of the *lac* structural genes. An inactive repressor results in the constitutive, unregulated, expression of these genes. Using recombinant DNA techniques described in Chapter 7, a plasmid-containing wild-type *lacI* (but not the rest of the lactose operon) can be introduced into constitutive *lacI* mutant cells. Such cells synthesize both active and inactive repressor molecules. Under these conditions, normal wild-type regulation of the lactose operon occurs. Thus, in genetic terms, wild-type induction is dominant over mutant constitutivity.

Operator Sequence of Lactose Operon Is Contiguous with a Promoter and Three Structural Genes

The control elements upstream of the structural genes of the lactose operon are the operator and the promoter. The operator was identified, like *lacI*, by mutations that affect transcription of the *lacZYA* region. Some of these mutations result in the constitutive synthesis of

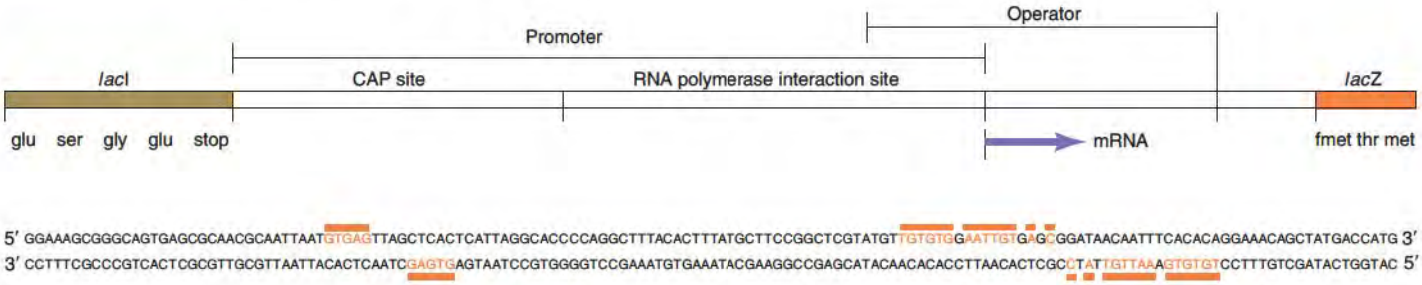

Figure 8.4 Nucleotide sequence of control elements of lactose operon. The end of lacI gene (coding for the lactose repressor) and beginning of lacZ gene (coding for β-galactosidase) are also shown. Lines above and below the sequence indicate symmetrical sequences within the CAP site and operator.

lac mRNA; that is, they are **operator-constitutive mutations**. In these cases the operator DNA sequence has one or more base pair changes so the repressor no longer binds as tightly to the sequence. Thus, the repressor is less effective in preventing RNA polymerase from initiating transcription.

In contrast to mutations in *lac*I which encode the diffusible repressor, mutations in the operator do not change a diffusible protein. They exert their influence on transcription of only the three *lac* genes immediately downstream of the operator on the same DNA molecule. If a second lactose operon is introduced into a bacterium on a recombinant plasmid, the operator of one operon has no influence action on the other operon. Thus, an operon with a wild-type operator will be repressed under the usual conditions, whereas in the same engineered bacterium a second operon with an operator-constitutive mutation will be continuously transcribed.

Operator mutations are frequently referred to as **cis-dominant** to emphasize they affect only adjacent genes on the same DNA molecule. Cis-dominant mutations occur in DNA sequences that are recognized by proteins rather than in DNA sequences that code for the diffusible proteins. **Trans-dominant** mutations occur in genes that specify diffusible products. Therefore, cis-dominant mutations also occur in promoter and transcription termination sequences, whereas trans-dominant mutations also occur in genes for subunit proteins of RNA polymerase, ribosomal proteins, and so on.

Figure 8.4 shows the sequence of the *lac* operator and promoter. The operator sequence has an axis of **dyad symmetry**. The sequence of the upper strand on the left side of the operator is nearly identical to that of the lower strand on the right side; only three differences occur. This symmetry in the DNA recognition sequence reflects symmetry in the tetrameric repressor and facilitates tight binding of the repressor subunits to the operator. Dyad symmetry in the double-stranded DNA sequence is a common feature of many protein-binding or recognition sites, including most recognition sites for restriction enzymes.

The *lac* operator of about 30 bp is an extremely small fraction of the total *E. coli* genome and occupies an even smaller fraction of the volume of the cell. However, the approximately 10 tetrameric repressors are also confined to a small fraction of the cell volume. Since the repressor gene is very close to the *lac* operator, the repressor does not have far to diffuse if its translation begins before its mRNA is fully synthesized. More importantly, the repressor has a low general affinity for all DNA sequences. When the inducer binds to the repressor, its affinity for the operator is reduced about 1000-fold, but its low affinity for random DNA sequences is unaltered. Therefore, all of the lactose repressors in the cell are in loose association with DNA. When binding of inducer releases a repressor molecule from the operator, it quickly binds a nearby DNA region. Therefore, induction redistributes the repressor on the DNA rather than generates freely diffusing repressor molecules.

How does lactose enter a cell in the first place if the *lac*Y gene encoding the permease is repressed, yet permease is required for lactose transport across the cell membrane? Even in the repressed state, there is a very low basal level of transcription of the *lac* operon that provides five or six molecules of permease per cell. Perhaps this is just enough to get a few molecules of lactose inside the cell and begin the process.

Another curious observation is that lactose is not the natural inducer of the lactose operon. When the repressor is isolated from fully induced cells, the small molecule bound to each repressor monomer is **allolactose**, not lactose. Allolactose, like lactose, is composed of galactose and glucose, but the linkage between the two sugars is different. A side reaction of β-galactosidase (which normally breaks down lactose to galactose and glucose) converts these two products to allolactose.

Therefore, a few molecules of lactose are taken up and converted by β-galactosidase to allolactose, which binds to the repressor and induces the operon. Further confirmation that lactose is not the real inducer comes from experiments indicating that binding of lactose to purified repressor actually increases the repressor's affinity for the operator. Therefore, in the induced state a small amount of allolactose must be present to overcome this *anti-inducer* effect of lactose.

RNA Polymerase and a Regulator Protein Recognize Promoter Sequence of Lactose Operon

Immediately upstream of the *lac* operator is the promoter. This sequence contains binding sites for RNA polymerase and **catabolite activator protein (CAP;** also called **cAMP receptor protein** or **CRP)** (Figure 8.4). The site to which RNA polymerase binds has been identified by genetic and biochemical approaches. Point mutations and deletions (or insertions) in this region dramatically affect RNA polymerase binding. The end points of the sequence to which RNA polymerase binds were identified by DNase protection experiments. Purified RNA polymerase was bound to the *lac* promoter region cloned in a bacteriophage DNA or a plasmid, and this protein–DNA complex was digested with DNase I. The DNA segment protected from degradation by DNase was recovered, and its sequence determined. The ends of this protected segment varied slightly with different DNA molecules but corresponded closely to the boundaries of the RNA polymerase-binding site shown in Figure 8.4.

The RNA polymerase-binding site does not have symmetrical elements like the operator sequence. This is not surprising since RNA polymerase must associate with DNA in an asymmetrical fashion for transcription to be initiated in only one direction. However, the part of the promoter sequence recognized by CAP does contain some symmetry.

Catabolite Activator Protein Binds Lactose Promoter

E. coli prefers glucose over other sugars as a carbon source. For example, if both glucose and lactose are in the medium, the bacteria selectively metabolize glucose. Figure 8.5 shows that β-galactosidase does not appear until the glucose is depleted. This indicates that glucose interferes with induction of the lactose operon, a process called **catabolite repression** since it occurs during the catabolism of glucose. An identical effect is seen with other inducible operons, including the arabinose and galactose operons. This is probably a general coordinating system for turning off synthesis of unwanted enzymes when glucose is present.

Catabolite repression occurs because glucose inhibits adenylate cyclase, which synthesizes **cyclic AMP (cAMP)**, leading to a lower intracellular concentration of cAMP. cAMP forms a complex with **Catabolite Activator Protein (CAP)**, which then binds the CAP regulatory site at promoters of lactose (and other) operons (Figure 8.6). The CAP–cAMP complex exerts a positive control on transcription by causing the DNA helix to bend, or kink, about 90° at the site of the binding. This DNA bend and the interaction between CAP–cAMP and RNA polymerase activate transcription initiation. If the CAP site is not occupied, RNA polymerase has difficulty binding to the promoter and transcription initiation is much less efficient.

The lactose operon demonstrates how bacteria can coordinate a general response to a metabolic condition (the need to use a sugar as an energy or carbon source) and a specific response to that condition (the need to utilize lactose as the sugar).

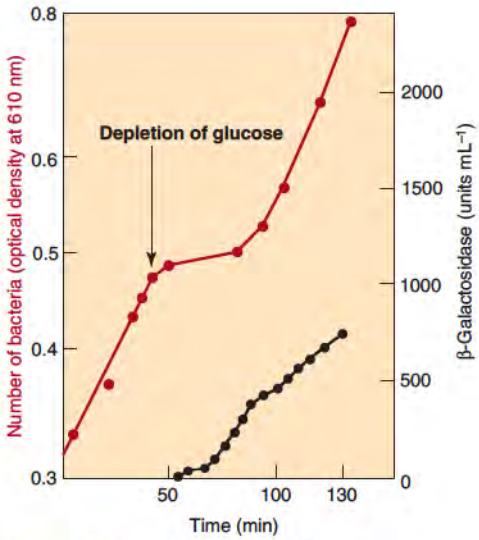

Figure 8.5 Lack of synthesis of β-galactosidase in *E. coli* when glucose is present. Bacteria are growing in a medium containing initially 0.4 mg glucose/mL and 2 mg lactose/mL. Left-hand ordinate indicates optical density of growing culture, an indicator of the number of bacterial cells. Right-hand ordinate indicates units of β-galactosidase per milliliter. Note that appearance of β-galactosidase is delayed until the glucose is depleted.
Redrawn from Epstein, W., Naono, S., and Gros, F. *Biochem. Biophys. Res. Commun.* 24: 588, 1966.

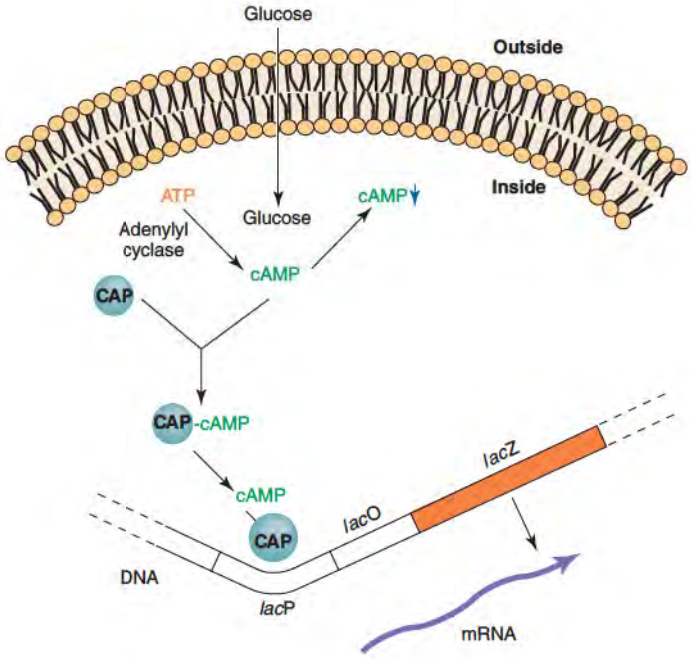

Figure 8.6 Control of *lac*P by cAMP. A CAP–cAMP complex binds to CAP site and enhances transcription at *lac*P. Catabolite repression occurs when glucose lowers intracellular concentration of cAMP. This reduces the amount of the CAP–cAMP complex and decreases transcription from *lac*P and from promoters of several other operons.

8.4 • TRYPTOPHAN OPERON OF *E. COLI*

Bacteria must have the proper amount and relative balance of the 20 amino acids that make up proteins. **Tryptophan**, for example, is required for the synthesis of all proteins that contain it. Therefore, if tryptophan is not present in sufficient quantity in the medium, the bacterial cell has to make it. In contrast, lactose is not absolutely required for the cell's growth; many other sugars can substitute for it. As a result, synthesis of biosynthetic enzymes for tryptophan is regulated differently than synthesis of proteins encoded by the lactose operon.

Tryptophan Operon Is Controlled by a Repressor Protein

In *E. coli* tryptophan is synthesized from chorismic acid in a five-step pathway catalyzed by three enzymes (Figure 8.7). The **tryptophan operon** contains five structural genes that code for these three enzymes (two of which contain two different subunits). Upstream from this gene cluster is a promoter where transcription begins and an operator to which a repressor protein encoded by a separate *trp*R gene binds. Transcription of the lactose operon is generally *turned off*, or repressed, unless induced by a small molecule inducer. The tryptophan operon, on the other hand, is always active, or derepressed, unless it is repressed by a small molecule **corepressor**, which for the tryptophan operon is tryptophan itself.

Tryptophan biosynthesis is regulated by both the synthesis and the activity of enzymes that catalyze the pathway. For example, anthranilate synthetase, which catalyzes the first step, contains two subunits encoded by *trp*E and *trp*D and its enzyme activity is regulated by **feedback inhibition**. This is a common short-term means of regulating the first committed step in a metabolic pathway. Tryptophan can bind to an allosteric site on anthranilate synthetase and prevent its enzymatic activity. Thus, as the concentration of tryptophan builds up, it inhibits anthranilate synthetase. Tryptophan also is a corepressor that shuts down transcription of the tryptophan operon. Feedback inhibition is a short-term control with an immediate effect on the pathway, whereas repression takes longer but has the more permanent effect of repressing transcription.

The tryptophan repressor is a homodimer whose subunits have 108 amino acids each. Under normal conditions about 20 molecules of the repressor dimer are present. The repressor must be complexed with two molecules of tryptophan to bind to the operator. Recall that the lactose repressor binds its operator only in the absence of its inducer.

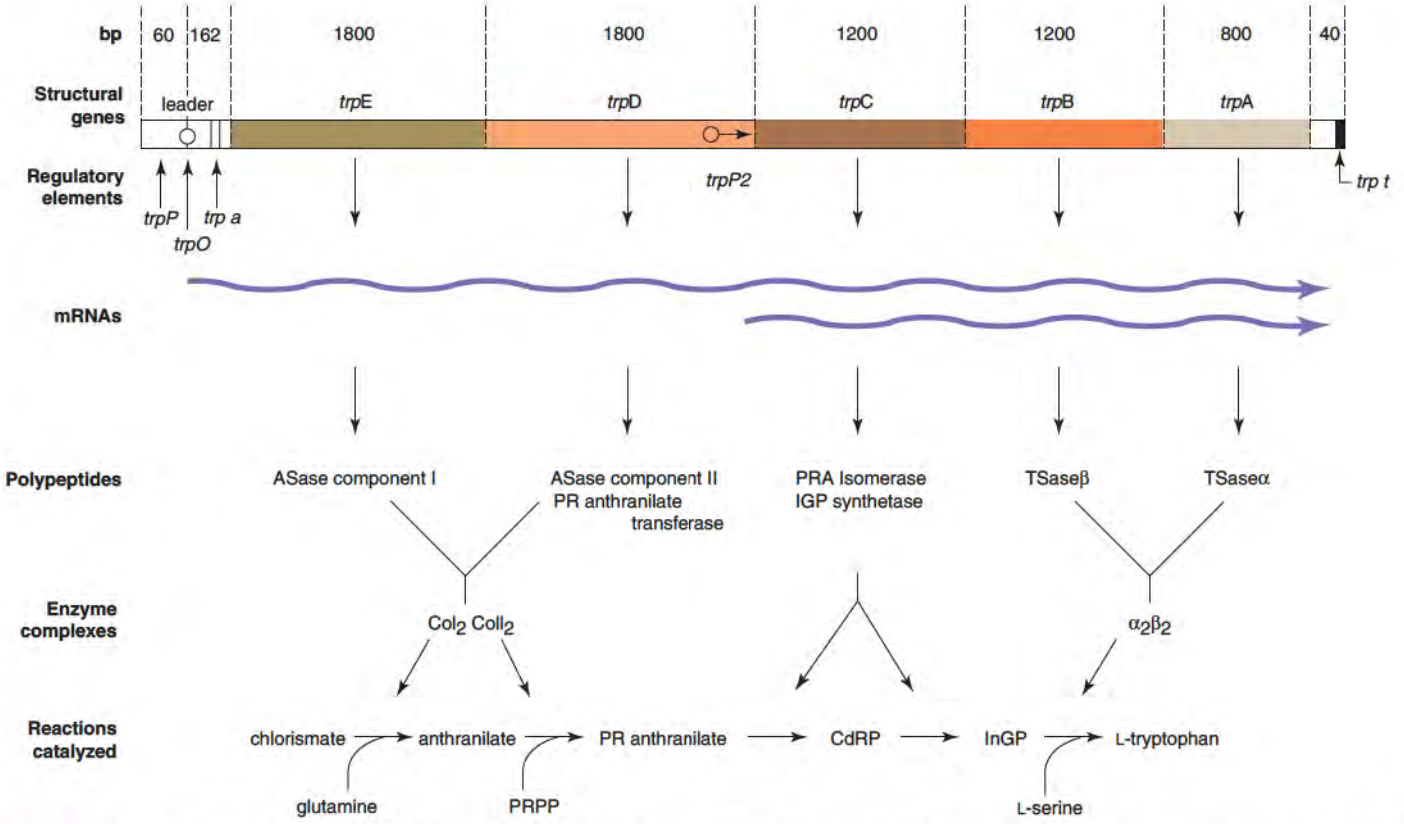

Figure 8.7 Genes of tryptophan operon of E. *coli*. Regulatory elements are the primary promoter (*trp*P), operator (*trp*O), attenuator (*trp*a), secondary internal promoter (*trp*P2), and terminator (*trp*t). Direction of mRNA synthesis is indicated by wavy arrows representing mRNAs. CoI_2 and $CoII_2$ signify components I and II, respectively, of the anthranilate synthetase (ASase) complex; PR-anthranilate is *N*-5′-phosphoribosyl-anthranilate; CdRP is 1-(o-carboxy-phenylamino)-1-deoxyribulose-5-phosphate; InGP is indole-3-glycerol phosphate; PRPP is 5-phosphoribosyl-1-pyrophosphate; and TSase is tryptophan synthetase.
Described in Yanofsky, C. *Trends in Genet.* 20: 367, 2004.

The tryptophan repressor also regulates transcription of *trp*R, its own gene. As tryptophan accumulates in cells, the repressor–tryptophan complex binds to a region upstream of *trp*R, turning off its transcription and maintaining the equilibrium of 20 repressors per cell. The *trp* operator occurs entirely within the *trp* promoter rather than adjacent to it (Figure 8.8). The operator is a region of dyad symmetry, and the mechanism for preventing transcription is the same as in the lactose operon; that is, binding of the repressor–co-repressor complex to the operator prevents binding of RNA polymerase.

Repression decreases the rate of transcription initiation at the *trp* promoter by about 80-fold. (The basal level of lactose operon gene products is about 1000-fold lower than the induced level.) However, the tryptophan operon contains additional regulatory elements. A secondary promoter designated *trp*P2 is located within the coding sequence of *trp*D (Figure 8.7) and is not regulated by the tryptophan repressor. Transcription from it occurs constitutively at a relatively low rate to generate an mRNA that contains the coding sequences for *trp*CBA. Thus, two polycistronic mRNAs are derived from the tryptophan

Figure 8.8 Nucleotide sequence of control elements of tryptophan operon. Boxes above and below sequence indicate symmetrical sequences within operator.

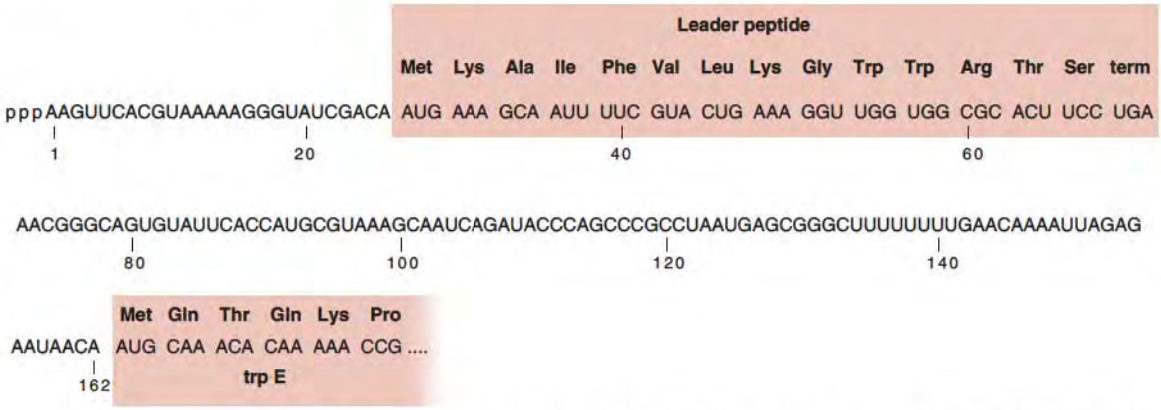

Figure 8.9 Nucleotide sequence of leader RNA from tryptophan operon. The 14 amino acids of the putative leader peptide are indicated over their codons.

operon, one containing all five structural genes and the other possessing only the last three.

A second internal promoter may be needed because three of the five genes do not contain a tryptophan codon; only *trp*B and *trp*C contain a tryptophan codon. Thus, under extreme tryptophan starvation, these two proteins are not synthesized, preventing the pathway from being activated. However, since both of these genes lie downstream of the unregulated second promoter, their protein products will always be present at the basal level necessary to maintain the pathway.

Attenuator Region of Tryptophan Operon

Another important control element of the tryptophan operon not present in the lactose operon is the **attenuator** region (Figure 8.9), which lies within the 162 nucleotides between the promoter and the initiator methionine codon of *trp*E. Its existence was first deduced from mutations that mapped in this region and increased transcription of all five structural genes. Within this region is the **leader sequence** of 14 adjacent codons that begins with a methionine codon and ends with an in-phase termination codon. These codons are preceded by a canonical ribosome-binding site and could potentially specify a 14-residue leader peptide. This peptide has not been detected in bacterial cells, perhaps because it is degraded very rapidly.

The attenuator region provides RNA polymerase with a second chance to regulate transcription of the tryptophan operon. In the presence of tryptophan, transcription begins at the promoter but it is prematurely terminated at the end of the attenuator region. This produces a short 140-nucleotide transcript. In the absence of tryptophan, the attenuator region has no effect on transcription, and the entire **polycistronic mRNA** of the five structural genes is synthesized. Therefore, at both the operator and attenuator, tryptophan exerts the same general influence. At the operator, it participates in repressing transcription, and at the attenuator it terminates transcription by those RNA polymerases that have escaped repression. Attenuation has about a 10-fold effect on transcription of the tryptophan structural genes. Derepression at the operator has an 80-fold effect, so transcription of the tryptophan operon is regulated over an 800-fold range.

Transcription is terminated at the attenuator site by cooperative interaction between transcription and translation. The tryptophan leader sequence has two adjacent tryptophan codons at positions 10 and 11(Figure 8.9). This is unusual since tryptophan is a relatively rare amino acid in *E. coli*. These codons provided an early clue that $tRNA^{trp}$ is involved in attenuation. If tryptophan in the cell is low, the amount of charged tryptophanyl-$tRNA^{trp}$ will also be low. The ribosomes will be unable to translate through the two tryptophan codons and will stall in the leader RNA sequence.

The RNA sequence of the attenuator region can adopt several secondary structures (Figure 8.10). The position of the ribosome on the leader sequence determines which

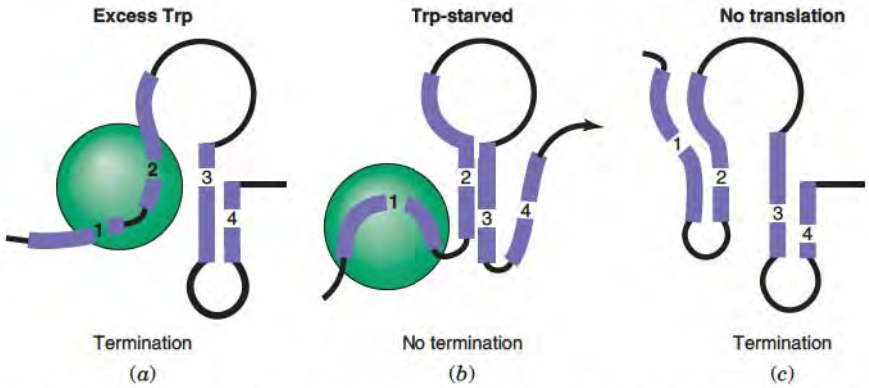

Figure 8.10 Schematic model for attenuation in the tryptophan operon of *E. coli*. (*a*) Under conditions of excess tryptophan, the ribosome (green sphere) translating the newly transcribed leader RNA synthesizes the complete leader peptide. During this synthesis the ribosome binds to regions 1 and 2 of the RNA and prevents formation of stem and loop 1–2 or 2–3. Stem and loop 3–4 will be free to form and signal the RNA polymerase molecule (not shown) to terminate transcription. (*b*) Under conditions of tryptophan starvation, tryptophanyl-tRNA^{Trp} will be limiting, and the ribosome will stall at the adjacent tryptophan codons at the beginning of region 1 in the leader peptide-coding region. Because region 1 is bound to the ribosomes, stem and loop 2–3 will form, excluding formation of stem and loop 3–4, which is required as the signal for transcription termination. Therefore RNA polymerase continues transcription into the structural genes. (*c*) Under conditions in which the leader peptide is not translated, stem and loop 1–2 forms, preventing formation of stem and loop 2–3, and permitting formation of stem and loop 3–4. This signals transcription termination.
Reproduced with permission from Oxender, D. L., Zurawski, G., and Yanofsky, C. *Proc. Natl. Acad. Sci. USA* 76: 5524, 1979.

one occurs. The secondary structure, in turn, is recognized by the RNA polymerase that has transcribed through this region. The structure that forms when a ribosome is not stalled at the tryptophan codons is a termination signal for the RNA polymerase, so that transcription stops after the synthesis of a 140-nucleotide transcript, which is quickly degraded. The secondary structure that forms when the ribosomes are stalled at the tryptophan codons is not recognized as a termination signal, and transcription continues into the *trp*E gene.

Transcription Attenuation Controls Other Operons for Amino Acid Biosynthesis

Transcription attenuation does not occur in eukaryotic organisms because transcription (in the nucleus) and translation (in the cytoplasm) take place in different cellular compartments. However, attenuation is common in bacterial gene expression and occurs in at least six other operons for enzymes catalyzing amino acid biosynthetic pathways. Figure 8.11 shows the **leader peptide** sequences specified by these operons. In each, the leader peptide has several copies of the amino acid that is the end product of the pathway. The 16-residue leader peptide encoded in the histidine operon contains seven contiguous histidines. Starvation for histidine decreases the amount of histidinyl-tRNA^{his} and increases transcription of the *his* operon. The nucleotide sequence of the attenuator region suggests that ribosome stalling at these codons influences the formation of alternate hairpin loops, one of which resembles a termination hairpin followed

Operon	Leader peptide sequence	Regulatory amino acids
his	Met-Thr-Arg-Val-Gln-Phe-Lys-His-His-His-His-His-His-His-Pro-Asp	His
*phe*A	Met-Lys-His-Ile-Pro-Phe-Phe-Phe-Ala-Phe-Phe-Phe-Thr-Phe-Pro	Phe
thr	Met-Lys-Arg-Ile-Ser-Thr-Thr-Ile-Thr-Thr-Thr-Ile-Thr-Ile-Thr-Thr-Gly-Asn-Gly-Ala-Gly	Thr Ile
leu	Met-Ser-His-Ile-Val-Arg-Phe-Thr-Gly-Leu-Leu-Leu-Leu-Asn-Ala-Phe-Ile-Val-Arg-Gly-Arg-Pro-Val-Gly-Gly-Ile-Gln-His	Leu
ilv	Met-Thr-Ala-Leu-Leu-Arg-Val-Ile-Ser-Leu-Val-Val-Ile-Ser-Val-Val-Val-Ile-Ile-Ile-Pro-Pro-Cys-Gly-Ala-Ala-Leu-Gly-Arg-Gly-Lys-Ala	Leu, Val, Ile

Figure 8.11 Leader peptide sequences specified by biosynthetic operons of *E. coli*. All of the leader peptide sequences contain multiple copies of amino acid(s) synthesized by enzymes encoded by that operon.

by several U residues. Unlike the *trp* operon, transcription of the *his* operon is regulated primarily by attenuation since it does not possess an operator recognized by a repressor protein. Instead, the ribosome acts rather like a positive regulator protein, similar to the cAMP–CAP complex in the *lac* operon. If the ribosome is bound to (that is, stalled at) the attenuator site, transcription of the downstream structural genes is enhanced. If the ribosome is not bound, transcription of these genes is greatly reduced.

Transcription of some operons, shown in Figure 8.11, can be attenuated by more than one amino acid. For example, the *thr* operon is attenuated by threonine or isoleucine; the *ilv* operon by leucine, valine, or isoleucine. This effect can be explained in each case by stalling of the ribosome at the corresponding codon, which interferes with formation of a termination hairpin. It is possible that in longer leader sequences, stalling at more than one codon is necessary to achieve maximal transcription through the attenuation region.

8.5 • OTHER BACTERIAL OPERONS

Synthesis of Ribosomal Proteins Is Regulated in a Coordinated Manner

Many bacterial operons possess the same general regulatory mechanisms as the *lac*, *trp*, and *his* operons. However, each operon has its own distinctive characteristics. One example is the structural genes for the 70 or more proteins that compose a ribosome (Figure 8.12). Each ribosome contains one copy of each **ribosomal protein** (except for protein L7–L12, which is probably present in four copies). Therefore, all 70 proteins are required in equimolar amounts, and it makes sense that their synthesis is regulated in a coordinated fashion. Six different operons, containing about one-half of the ribosomal protein genes, occur in two major gene clusters. One cluster contains four adjacent operons (*Spc*, *S10*, *str*, and *α*), and the other contains two operons (*L11* and *rif*) located elsewhere in the *E. coli* chromosome. There is no obvious pattern in the distribution of genes among these operons. Some operons code for proteins of one ribosomal subunit; others code for proteins of both subunits. These operons also contain genes for other (related) proteins. For example, the *str* operon contains genes for soluble translation elongation factors, EF-Tu and EF-G, and genes for some proteins in the 30S ribosomal subunit. The α operon contains genes for proteins of both ribosomal subunits and a gene for the α subunit of RNA polymerase. The *rif* operon has genes for the β and β' subunits of RNA polymerase and for ribosomal proteins.

A common feature of the six operons for ribosomal proteins is that their expression is regulated by one of their own structural gene products; that is, they are **self-regulated**. In some cases, regulation occurs at the level of translation, not transcription as discussed for

Operon	Regulator protein	Proteins specified by the operon
Spc	S8	L14-L24-L5-S14-S8-L6-L18-S5-L15-L30
S10	L4	S10-L3-L2-L4-L23-S19-L22-S3-S17-L16-L29
str	S7	S12-S7-EF.G-EF.Tu
α	S4	S13-S11-S4-α-L17
L11	L1	L11-L1
rif	L10	L10-L7-β–β′

Figure 8.12 Operons containing genes for ribosomal proteins *E. coli*. Genes for protein components of the small (S) and large (L) ribosomal subunits of *E. coli* are clustered on several operons. Some of these operons also contain genes for RNA polymerase subunits α, β, and β', and protein synthesis factors EF.G and EF.Tu. At least one protein product of each operon usually regulates expression of that operon (p. 306).

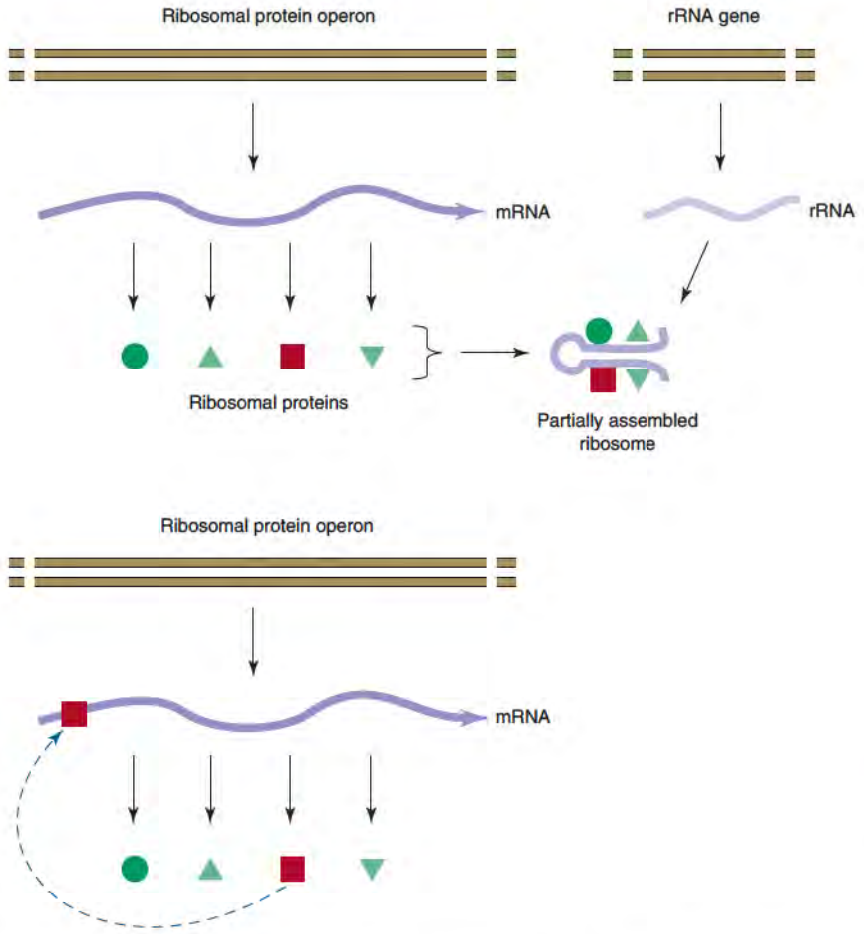

Figure 8.13 Self-regulation of ribosomal protein synthesis. If free rRNA is not available for assembly of new ribosomal subunits, individual ribosomal proteins bind to polycistronic mRNA from their own operon, blocking further translation.

the *lac* and *trp* operons. After the polycistronic mRNA is made, the regulatory ribosomal protein binds to this mRNA and determines which regions, if any, are translated. In general, the ribosomal protein that regulates expression of its own operon associates with ribosomal RNA (rRNA) in the ribosome. This protein has a high affinity for rRNA and a lower affinity for one or more regions of its own mRNA. Therefore, competition occurs between rRNA and the operon's mRNA for binding with the protein. As the protein accumulates to a higher level than free rRNA, it binds to its own mRNA and prevents protein synthesis at one or more of the coding sequences on this mRNA (Figure 8.13). As more ribosomes are formed, the excess of this protein is used up and translation of its mRNA can begin again.

Stringent Response Controls Synthesis of rRNAs and tRNAs

Bacteria respond in several ways to **extreme general stress**. One such situation is when there are insufficient amino acids to maintain protein synthesis. Under this condition the cell invokes the **stringent response** that reduces synthesis of rRNAs and tRNAs about 20-fold. Synthesis of mRNAs also decreases about 3-fold.

The stringent response is triggered by the presence of an uncharged tRNA in the A site of the ribosome, which occurs when the concentration of the corresponding charged tRNA is very low. The first result is that further peptide elongation by the ribosome stops. This stoppage causes a protein called the **stringent factor**, the product of the relA gene, to synthesize **guanosine tetraphosphate** (ppGpp) and **guanosine pentaphosphate** (pppGpp) from ATP and GTP or GDP as shown in Figure 8.14. Stringent factor is loosely associated with some ribosomes of the cell. Perhaps a conformational change in the ribosome is induced by the presence of an uncharged tRNA in the A site, which, in turn, activates the associated stringent factor. The exact functions of ppGpp and pppGpp are not known. However, they inhibit transcription initiation of rRNA and tRNA genes and they affect transcription of some operons more than others.

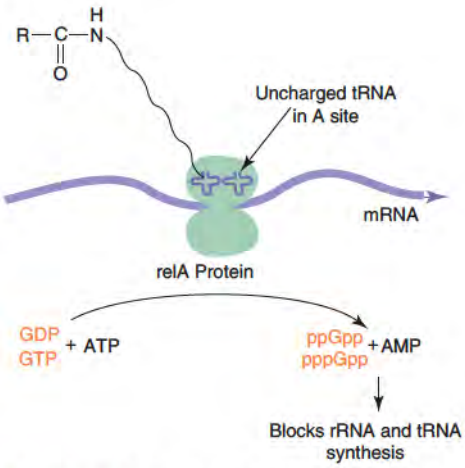

Figure 8.14 Stringent control of protein synthesis in *E. coli*. During extreme amino acid starvation, an uncharged tRNA in the A site of the ribosome activates relA protein to synthesize ppGpp and pppGpp, which are involved in decreasing transcription of the genes coding for rRNAs and tRNAs.

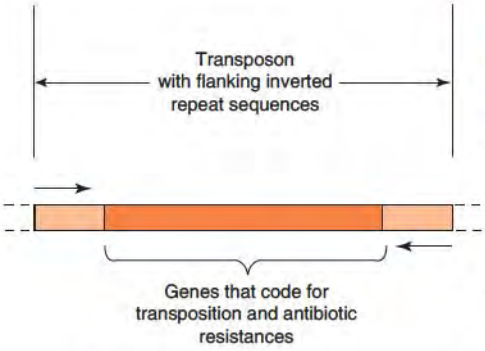

Figure 8.15 General structure of transposons. Transposons are relatively rare mobile segments of DNA that contain genes coding for their own rearrangement and often have genes that specify resistance to various antibiotics.

CLINICAL CORRELATION 8.1

Transmissible Multiple-Drug Resistance

An alarming trend is that pathogenic bacteria are becoming increasingly resistant to a large number of antibiotics. Many cases have been documented in which a bacterial strain in a patient being treated with one antibiotic suddenly became resistant to that antibiotic and, simultaneously, to several other antibiotics even though the bacterial strain had never been previously exposed to these other antibiotics. This occurs when a bacterium suddenly acquires from another bacterial strain a plasmid that contains several different transposons, each containing one or more antibiotic-resistance genes. Examples include the genes encoding β-lactamase, which inactivates penicillins and cephalosporins; chloramphenicol acetyltransferase, which inactivates chloramphenicol; and phosphotransferases, which modify aminoglycosides such as neomycin and gentamycin.

Neu, H. C. The crisis in antibiotic resistance. *Science* 257:1064, 1992.

8.6 • BACTERIAL TRANSPOSONS

Transposons Are Mobile Segments of DNA

The vast majority of bacterial genes have fixed locations in the chromosome. In fact, the genetic maps of *E. coli* and *Salmonella typhimurium* are very similar, indicating the lack of much evolutionary movement of most genes within bacterial chromosomes. There is a small class of bacterial genes, however, in which newly duplicated gene copies "jump" from one genomic site to another with a frequency of about 10^{-7} per generation, the same rate as spontaneous point mutations. These mobile segments of DNA are called **transposable elements** or **transposons** (Figure 8.15). Some genes within bacterial transposons control the presence and transposition of the transposon itself, whereas others, usually antibiotic-resistance genes, provide the bacterium with a selective advantage against other bacteria.

Transposons were first detected as rare insertions of foreign DNA into structural genes of bacterial operons. Usually, these insertions interfere with expression of the affected structural gene and all downstream genes of the operon. This is not surprising since insertions can destroy the translation-reading frame, introduce transcription termination signals, affect the mRNA stability, and so on. Many transposons and the sites into which they insert have been isolated using recombinant DNA techniques and have been extensively characterized.

Some transposons consist of a few thousand base pairs and contain two or three genes; others are much longer and contain many genes. Sometimes, small transposons can occur within a large transposon. All active transposons contain at least one gene that codes for a **transposase**, which is required for the transposition, or "jumping" event. Often they contain genes that code for resistance to antibiotics or heavy metals. Most transpositions involve generation of an additional copy of the transposon and insertion of this copy into another location. The original copy is unaffected by insertion of its duplicate into a new target site. Transposons contain short inverted **terminal repeat sequences** that are essential for the insertion mechanism, and are often used to define the two boundaries of a transposon. Most target sites are fairly random in sequence, although some transposons have a propensity for insertion at specific "hot spots." The duplicated transposon can be located in a different DNA molecule than its donor. Frequently, transposons are found on plasmids that pass from one bacterial strain to another and are the source of a suddenly acquired resistance to one or more antibiotics by a bacterium (Clin. Corr. 8.1).

Transposon *Tn*3 Contains Three Structural Genes

An example of a transposon is **transposon *Tn*3**, which contains 4957 bp including inverted repeats of 38 bp at each end (Figure 8.16). Three genes are present in *Tn*3. One codes for β-lactamase, which hydrolyzes ampicillin and renders the cell resistant to this antibiotic. The others, *tnp*A and *tnp*R, code for a transposase and a repressor protein, respectively. The transposase contains 1021 amino acids and binds to single-stranded DNA. It recognizes the repetitive ends of the transposon and participates in cleavage of the target site into which the new transposon copy inserts. The repressor protein of 185 amino acids controls

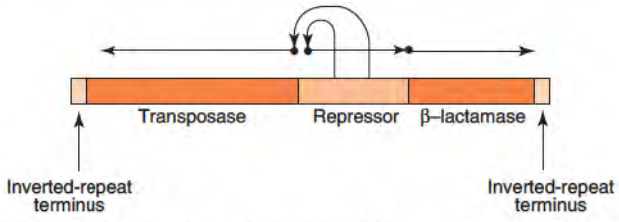

Figure 8.16 Functional components of the transposon *Tn*3. Genetic and DNA sequence analyses show there are four distinct regions: the 38-bp inverted repeat termini; a gene for the enzyme β-lactamase, which confers resistance to ampicillin and related antibiotics; a gene encoding an enzyme required for transposition (transposase); and a gene for a repressor protein that controls transcription of the genes for the transposase and the repressor itself. Horizontal arrows indicate directions of transcription. Redrawn from Cohen, S. N., and Shapiro, J. A. *Sci. Amer.* 242:40, 1980. W. H. Freeman and Company, Copyright © 1980.

transcription of both the transposase gene and its own gene. *tnp*A and *tnp*R are transcribed divergently from a 163-bp control region located between them that binds the repressor. The repressor also participates in the insertion of the new transposon, but does not affect transcription of the ampicillin-resistance gene.

Mutations in *tnp*A that inactivate the transposase decrease the frequency of *Tn*3 transposition. Those in t*np*R that inactivate the repressor increase the frequency of transposition. These mutations de-repress *tnp*A resulting in more molecules of the transposase, which enhances the formation of more duplicated transposon copies. They also derepress *tnp*R, but since the repressor is inactive, the depression has no effect.

Transposons located on bacterial plasmids are of increasing importance in clinical uses of antibiotics. Bacterial plasmids that have not been altered for experimental use usually contain genes that facilitate their transfer from one bacterium to another. As these plasmids transfer among different infecting bacterial strains, their transposons containing **antibiotic-resistance genes** are moved into new bacterial strains. Once inside a new bacterium, the transposon can be duplicated onto the chromosome and become permanently established in that cell's lineage. The result is that more and more pathogenic bacterial strains have become resistant to an increasing number of antibiotics (Clin. Corr. 8.2).

8.7 • GENE EXPRESSION IN EUKARYOTES

Gene transcription in eukaryotic organisms is also regulated to provide the appropriate response to biological needs. In addition to modulating gene expression in response to nutritional or environmental conditions, multicellular organisms regulate the expression of specialized genes that drive cellular differentiation and typify specific cell types. Some genes, referred to as housekeeping genes, are expressed in most cells, other genes are activated on demand, and still other genes are rendered permanently inactive in all but a few cell types. In eukaryotic cells, the nuclear membrane serves as a barrier that selectively allows some proteins access to DNA while keeping others in the cytosol. In bacteria one RNA polymerase is responsible for transcription of all RNAs (tRNA, rRNA, and mRNA). In eukaryotic organisms, three different RNA polymerases are used (p. 189). RNA polymerase I transcribes the rRNA genes, RNA polymerase II the protein-encoding genes whose transcripts become mRNAs, and RNA polymerase III the genes for tRNAs and for most other small RNAs. Although some principles for eukaryotic gene activation and control are applicable for all three RNA polymerases, in this section the focus will be on transcription by RNA polymerase II. RNA polymerase II is composed of at least 10 different subunits, ranging in size from 10 to 220 kDa. Some of the subunits are also part of the RNA polymerase I and III complexes; others are unique to RNA polymerase II. The largest subunit of RNA polymerase II has, depending on the species, as many as 52 repeats of the amino acid motif PTSPSYS in its C-terminal domain (CTD). A distinguishing feature of these repeats is that threonine (T), serine (S) and tyrosine (Y) can be phosphorylated.

To better understand the regulation of transcription in eukaryotes, it is useful to recall the organization of DNA into **chromatin** and the role of DNA modification, specifically **methylation** of cytosine, on gene activation. In addition, we will consider how RNA polymerase II is positioned at the appropriate spot in the promoter of a gene to transcribe that gene by the formation of a preinitiation complex that involves assembly of **general transcription factors (TFs)** with RNA polymerase II. Next, we will look at how specific gene activity can be regulated through the use of enhancers, **transcription factor–binding sites** and **RNA polymerase assembly sites.** Finally, we will discuss the activation of transcription by specific transcription factors, some of their general characteristics and how they are regulated.

Eukaryotic DNA Is Bound by Histones to Form Chromatin

Segments of eukaryotic DNA are wrapped around an octamer of histone proteins that contain two molecules each of histone H2A, H2B, H3, and H4 to form **nucleosomes** (p. 55). Histones associate with DNA through electrostatic interactions. Histones have a large number of positively charged lysine residues that interact with the negatively charged phosphodiester backbone of DNA. In most cells histone H1 or H5 binds when the octamer–DNA association is established. About 200 bp of DNA make up a single nucleosomal unit, with about 130–160 bp

CLINICAL CORRELATION 8.2

The Bacterial Pathogen of the Stomach: *Helicobacter pylori*

Helicobacter pylori (*H. pylori*) is a gram-negative bacterium that infects the stomach and duodenum of more than 50% of the world's human population. The organism's helical shape enhances its motility in the mucus overlying the gastric mucosa. Although most infected people do not exhibit any symptoms, *H. pylori* is known to cause many cases of peptic ulcers (lesions in the lining of the stomach or duodenum), gastritis, duodentis and stomach cancers. The bacterium survives in the highly acidic environment of the stomach by synthesizing a large amount of urease enzyme, which metabolizes stomach urea to carbon dioxide and ammonia that neutralizes gastric acid. Acid pH increases the expression of urease and a proton-gated urea channel protein of *H. pylori* at the level of both transcription and mRNA stability. *H. pylori* is typically treated with a therapy of three or more antibiotics, but some isolates of *H. pylori* have been found that exhibit drug resistance. Two Australian physicians, Robin Warren and Barry Marshall, received the 2005 Nobel Prize in Medicine for their work on *H. pylori.*

Scott, D. R., Marcus, E. A., Wen, Y., Oh, J., and Sachs, G. Gene expression *in vivo* shows that *Helicobacter pylori* colonizes an acidic niche on the gastric surface. *Proc. Natl. Acad. Sci. USA*104:7235, 2007; and Blaser, M. J. The endangered species in the stomach. *Sci. Amer.* 292:38, 2005.

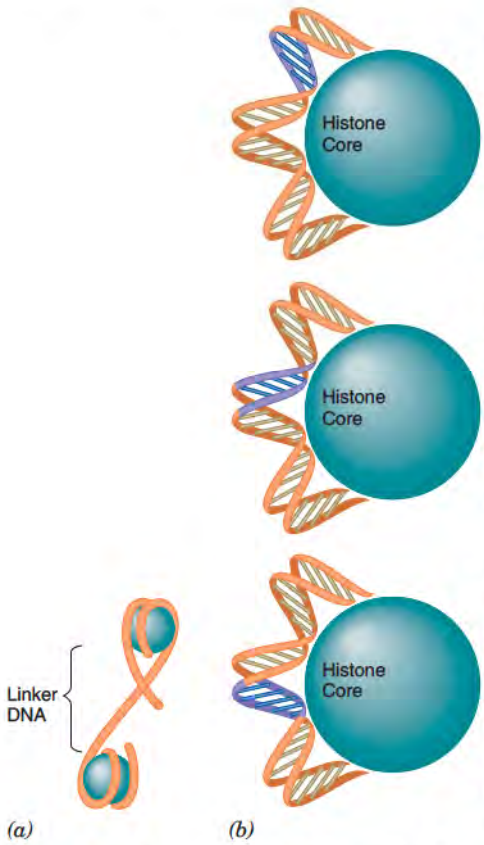

Figure 8.17 Access to specific sequences in major and minor groove of the DNA depends on nucleosome positioning. (*a*) DNA wound around the core histone octamer (two molecules each of histone H2A, H2B, H3 and H4) is called the nucleosome core particle. Under most conditions histone H1 or H5 (not shown) associates with DNA where the winding around the histone octamer begins. DNA between nucleosome core particles is called linker DNA. When exposed to agents like micrococcal nuclease, linker regions are more accessible than DNA wound around the histone core particle. (*b*) Within the nucleosome, the side of the helix facing away from the histone core is accessible, but the side facing in is not. If we rotate the helix with respect to the histone core of a nucleosome and follow the position of the same five base pairs, the access to the major and minor groove to other interactions is changed depending on whether the base pair is on the inside or the outside of the wrapped nucleosome core particle.
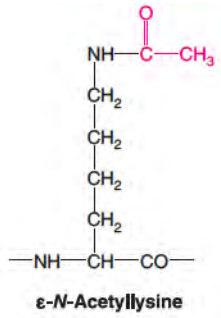
Redrawn from Wolffe, A. P. *Chromatin: Structure and Function,* 3d ed.: New York: Academic Press, 1998.

in direct contact with the octamer core. Some of the remaining DNA binds histones H1 and H5, and the rest is the **linker** DNA between nucleosomes. Although the histone octamer–DNA interaction is not sequence specific, some sequence-dependent patterns of association have been noted. When, for instance, the double-stranded DNA helix bends because of the presence of an AT-rich region, the minor groove generally faces the nucleosome core particle. In GC-rich regions, the minor groove faces away from the histone octamer core. Despite these tendencies, there is not a clear way to predict the sequences within a DNA duplex that will compose the major and minor grooves on the outside of the nucleosome complex. This positioning is important because assembly of the transcription initiator complex and binding of other proteins that influence gene expression need access to the grooves in the DNA duplex. Sequence-specific interactions occur via hydrogen bonds formed with the edges of the base pairs in the major or minor groove. When DNA is wrapped around a histone octamer, the specific DNA sequences that bind transcription factors may be occluded. The complete removal of DNA from the nucleosome is not required to allow access to specific sequences. By rolling the DNA helix relative to the histone octamer, different major and minor groove contacts can be made available on the outer surface of the nucleosome (Figure 8.17).

Genes that are not transcribed within a particular cell form highly condensed heterochromatin. In contrast, transcriptionally active regions of DNA have a less condensed, more open structure. Part of this difference is due to posttranslational modification of histones. The acetylation of the ε-amino group of the lysine residues near the N-termini of histones reduces net positive charge and thus weakens the electrostatic attraction between the histones and the DNA. In general, acetylation of histones leads to activation of gene expression, whereas deacetylation reverses the effect. Acetylation of histones, and the subsequent repositioning of the nucleosome by the destabilization of histone DNA interactions, is important in providing sequence-specific access to DNA (Figure 8.18). Modification of histones is thought to be critical in epigenetic control of gene expression as will be discussed later in this chapter.



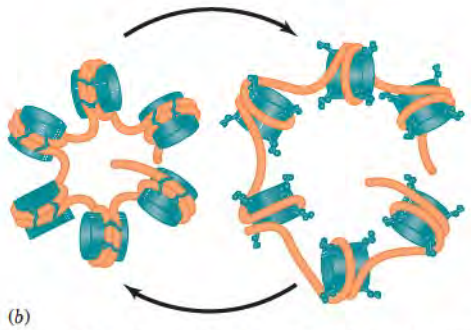


Figure 8.18 Strength of histone DNA association is modified by acetylation of lysine residues in the N-terminus of histone proteins. Histones that make up the core octamer contain lysine residues that, by virtue of their positively charged side group can promote interaction with the negatively charged phosphodiester linkages of DNA. Modification of the lysines by acetylation replaces the positive charge with a neutral acetyl group and weakens the electrostatic interaction between the octamer core and the DNA. This process is reversible, and the acetylation and deacetylation of histones provides a way to loosen or tighten chromatin structure.
Redrawn from Wolffe, A. P. The cancer-chromatin connection. *Sci. and Med.* 6:28, 1999.

The relative position of a nucleosome can also be influenced by the SWI–SNF complex, first identified and best characterized in the yeast *S. cerevisiae* and named after mating type switching and sucrose non-fermenting strains. This complex contains about 10 proteins and interacts with the C-terminal domain of the large subunit of RNA polymerase II disrupting nucleosomal arrays in an ATP-dependent manner. The result is to open regions of DNA for interaction with transcription factors, and thus facilitate gene activation. There are fewer SWI/SNF complexes in the cell than genes being transcribed, suggesting that the SWI /SNF complex acts in a catalytic manner (Clin. Corr. 8.3).

Methylation of DNA Correlates with Gene Inactivation

Methylation of human DNA involves formation of 5-methylcytosine (Figure 8.19). The reaction is sequence specific with 5′CpG3′ as a substrate. The result is that both strands of the duplex are methylated. About 70% of CpG sequences in human DNA are methylated. Methylation is implicated in the **imprinting** of genomic DNA. In imprinting, the methylation patterns of DNA inherited from the sperm or egg correlate with choice of allelic expression. Methylation patterns are conserved after replication by a hemimethylase (which recognizes methylation in the parental strand and methylates the newly replicated strand). More recently it has been suggested that methylation of DNA that results in gene silencing can be induced by the action of siRNA (short interfering RNA) that are complementary to the sequence that is methylated.

A terminology often encountered in the DNA methylation literature is *CpG islands* or *CpG-rich regions*. The sequence CpG is under represented in the genome. This is likely due to the accumulation, over many generations, of C to T transitions caused by the deamination of 5-methylcytosine. Maintenance of CpGs is presumably due to selective pressure to maintain a regulatory region. In fact CpG islands are most commonly found in gene promoter regions. Methylation of DNA often correlates with lack of transcriptional activity. This is thought to be mediated by proteins that recognize and bind methylated DNA, which prevents binding of transcription factors. Methylation of DNA correlates with deacetylation of histones, providing two different means of repression of transcription at a specific location (Figure 8.20).

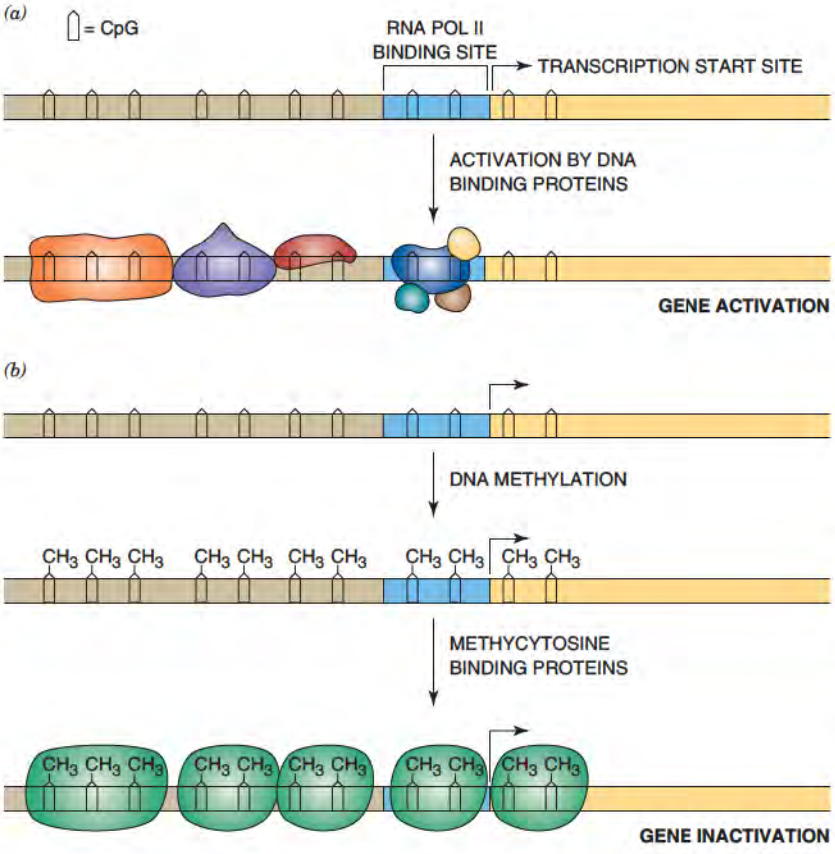

Figure 8.20 Methylation of DNA leads to altered gene activity. For maximal transcription of most genes transcription factors must recognize and bind to specific sequences of DNA in the promoter region. Their interaction with the DNA and the general transcription factors in the RNA polymerase II initiation complex leads to the expression of a gene. Methylation of DNA, specifically the formation of 5-methyl cytosine, provides a new target for protein DNA interaction. The association of 5-meC DNA binding proteins with methylated DNA may block the ability of other transcription factors to bind to DNA. This inhibition is usually not through the sequence specific competition for DNA binding, but rather by steric hindrance.

CLINICAL CORRELATION 8.3

Rubinstein–Taybi Syndrome

Regulation of histone acetylation influences activation and inactivation of gene expression. Two major enzymes responsible for acetylation of histones in mammalian cells are the acetyltransferases p300 and CBP. p300 was named for its molecular mass and CBP stands for CREB binding protein, with CREB (a cAMP regulatory-element binding protein) being a transcription factor. These acetyltransferases allow activation of appropriate genes in association with CREB and other transcription factors, leading to the opening of chromatin structure through weakening of histone–DNA interactions.

Rubinstein–Taybi syndrome (OMIM 180849), characterized by mental retardation and other developmental abnormalities, is caused by point mutations, small deletions, and rearrangements in the CBP gene. More severe developmental defects correspond to substantially more mutations. The complete loss of the CBP gene product is probably lethal.

Hypermethylation of DNA is a common feature in cells of cancerous tissue. There is increasing evidence that methylation occurs in genes encoding proteins that would direct abnormally dividing cells into programmed cell death (apoptosis). Conversely, in mammalian totipotent and pluripotent cells, such as a fertilized egg and cells of the very early embryo, DNA undergoes fairly global demethylation.

8.8 • PREINITIATION COMPLEX IN EUKARYOTES: TRANSCRIPTION FACTORS, RNA POLYMERASE II, AND DNA

Unlike bacterial RNA polymerase, eukaryotic RNA polymerase II does not undergo sequence-specific binding to eukaryotic promoters. Rather, an initiation complex is formed through the initial contact of the promoter with the general transcription factor TFIID. TFIID is one of at least six general transcription factors (TFIIA, TFIIB, TFIID, TFIIE, TFIIF, and TFIIH) required for basal transcription by RNA polymerase II. The nomenclature TFII reflects that they are transcription factors involved in the assembly of the RNA polymerase II preinitiation complex (Table 8.1).

TFIID is a multi-subunit complex that contains the TATA binding protein (TBP) and a number of different TAFs (TBP-associated factors). TFIID binds in the minor groove of DNA at a consensus sequence called the TATA box, located about 27 bp upstream of the transcription start site. The TATA box must be accessible to TFIID, so it cannot be on the inner face of a nucleosome core particle if the preinitiation complex is to form. Interaction of TBP with the DNA causes a large distortion in the DNA duplex (Figure 8.21). TBP was once thought to be essential for transcription using any RNA polymerase, but the recent identification of additional TLFs (TBP-like factors) suggests that some genes use an alternate protein. After binding to the TATA box, TBP directs assembly of the preinitiation complex by ordered addition of several general transcription factors and RNA polymerase II (Figure 8.22). Recall that the large subunit of RNA polymerase II has a C-terminal domain (CTD) containing many repeats of the amino acid sequence PTSPSYS.

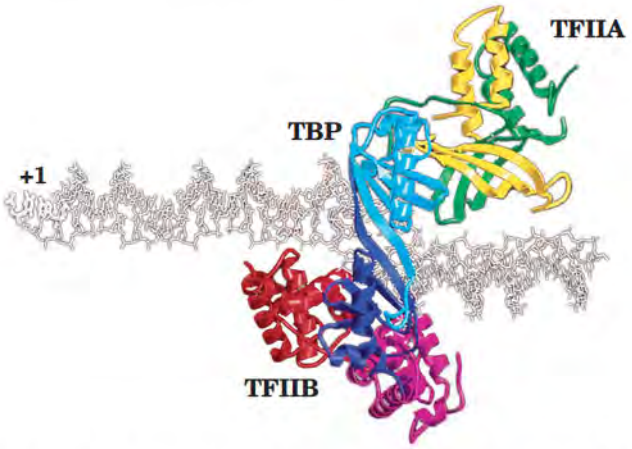

Figure 8.21 **The TATA binding protein (TBP) has been cocrystallized with DNA** The first step in forming the transcription complex that allows RNA polymerase II mediated gene transcription is the association of the general transcription factor TFIID with DNA. In most cases this is mediated through one of the proteins of the TFIID protein complex, TBP, which binds to DNA through contacts with the sequence TATAA. The cocrystallization of TBP with DNA allowed a closer look at the interaction and indicated that binding of TBP introduced a significant bend in the DNA. Included in the figure are two other general transcription factors, TFIIA and TFIIB, neither of which are involved in the initial contact with DNA. TFIIA binds to TBP and stabilizes the TBP–DNA interaction. TFIIB binds to TBP, leads to the recruitment of RNA polymerase II to the initiation complex, and is involved in identification of the transcription start site.
Figure reproduced with permission from Voet, D., Voet, J., and Pratt, C. W. *Fundamentals of Biochemistry.* New York: Wiley, 1999. © (1999) John Wiley & Sons, Inc.

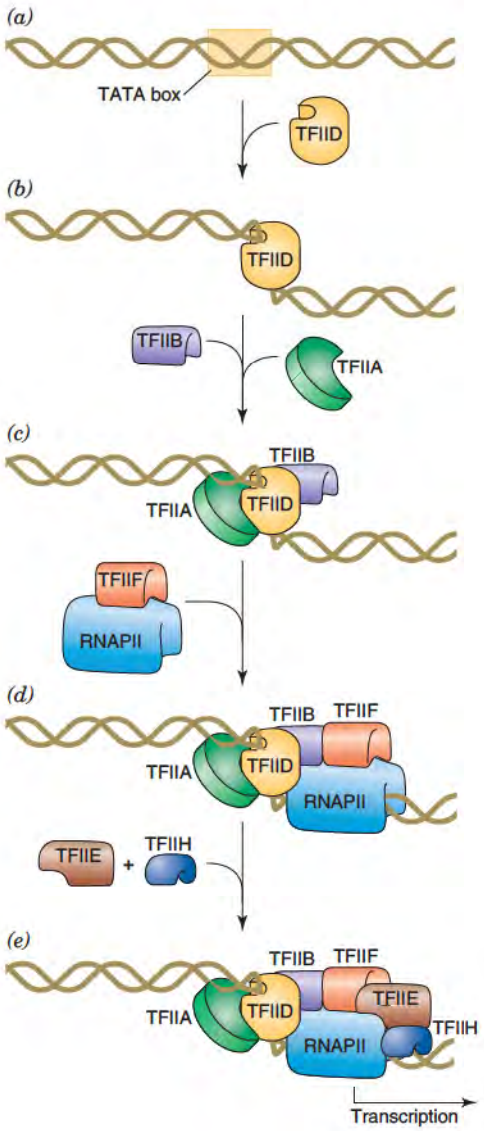

Figure 8.22 Formation of the initiation complex for genes transcribed by RNA polymerase II is ordered. The current models of initiation complex assembly include the following steps: (*a*) The promoter region of a gene with a TATA box before TFIID binding. (*b*) TFIID, which includes TBP binds at the TATA box and bends the DNA. (*c*) The DNA–TFIID complex serves as a coordination site for binding other general transcription factors. The TFIID complex associates with TFIIA and TFIIB. TFIIA serves to stabilize the TFIID DNA interaction, and TFIIB provides an appropriate interaction site for the binding of RNA polymerase II. (*d*) TFIIF and RNA polymerase II join the complex. At this stage the carboxy-terminal domain (CTD) of RNA polymerase II is unphosphorylated. TFIIF is thought to destabilize nonspecific RNA polymerase II DNA interactions, thus targeting the RNA polymerase II to the growing initiation complex. (*e*) Two additional general transcription factors join the complex. TFIIE recruits TFIIH to the complex. TFIIH has helicase, ATPase, and kinase activity. TFIIH is thought to mediate transient opening of the DNA duplex and also the phosphorylation of the CTD of RNA polymerase II allowing the polymerase to leave the initiation complex and start transcription.
Redrawn from Voet, D., Voet, J., and Pratt, C. W. *Fundamentals of Biochemistry*. New York: Wiley, 1999. © (1999) Wiley.

The entry of RNA polymerase II into the preinitiation complex occurs when its CTD is not phosphorylated. However, the movement of RNA polymerase II away from the assembly site is correlated with phosphorylation of the CTD. Thus, the assembly of the preinitiation complex does not ensure transcription; further signaling, such as phosphorylation, must occur for transcription to begin.

Formation of the preinitiation complex allows the ATP-dependent helicase activity associated with TFIIH to open the two strands of the DNA and provides a template for the subsequent elongation phase of RNA synthesis. TFIID remains behind, still bound to the TATA box, to promote the assembly of additional preinitiation complexes. TFIIF moves with RNA polymerase II during the elongation phase, but the other general transcription factors dissociate from the elongation complex.

Eukaryotic Promoters and Other Sequences That Influence Transcription

Promoters of eukaryotic genes transcribed by RNA polymerase II are operationally defined as those sequences that influence the initiation of gene transcription. The hallmark of eukaryotic promoters is their utilization of multiple transcription factor–binding sites to regulate gene activity. In general, these binding sites are relatively close to the TATA box that marks the site of assembly of the preinitiation complex. Other consensus sequences often found in

Figure 8.23 DNA sequences in genes transcribed in eukaryotes typically contain a TATA box and may contain a CAAT box, GC-rich regions (GC boxes), and multiple transcription factor–binding sites.

eukaryotic promoters include the CAAT box and GC boxes (Figure 8.23). The exact position of the CAAT box and the position, orientation, and number of GC boxes varies among promoters. The CAAT box is a binding site for several different transcription factors, including NF1. The presence of a CAAT box usually indicates a strong promoter. The GC box provides a binding site for the transcription factor SP1 and is characteristic of many housekeeping genes.

Binding of transcription factors to other sequences in promoters may be influenced by a signaling molecule, such as hormones associated with steroid response transcription factors, or by modification, such as phosphorylation of amino acids. DNA sequences that bind regulated transcription factors are often referred to as **response elements**. Transcription factors may be unique to specific tissues or appear at developmentally specific times. The relative effectiveness of regulatory sequences in promoters depends upon their orientation or directionality, and may be diminished by altering their distance from the TATA box.

Many cellular and viral genomes also have **enhancer elements** that bind proteins that activate transcription. Enhancers differ from promoter sequences in two important respects. First, enhancers can be located many thousands of base pairs away from the preinitiation complex assembly site and can be either upstream or downstream of the transcription start site. Secondly, the enhancer element can act in either orientation. Transcription factors that bind to response elements close to the transcription initiation site may act directly with the initiation complex or through the use of proteins that make a bridge to the initiator complex (see Figure 8.30, p. 328). It is quite common for proteins influencing transcription to serve this bridging function. However, the linear distance between an enhancer and the preinitiation complex may be very large. Transcription factors bound to enhancers are brought together with the preinitiation complex by looping of the DNA. This helps to explain how the enhancer can act at a distance and why the orientation of the enhancer sequence does not matter. Once the protein binds to the enhancer, the proper alignment of the protein with the preinitiation complex is adjusted as the DNA loops back.

Modular Design of Eukaryotic Transcription Factors

Eukaryotic transcription factors have multiple domains that carry out specific interactions. The DNA recognition domains contribute site-specific binding, and the activation domains contact general transcription factors, RNA polymerase II, or other regulators of transcription. Many transcription factors also have dimerization domains that promote the formation of homodimers or heterodimers, protein interaction domains that allow association with proteins like histone acetylase or domains that bind to coactivators. Coactivators include steroid hormones and cAMP that change the ability of the transcription factor to bind DNA or serve as an activator. The domains involved in such activities can be grouped into a few characteristic motifs.

Common Motifs in Proteins That Bind DNA and Regulate Transcription.

Several amino acid motifs are commonly found in transcription factors (transacting regulators). They include **helix–turn–helix (HTH)**, **zinc finger**, **helix–loop–helix (HLH)**, and basic region-leucine zipper (bZIP) proteins (p. 324). These motifs are present in about 80% of known sequence-specific binding proteins.

The lactose repressor of *E. coli* (see Section 8.3) and a group of developmentally important transcription factors called homeodomain proteins are among the proteins with the **h**elix–**t**urn–**h**elix (HTH) motif. The homeodomain is the DNA recognition portion of these transcription factors. Homeodomain proteins were first identified in the fruit fly

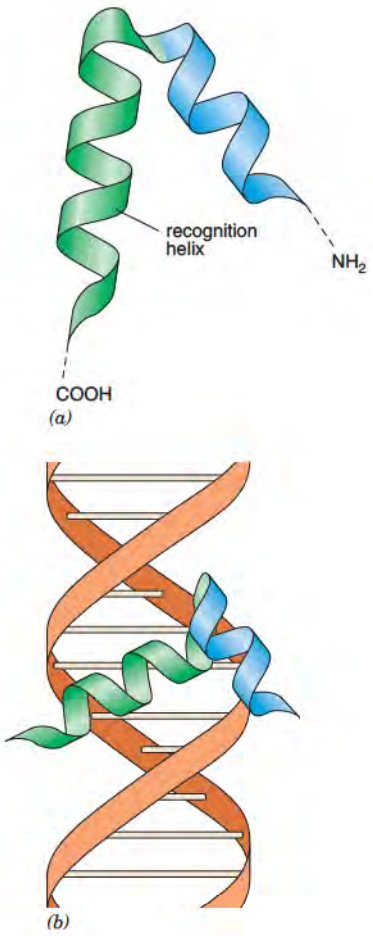

Figure 8.24 Helix–turn–helix proteins use one helix to bind in the major groove while the other supports that binding through hydrophobic interaction. (*a*) The HTH domain of a protein typically contains about 20 amino acids that form two α-helices, joined by a nonhelical turn. (*b*) The dimensions of the α helix of the protein allow it to fit into the major groove of the DNA helix. The helix that interacts directly with the DNA (the recognition helix) includes amino acids with side chains capable of forming hydrogen bonds with specific bases that are exposed in the major groove. The second helix does not directly interact with DNA, but stabilizes the binding of the recognition helix through hydrophobic interactions. Thus, both helices include amino acids like valine or leucine that allow these hydrophobic interactions to occur. Redrawn from Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K., and Watson, J. *Molecular Biology of the Cell.* New York: Garland, 1994.

when mutations in genes' encoding them led to homeosis, or the replacement of one part of the body for another. For instance, one mutation in a homeodomain protein can cause legs to form where antennae should be. Homeodomain proteins are key regulators in mammalian development as well. The HTH motif is about 20 amino acids and forms a relatively small part of a much larger protein. Within the motif the first seven amino acids form one helix followed by a four-amino acid turn and then a nine-amino acid helix. The second helix is the *recognition helix* that binds in a sequence-specific manner in the major groove, while hydrophobic interactions between the first and second helix stabilize the structure. The rest of the protein may have allosteric sites that bind to regulatory molecules and regions that allow other protein–protein interactions (Figure 8.24).

TFIIIA, a general transcription factor that binds to promoters of RNA polymerase III-transcribed genes, SP1 (which gives 10- to 20-fold stimulation of all genes with GC boxes), Gal4 in yeast, and the steroid hormone receptor superfamily are all examples of zinc finger proteins. Different subclasses of zinc finger proteins are defined by the specific amino acids that coordinate Zn binding. For instance, in TFIIIA two cysteines and two histidines coordinate Zn binding and are in the C2H2 class, whereas the steroid hormone receptor transcription factors use four Cys for each Zn and are of the C_4 class. The zinc finger motif binds in the major groove of the DNA in a sequence-specific manner, mediated by an alpha helix formed on one side of the finger region. As was seen with HLH proteins, the α-helix fits in the major groove and amino acid side chains form hydrogen bonds with the bases for sequence-specific binding (p. 322).

The two classes of zinc finger proteins have binding sites characteristic of the way each class positions itself on DNA. For TFIIIA, sequential zinc fingers follow the major groove, each forming hydrogen bonds with specific bases. Zinc finger proteins of the C_4 class, such as the steroid hormone receptor transcription factors, use one zinc finger to bind to DNA and a second zinc finger to stabilize DNA binding by the first. The steroid hormone

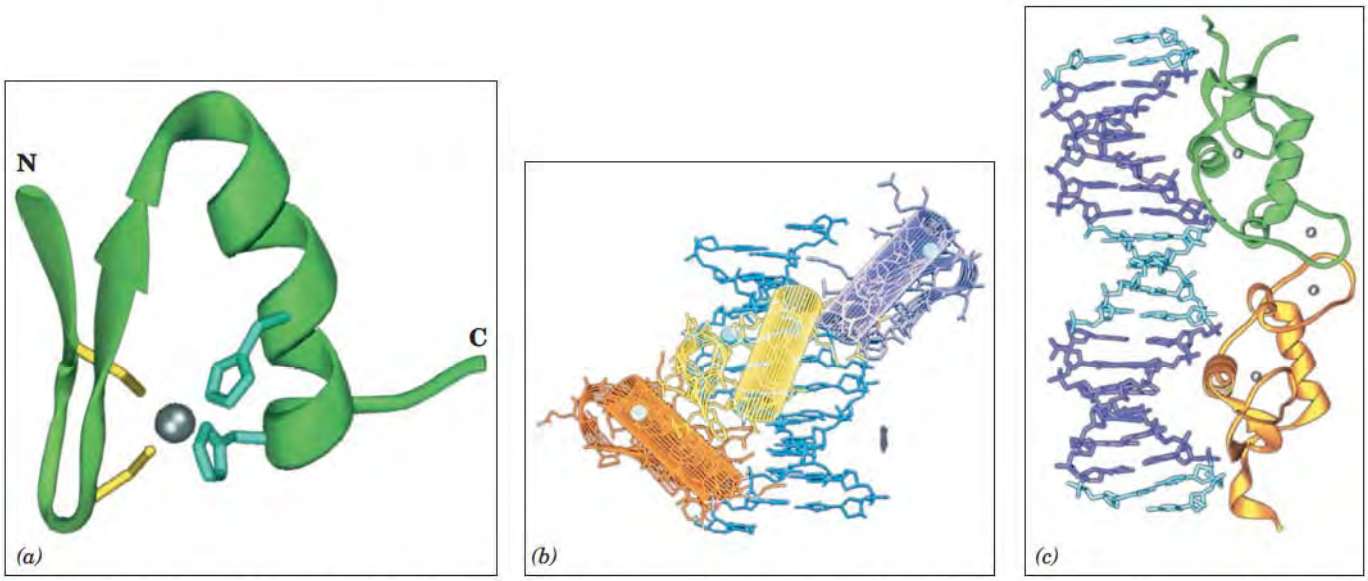

Figure 8.25 Two different Zn finger motifs are found in transcription factors. Although both Zn finger proteins use the coordinate binding of a Zn molecule to assume their final structure, there are recognizable differences in the two major motifs that have been identified. Both classes take advantage of the formation of α-helical structure to form domains that bind in the major groove of DNA. (*a*) The C2H2 class includes proteins that may have many Zn finger domains. Each α-helix from a Zn finger has the potential to bind in a sequence-specific manner to sites along the major groove. The result may be a procession of protein DNA interactions each dependent on the particular array of amino acid side chains found in each α-helical domain of the Zn finger protein. (*b*) The Cx class of Zn finger proteins commonly has two Zn finger domains. The α-helix from one Zn finger binds the DNA in the major groove, while the α-helix in the other Zn finger supports that interaction by hydrophobic interactions with the domain binding to the DNA. The Cx class of Zn finger proteins normally binds DNA by forming dimers. Shown in (*c*) is the interaction of the estrogen receptor dimer, with each monomer contacting the DNA. Zn molecules are indicated by spheres. (*a*) Reproduced with permission from Voet, D., and Voet, J. G. *Biochemistry,* 2d ed. New York: Wiley, 1995. © (1995) John Wiley & Sons, Inc. Part (*b*) and (*c*) generously supplied by C. Pabo, M.I.T.

receptor transcription factors associate with DNA as dimers. Their binding sites consist of two palindromic "half-sites" spaced to accommodate the two DNA-binding fingers of the dimer (Figure 8.25).

Basic region–leucine zipper (bZIP) proteins include fos, jun, and CREB. bZIP proteins contain leucine residues at every seventh position in an α-helix. These leucines form hydrophobic interactions with a second protein that also has this pattern of leucine repeats to form either homo- or a heterodimers (Figure 8.26).

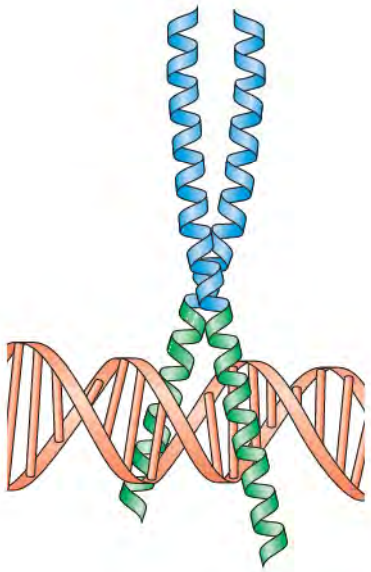

Figure 8.26 Leucine zipper proteins bind to DNA as dimers. Leucine zipper proteins form dimers by virtue of a leucine every seventh residue along an α-helix. These leucines form a hydrophobic face that interact with the hydrophobic face of a similar α-helix. The protein–protein interaction domains are in blue. The α helical regions may continue beyond the **protein–protein** interaction domain, allowing each monomer to bind to the major groove of DNA (green). For homodimers, the DNA-binding site is characterized by two recognizable and symmetric half-sites. Modified from Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K., and Watson, J. *Molecular Biology of the Cell.* New York: Garland, 1994.

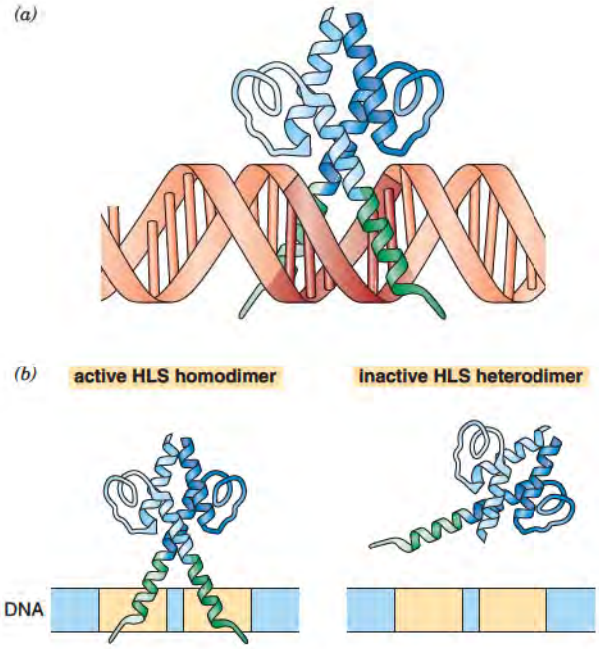

Figure 8.27 Transcription factor dimer formation is mediated through helix–loop–helix interactions. The helix–loop–helix motif brings together two monomers to form a dimer that binds to DNA. (*a*) Each monomer has two helices joined by a loop. One helix is used for protein–protein interaction; the other is used to bind the major groove of DNA. Thus, the dimer consists of a four-helix bundle. If the dimer is formed by two identical monomers, then the DNA-binding sites are expected to be very similar or identical; however, if the monomers are different proteins (forming heterodimers), then the DNA-binding sites may be unrelated. (*b*) When transcription factors bind as dimers, the presence of a truncated monomer can prevent DNA binding even in the presence of full-length monomers. For example, if the protein dimerization helix is made without the DNA-binding domain, the dimerization with a full-length monomer produces a product unable to bind effectively to DNA.
Modified from Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K., and Watson, J. *Molecular Biology of the Cell.* New York: Garland, 1994.

bZip proteins have a DNA-binding domain composed of a basic region, defined by the presence of arginine and lysine, located seven amino acids before the first leucine and α-helix. The basic amino acids stabilize the DNA–protein association through electrostatic interactions with the negatively charged DNA backbone in addition to forming hydrogen bonds in the major groove. Homodimer-binding sites have dyad symmetry, whereas this symmetry is not found in heterodimer-binding sites.

The helix–loop–helix class of transcription factors includes myoD, myc, and max. Two amphipathic α-helical segments separated by an intervening loop characterize helix–loop–helix proteins. The helices are not responsible for DNA-binding, as in the zinc finger proteins, but for dimerization with another protein. As was described for the bZip proteins, the dimers formed can be homo- or heterodimers. The DNA-binding domain is an extension of one of the α helices that form the four-helix bundle generated by dimerization (Figure 8.27).

8.9 • REGULATION OF EUKARYOTIC GENE EXPRESSION

As indicated above, a relatively small region of a regulatory protein may be dedicated to sequence-specific binding of DNA, whereas other domains are involved in protein–protein or ligand interactions. Several characteristic activation domains have been identified, including acidic domains (high concentration of amino acids with acidic side chains), glutamine-rich domains, and proline-rich domains. Experimentally, overproduction of any of these domains by recombinant techniques, even without their corresponding DNA-binding domain, can lead to inappropriate activation of transcription from a variety of genes. They appear to activate transcription by increasing the rate of assembly of the preinitiation complex. Some interact directly with TFIID to enhance binding to the TATA box, whereas others interact with TFIIB or TAFs that are part of the TFIID complex. When multiple transcription factors bind to a promoter, they can have a combinatorial effect on the binding and assembly of the preinitiation complex. Activation domains of many transcription factors target the same proteins in the preinitiation complex. Thus, transcription regulation is linked to the placement of DNA-binding sites and not to protein–protein interactions unique to a specific gene.

Transcription factors can also regulate gene expression by recruitment of other proteins to the promoter area. These proteins may not bind DNA but form a bridge between the DNA-bound transcription factor and the initiation complex. Alternatively, the interacting

CLINICAL CORRELATION 8.4

Tamoxifen and Targeting of Estrogen Receptor

Tamoxifen, a drug used to treat breast cancer, is a competitive inhibitor of the estrogen receptor (ER). Breast cancer cells respond to normal estrogen by increasing their proliferation rate. Estrogen activates the estrogen receptor, whereas tamoxifen prevents normal activation and reduces transcription from genes regulated by the estrogen receptor, and hence reduces growth of breast cancer cells. The National Cancer Institute in 2004 stated, "The benefits of tamoxifen as a treatment for breast cancer are firmly established and far outweigh the potential risks." However, tamoxifen treatment can increase the risk of uterine cancer. The apparent cause lies in the presence of two estrogen receptor subtypes (α and β). Both subtypes exist in breast tissue but estrogen receptor-α predominates in uterine tissue. In uterine tissue tamoxifen apparently activates receptor-α, rather than inhibiting it. The result is stimulation of transcription in conjunction with transcription factors fos and jun.

Paech, K., Webb, P., Kuiper, G., Nilsson, S., et al. Differential ligand activation of estrogen receptors ERα and ERβ at AP1 sites. *Science* 277:1508, 1997.

protein may bring chromatin modification enzymes, such as histone acetylase (for example, the CBP–p300 complex) to specific genes. Acetylation of histones loosens chromatin structure. Some regulated transcription factors that recruit the CBP–p300 complex, and the molecules or events to which they respond, are CREB and cAMP, SREBP and cholesterol, NFkB and cytokines, and p53 and growth arrest.

Transcription factors that reduce gene expression may preemptively bind to the DNA, either to the same sequence as a positive factor or more globally, such as the negative effect of methylated DNA-binding proteins. Alternatively, negative factors may inhibit binding or assembly of the preinitiation complex or bind to a positive transcription factor to prevent its binding to DNA or speed its degradation.

Regulating the Regulators

Transcription factors are regulated in a variety of ways. Probably the simplest examples are those which are synthesized only in specialized cells or at specific times in development. Some are regulated by cofactor binding, which may either inhibit or stimulate their binding to DNA. For transcription factors that form dimers, the formation of nonproductive homo- or heterodimer complexes can alter DNA binding or the protein–protein interactions that allow gene activation. Posttranslational modification, such as protein processing or phosphorylation, may affect transcription factor binding to DNA or other proteins, and their ability to move from the cytoplasm into the nucleus (Clin. Corrs. 8.4 and 8.5).

Since enhancers can act over long distances and in either orientation, there needs to be a way to ensure they are acting on the correct gene. This is accomplished by the use of insulator sequences that set the boundaries of influence of an enhancer. Insulators are DNA sequences that when bound to the Zn finger protein CCTF (CCCTC-binding factor) and positioned between an enhancer and the TATA box, prevent enhancer-mediated gene activation. An additional activity of insulators is to prevent the spread of heterochromatin that would lead to gene silencing.

Activation of Transcription of the LDL Receptor Gene Illustrates Many Features Found in Eukaryotic Gene Regulation.

The description of the regulation of expression of specific eukaryotic genes can rapidly turn into an alphabet soup of transcription factors and regulators of transcription factors that makes sense to researchers studying that gene, but is confusing to most others. However, many features of transcription factors described above are illustrated by the transcriptional control of the gene for the low-density lipoprotein (LDL) receptor. This gene is transcribed in response to the lack of cellular cholesterol. Increased transcription leads to an increased amount of the LDL receptor and enhanced uptake of LDLs and their cholesterol in the blood (p. 724).

The promoter of the LDL receptor gene has a TATA box and binding sites for a variety of transcription factors (Figure 8.28). The TATA box provides the site for TFIID binding

CLINICAL CORRELATION 8.5

Transcription Factors and Cardiovascular Disease

Among genes recently identified as causing human cardiovascular disease are two that encode transcription factors. One, Nkx2–5, is a homeodomain-containing protein. Homeodomain proteins often are involved in regulating cell fate in embryonic cells and Nkx2–5 regulates genes involved in heart formation. Mutations in one allele of Nkx2–5 are linked to atrial septal defects and conduction defects. The null mutation in the mouse is embryonic lethal. Mutations in the other gene, Tbx, are responsible for Holt–Oram syndrome. Holt–Oram syndrome often includes atrial septal defects (ASD), ventricular septal defects (VSD) conduction defects and defects in hand and arm development.

Holt–Oram syndrome is caused by mutations in TBX5, a member of the Brachyury (T) gene family. *Nature Genetics* 15:21, 1997.

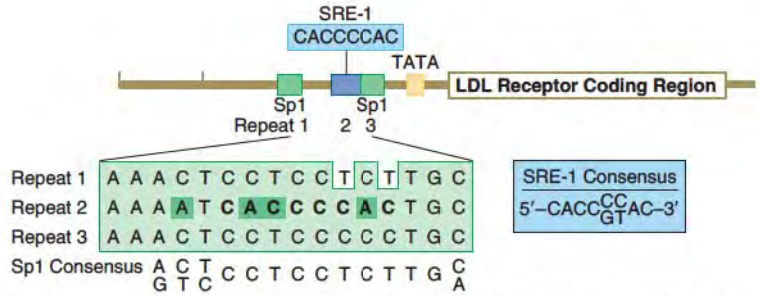

Figure 8.28 A schematic of the LDL receptor gene promoter. The LDL receptor gene promoter, like most eukaryotic genes, has several different transcription factor–binding sites. Shown here are the principal sites involved in regulating the LDL receptor gene in response to cholesterol levels. They include the TATA box, just upstream from the transcription initiation site, several GC boxes (Sp1-binding sites), and the response element (SRE) where SREBP binds. Modified from Goldstein, J. L., and Brown, M. S. Regulation of the mevalonate pathway. *Nature* 343:425, 1990.

and the formation of the preinitiation complex with RNA polymerase II. There are three consensus binding sites for the zinc finger containing transcription factor Sp1 (recall that Sp1 binds to GC boxes in promoters). Sp1 has a glutamine-rich activation domain, which is thought to help recruit TFIID to the TATA box. This recruitment needs an additional factor called the **c**ofactor **r**equired for **Sp**1 activation (CRSP). However, the binding of Sp1 is not sufficient to activate transcription of the gene. Activation requires the participation of a second transcription factor, **s**terol **r**esponsive **e**lement-**b**inding **p**rotein 1a (SREBP-1a). SREBP-1a is a helix–loop–helix–leucine zipper protein that binds to the sterol response element between the Sp1-binding sites in the LDL receptor gene.

The capacity to respond to the concentration of cholesterol is controlled by the release of SREBP from a membrane-bound state that prevents it from being transported into the nucleus. SREBP-1a contains two domains that loop through the membrane of the endoplasmic reticulum (ER), leaving the domains capable of serving as a transcription factor exposed to the cytoplasm but tethered to the ER. In order for SRCBP-1a to move to the nucleus, it must be cleaved by two proteolytic steps, the first of which is carried out by a protease found in an active form in a post-ER compartment called the cis-Golgi. Transport of SRCBP-1a to the cis-Golgi requires **S**REBP **c**leavage **a**ctivating **p**rotein (**SCAP**), which also is partially embedded in the ER membrane. SCAP has a cholesterol-sensing region, and when membrane cholesterol levels are low, the SCAP–SRCBP-1a complex is transported to the cis-Golgi, where proteolysis of SRCBP-1a occurs, releasing the cytoplasmic domain, the transcription factor, for entry into the nucleus (Figure 8.29). Once there, it binds the **s**teroid **r**esponse **e**lement (SRE)

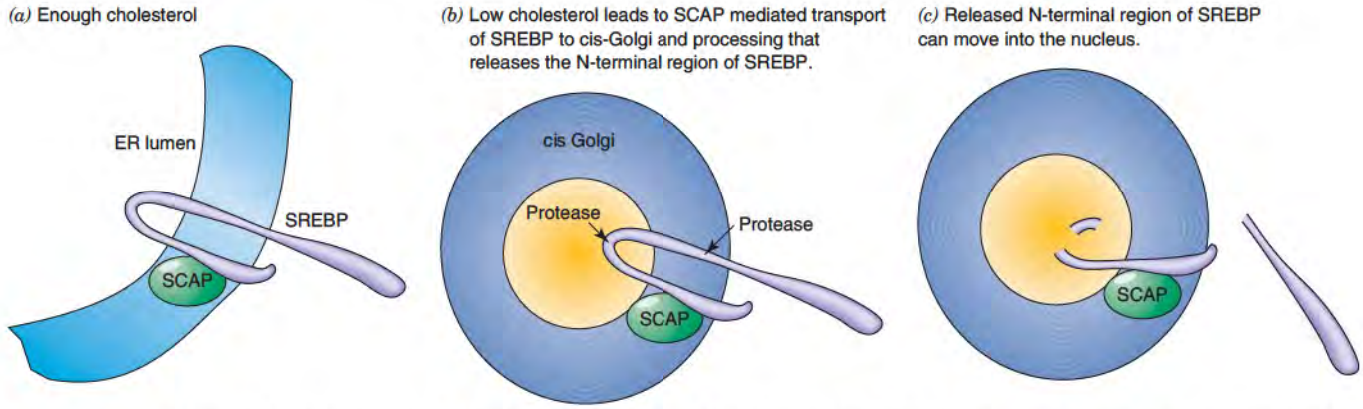

Figure 8.29 SREBP is released from membrane-bound precursor by protease action. (*a*) The sterol responsive element-binding protein (SREBP) is synthesized as a precursor protein that must be proteolytically processed before it acts as a transcription factor. The precursor is tethered to the membrane of the ER by two membrane-spanning regions. It is in close association with SREBP cleavage-activating protein (SCAP), but remains unprocessed when cholesterol levels in the ER membrane are normal. (*b*) SCAP senses low levels of cholesterol and moves with SREBP to the cis-Golgi where two different proteases cleave SREBP, (*c*) allowing the cytoplasmic domain to move to the nucleus. In this way the SREBP does not activate the LDL receptor gene unless cholesterol levels are low.
Modified from Brown, M. S., Ye, J., Rawson, R. B., and Goldstein, J. L. Regulated intermembrane proteolysis: A control mechanism conserved from bacteria to humans. *Cell* 100:391, 2000.

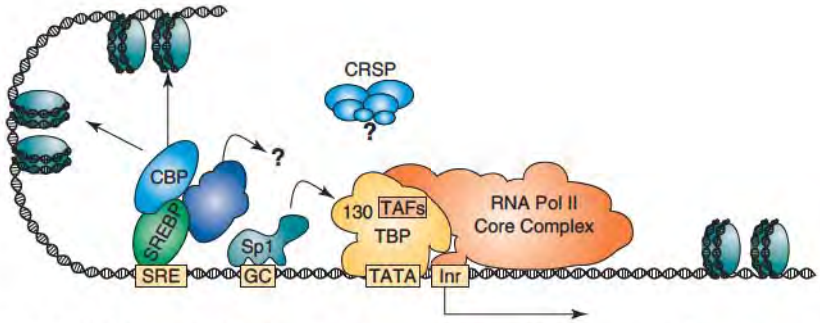

Figure 8.30 LDL receptor gene is activated through coordinate effect of several transcription factors. Activation of the LDL receptor gene requires several factors. Once SREBP, Sp1, and the cofactor required for Sp1 activation (CRSP) bind, the histone CBP is recruited to the promoter region. This combination of factors provides the positive signal needed to enhance binding of the initiation complex to the TATA box, and through recruitment of CBP, with its histone acetyl transferase activity, also affects nearby chromatin structure.
Modified from Naar, A. M., Ryu, S., and Tijian, R. Cofactor requirements for transcriptional activation by Sp1. *Cold Spring Harbor Sym. Quant. Biol.* 63:189, 1998.

on the LDL promoter and recruits a histone acetyl transferase called CBP and other proteins to the promoter area. Then, acting with SP1 and CRSP, the LDL receptor gene is transcribed (Figure 8.30). This illustrates the composite nature of eukaryotic gene regulation, in which activation of transcription factors, coordination of multiple transcription factors, and recruitment of chromatin remodeling enzymes work in concert to regulate gene expression.

Epigenetic Control of Gene Expression

The transcription factors discussed above regulate gene expression via interaction with specific DNA sequences. However, as noted earlier in this chapter, access to DNA can be an equally powerful regulator of gene expression. Modulating chromatin structure via histone modification, nucleosome remodeling, or modification of DNA via methylation can all be viewed as non-sequence-dependent regulation of gene expression. Non-sequence-dependent regulation of gene expression is often called epigenetic (Clin. Corr. 8.6).

Many posttranslational modifications have been identified on histones. Lysines can be acetylated, methylated (mono-, di-, and trimethylated), ubiquinated, and sumoylated. Arginines can be methylated (mono- or dimethylated) or deiminated (forming citrulline), serine and threonine can be phosphorylated, glutamate can be ADP-ribosylated, and proline can be isomerized. Over 60 enzymes that add or remove histone modifications have been identified, and some but not all of the modifications have been linked to gene activation or repression. Specific modifications can alter association of histones with DNA, other histones, other nucleosomes, and transcription factors. There is emerging evidence that specific small RNAs participate in the stable inheritance of histone modification patterns once a pattern is established.

CLINICAL CORRELATION 8.6

Cancer Treatment Using Drugs That Target Histone and DNA Modification: Epigenetic Therapy

Both DNA methylation and histone modification influence gene expression. For example, DNA methylation is normally associated with a reduction in gene expression, and in some cancers hypermethylation of DNA is found in the promoter regions of tumor suppression genes. DNA methylation mediated by DNA methyltransferase (DNMT) can be inhibited by 5-azacytidine and related nucleoside analogs. Several of these compounds have been approved by the FDA for treatment of myodysplastic syndrome and leukemia. Other nucleoside analogs and nonnucleoside analogs that inhibit DNMTs are being sought.

Inhibitors of histone deacetylase (HDAC) are also being sought, with the aim of restimulating tumor suppressor gene expression by allowing acetylation of histones to be retained and chromatin structure be more open. The HDAC inhibitor vorinostat was recently approved by the FDA for treatment of cutaneous T-cell lymphoma.

The use of these inhibitors, individually and as part of combination treatments with other cancer therapies, show great promise.

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. In an operon,
   - **A.** each gene of the operon is regulated independently.
   - **B.** control may be exerted via induction or via repression.
   - **C.** operator and promoter may be *trans* to the genes they regulate.
   - **D.** the structural genes are either not expressed at all or fully expressed.
   - **E.** control of gene expression consists exclusively of induction and repression.

2. The *E. coli lac*ZYA region will be upregulated if
   - **A.** there is a defect in binding of the inducer to the product of the *lac*I gene.
   - **B.** glucose and lactose are both present, but the cell cannot bind the CAP protein.
   - **C.** glucose and lactose are both readily available in the growth medium.
   - **D.** the operator has mutated so it can no longer bind the repressor.
   - **E.** the *lac* corepressor is not present.

3. All of the following describe an operon except
   A. it is a control mechanism for eukaryotic genes.
   B. it includes structural genes.
   C. it is expected to code for polycistronic mRNA.
   D. it contains control sequences such as an operator.
   E. it can have multiple promoters.

4. In bacteria, amino acid starvation is associated with the production of guanosine tetraphosphate and guanosine pentaphosphate. This situation is referred to as
   A. attenuation.
   B. corepression.
   C. repression.
   D. self-regulation.
   E. stringent response.

5. A number of specific sequences have been found in many promoter and operator regions. The sequence that is very closely associated with methylation of DNA is
   A. CG island.
   B. CAAT box.
   C. TATA box.
   D. CAP site.
   E. CTD.

6. In eukaryotic transcription by RNA polymerase II, formation of a preinitiation complex
   A. begins with the binding of a protein (TBP) to the TATA box of the promoter.
   B. involves the ordered addition of several transcription factors and the RNA polymerase.
   C. allows an ATP-dependent opening of the two strands of DNA.
   D. requires that the C-terminal domain of RNA polymerase II not be phosphorylated.
   E. all of the above.

Questions 7 and 8: Since the initiation of eukaryotic transcription involves the interaction of a multitude of transcription factors, there must be regulation of these. Estrogen normally binds to its nuclear receptor and the complex binds to the sterol response element to regulate transcription. Tamoxifen, a drug used to treat breast cancer, competes for the estrogen receptor and reduces transcription of the genes it regulates. Another type of alteration is seen in Holt–Oram syndrome in which there is a mutation in a gene for a transcription factor (Tbx), leading to defects in formation of the heart.

7. Response elements
   A. are proteins that bind to the promoter region.
   B. are more effective the closer they are to the TATA box.
   C. may be thousands of base pairs away from the preinitiation complex assembly.
   D. can be either upstream or downstream of the transcription start.
   E. bind transcription factors that interact with the initiation complex only upon looping of the DNA.

8. Transcription factors are frequently sequence-specific binding proteins and most likely have one of several specific structural motifs. The helix–turn–helix motif
   A. coordinates zinc between cysteines and histidines.
   B. joins two proteins via hydrophobic interactions between leucines.
   C. forms dimers held together by interaction of a helix on each monomer.
   D. has one helix that recognizes and binds in the major groove of DNA while hydrophobic interactions with a second helix stabilizes the structure.
   E. is the only motif that binds in the major groove of DNA.

Questions 9 and 10: The problem of pathogenic bacteria becoming resistant to a large number of antibiotics is a serious public health concern. A bacterial strain in a patient being treated with one antibiotic may suddenly become resistant not only to that antibiotic but to others as well even though it has not been exposed to the other antibiotics. This occurs when the bacteria acquire a plasmid from another strain that contains several different transposons.

9. All of the following phrases describe transposons except
   A. a means for the permanent incorporation of antibiotic resistance into the bacterial chromosome.
   B. contain short inverted terminal repeat sequences.
   C. code for an enzyme that synthesizes guanosine tetraphosphate and guanosine pentaphosphate, which inhibit further transposition.
   D. include at least one gene that codes for a transposase.
   E. contain varying numbers of genes.

10. In the operation of transposons,
    A. typically the transposon moves from its original site and relocates to a different site.
    B. a duplicated transposon must be inserted into the same DNA molecule as the original.
    C. all transposons are approximately the same size.
    D. the insertion sites must be in a consensus sequence.
    E. the transposase may recognize the repetitive ends of the transposon and participate in the cleavage of the recipient site.

Questions 11 and 12: Genes present in a region of DNA which is in the highly condensed heterochromatin form cannot be transcribed. To be transcribed, this region of DNA must change to a more open structure; this may occur by acetylation of histones by an acetyltransferase like CBP, CREB-binding protein. CREB is a transcription factor. Rubinstein–Taybi syndrome is caused by mutations of the CBP gene. Rubinstein–Taybi patients are mentally retarded and have other developmental abnormalities, the severity of which depends on the extent of mutation.

11. In chromatin,
    A. a nucleosome consists of four molecules of histones surrounding a DNA core.
    B. DNA positioned so that the major and minor grooves are on the outside of the nucleosome is more accessible for transcription than if the grooves face the interior.
    C. DNA must be completely removed from the nucleosome structure for transcription.
    D. linker DNA is the only DNA capable of binding transcription factors.
    E. the histone octamer consists of eight different kinds of histone proteins.

12. Acetylation of histones can lead to a more open DNA structure by
    - **A.** weakening the electrostatic attraction between histones and DNA.
    - **B.** causing histones to interact with the C-terminal domain (CTD) of RNA polymerase.
    - **C.** causing electrostatic repulsion between histones and DNA.
    - **D.** facilitating methylation of DNA.
    - **E.** attracting transcription factors to DNA.

Problems

13. What will be the status of transcription of the *lac* operon in (a) the presence of glucose and (b) the absence of glucose, in each case with lactose present, if there is a mutation that produces an inactive adenylate cyclase?

14. In an operon for synthesis of an amino acid that is controlled wholly or in part by attenuation, why does the presence of the amino acid prevent transcription of the whole operon while the absence of the amino acid permits it?

Answers

1. **B** Induction and repression are among the mechanisms used to control operons. A: The structural genes are under coordinate control. C: The operator and promoter are elements of the same strand of DNA as the operon they control, not diffusible. D: Typically, regulation of operators is somewhat leaky. E: Another mechanism for regulation of an operon is attenuation.
2. **D** If the operator is unable to bind the repressor, the rate of transcription is greater than the basal level. A: The product of the *lacI* gene is the repressor protein. When this protein binds an inducer, it no longer binds to the operator and transcription increases. Failure to bind an inducer prevents this sequence. B and C: In the presence of glucose, catabolite repression occurs. Glucose lowers the intracellular level of cAMP so there is no CAP–cAMP complex to activate transcription. E: The *lac* operon does not involve corepression.
3. **A** Operons are prokaryotic mechanisms. B and D: An operon is the complete regulatory unit of a set of clustered genes, including the structural genes, regulatory genes, and control elements, such as the operator. E: An operon may have more than one promoter, as does the tryptophan operon of *E. coli.*
4. **E** The mechanism is unclear but transcription initiation of rRNA is inhibited.
5. **A** Methylation is on the cytosine. B: This is a binding site for several transcription factors. C: This is the site where RNA pol II binds. D: This is the site in the *lac operon,* which binds the catabolite activator protein. E: This stands for the C-terminal domain of a protein and is not a DNA sequence.
6. **E** A: TBP is part of the general transcription factor TFIID. B: Many proteins are involved. C: The helicase activity is associated with one of the transcription factors (TFIIH). D: The CTD must be in the unphosphorylated form for RNA polymerase to enter the preinitiation complex.
7. **B** They are part of the promoter region. A: They are DNA sequences, not proteins. C, D, and E: These are characteristics of enhancers, which are also DNA sequences but not usually part of the promoter.
8. **D** The turn is only four amino acids so the two helices are very close. A: This is the zinc finger. B: This is called the leucine zipper (bZIP). C: This is characteristic of the helix–loop–helix. E: All of the motifs have some part that binds in the major group.
9. **C** These guanosine phosphates are synthesized by the product of the relA gene; they inhibit initiation of transcription of the rRNA and tRNA genes, shutting off protein synthesis in general. This is the stringent response.
10. **E** This has been demonstrated for transposon Tn3. A: Most transpositions involve generation of an additional copy of the transposon which is then inserted somewhere else in DNA. B: The copy could be inserted into a different DNA molecule. C: Length varies considerably, depending on the number of genes incorporated into the transposon. D: Most target sites seem to be fairly random in sequence although some transposons tend to insert at specific *hot spots.*
11. **B** Assembly of the transcription initiation complex and other proteins involved in gene expression need access to the grooves of DNA. A and E: The core of the nucleosome is an octamer of two molecules each of four different histones. C: A five-base pair shift in the association of DNA with the histone core is sufficient to change the orientation of the grooves and allow access. D: It seems to be the DNA associated with the nucleosome that is involved in binding transcription factors and other proteins.
12. **A** Acetylation of an ε-amino group of lysines near the N-terminus of histones changes a positive charge to a neutral species so there is less attraction to the negative phosphates of DNA. B: Histones do not interact directly with CTD of RNA polymerase II. C: The change is from positive to neutral, not negative, so there is no electrostatic repulsion. D: Methylation of DNA does affect transcription but is a separate phenomenon from acetylation of histones. E: The nucleosome undergoes repositioning.
13. Normally, glucose lowers the intracellular level of cAMP. There is then little or no CAP–cAMP complex to activate transcription so transcription of the operon is low. The same situation would exist in this mutation. Normally, in the absence of glucose, cAMP is high, positive control is exerted, and the *lac* operon is transcribed. In this mutation, cAMP cannot form since the enzyme for its formation is defective. There is no positive control and the *lac* operon will not be transcribed effectively.
14. Such operons will code for a leader peptide that has one or more codons for the amino acid in question. Once the RNA for the leader peptide has been synthesized, it can form different secondary structures depending on whether or not the ribosome is stalled at this region. If the ribosome does not stall because there is enough amino acid (and thus charged tRNA), the secondary structure is a termination signal and synthesis stops. If the ribosome stalls because of insufficient charged tRNA, the secondary structure that forms is not recognized as a termination signal and transcription through the operon continues.

Key Concepts

IMMUNOGLOBULINS

- Immunoglobulin molecules contain repeating homologous sequences that produce multiple immunoglobulin folds within the light (L) and heavy (H) chains of the basic four polypeptide $(LH)_2$ structure.
- The immunoglobin folds from different chains associate to form domains that function to bind antigen, activate complement, and promote polymerization in particular antibody classes.
- The N-terminal domains from the L and H chains (the V_H—V_L domains) have a hypervariable loop region that binds to the targeted antigen specific for that antibody.
- The immunoglobulin fold is a superfold, formed in a wide variety of molecules with non-homologous sequence and function.

SERINE PROTEASES

- Serine proteases are defined by a common catalytic mechanism with identical catalytically essential amino acid residues.
- Trypsin-like serine proteases have two β-barrel folds comprising the catalytic unit with the active site residues in the interdomain crevice. Through convergent evolution, other families of serine proteases have evolved with a nonhomologous tertiary structure, but with an identical catalytic mechanism to the proteases in the trypsin-like family.
- Substrate specificity for different physiological substrates among trypsin-family proteases is determined by the loop regions of the fold structures that provide secondary site interactions with the polypeptide substrates.

- Proteases catalyze reactions by stabilizing the tetrahedral structure and oxyanion of the hydrolytic transition state.
- Serine proteases are often synthesized as zymogens, activated by an upstream protease in an enzyme cascade, and inhibited by protein inhibitors known as serpins.

HEMOGLOBIN AND MYOGLOBIN

- Hemoglobin and myoglobin chains have identical fold structures.
- A heme prosthetic group is part of the O_2-binding site in hemoglobin and myoglobin globin chains.
- Hemoglobin has a quaternary structure with four heme units that bind oxygen with positive cooperativity through conformational changes in the subunit transferred from one heme site to other heme sites within the quaternary structure.
- Protons and 2, 3-bisphosphoglycerate molecules that dissociate from hemoglobin as it changes from the deoxy- to the oxy-conformation regulate the oxygen association–dissociation equilibrium through changes in their concentrations.
- Hemoglobin sequesters NO to deliver to the capillary wall on conversion to the deoxy-conformation.

BASAL LAMINA STRUCTURE

- The basal lamina is an extracellular molecularly organized structural complex composed of multiple protein subunits with an interacting core consisting of type IV collagen, laminin, nidogen/entactin, and perlecan heparan sulfate.
- Proteins of basal lamina are present in different isoforms and the isoforms expressed in a particular tissue are characteristic of the tissue that synthesizes its associated basement membrane.
- Laminin and type IV collagen self-polymerize to form defined molecular networks with binding sites for coproteins and for cell receptor proteins.
- The laminin of the basal lamina is interconnected to the intracellular cytoskeleton of bordering cells at focal adhesion receptor sites in the cellular plasma membranes.

9.1 • INTRODUCTION

The fundamentals of protein architecture were presented in Chapter 3. This chapter discusses the relationships between structure and function in three **protein families**: immunoglobulins, serine proteases, and hemoglobins by examination of amino acid sequence, structural organization, and biological function. The organization of proteins forming the basement membrane of the extracellular matrix that surrounds cells and tissues is also described.

Immunoglobulins provide examples of multidomain architecture that supports recognition and binding to foreign molecules and leads to their sequestration. Diversity among family members is the source of specific recognition of molecular and individual binding capabilities.

Serine proteases provide examples of enzymes that appear to have diverged through evolution to perform unique physiological functions, frequently within highly organized enzyme cascades. Similarities in their catalytic mechanisms and three-dimensional structures form a common link.

Hemoglobins offer examples of highly fine-tuned proteins that simultaneously perform multiple highly regulated physiological functions. They can accommodate small substitutions or mutations, many of which have clinical implications, and still retain their physiological functions. They reveal the diversity of amino acid sequence substitutions that can be structurally tolerated and allow the protein to function. Hemoglobin demonstrates on the atomic level how a protein performs multiple physiological functions in a regulated manner.

The **basement membrane** is an extracellular protein complex formed by cell secreted proteins that bind with each other to form a molecular network in the extracellular space that provides the boundaries and regulatory environment of the cells and tissues. It provides an example of a complex network composed of multiple different protein subunits that spontaneously associate into a specific molecular arrangement. Such protein networks provide essential intracellular as well as extracellular functions.

9.2 • ANTIBODY MOLECULES: THE IMMUNOGLOBULIN SUPERFAMILY OF PROTEINS

Antibody molecules are produced by lymphocytes in response to foreign compounds that can be proteins, complex carbohydrate polymers, or nucleic acid. They noncovalently associate with such foreign compounds present in the protein coat of invading viruses and bacterial cells,

initiating a process by which the invading organism is eliminated. Molecules that induce antibody production are called **antigens** and may contain multiple antigenic determinants or epitopes, small regions of the antigen molecule that elicit the production of a specific antibody to which the antigen binds. In proteins for example, an antigenic determinant may comprise only six or seven amino acid residues and a single protein may have many antigenic determinants.

A **hapten** is a small molecule that cannot alone elicit production of specific antibodies but when covalently attached to a larger molecule acts as an antigenic determinant and induces antibody synthesis. Although haptens need attachment to a larger molecule to elicit antibody synthesis, in their free state they bind strongly to antibody.

Each human has the potential to produce about 1×10^8 different antibody structures. All antibodies, however, have a similar overall structure. This has been determined from studies of their amino acid sequence and X-ray diffraction of the antibody molecule alone or in complex with antigen. Structural studies require pure homogeneous preparations of proteins. Antibodies are extremely difficult to purify from plasma because of the many thousands of different antibody molecules present. Homogeneous antibodies can be obtained, however, by the monoclonal hybridoma technique in which mouse myeloma cells are fused with mouse antibody-producing B lymphocytes to construct immortalized hybridoma cells that express a single antibody.

Antibody Molecules Contain Four Polypeptide Chains

Antibody molecules are glycoproteins composed of two light chains (L) of identical sequence combined with two identical heavy chains (H) to form the structure $(LH)_2$. In the most common immunoglobulin class, IgG, the H chains contain approximately 440 amino acids (50 kDa). The L chains contain about 220 amino acids (25 kDa). The four chains are covalently interconnected by disulfide bonds (Figures 9.1 and 9.2). Each H chain is associated

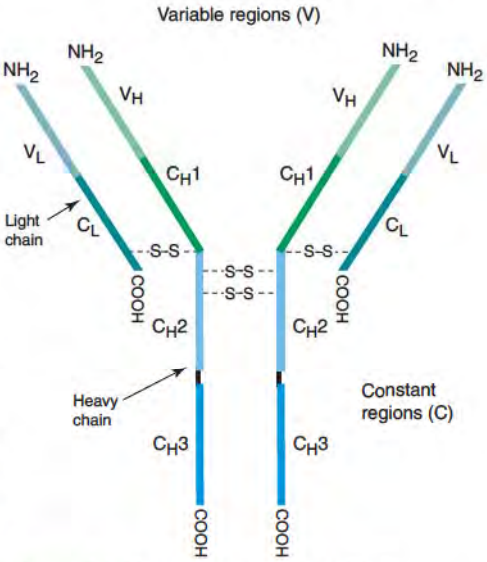

Figure 9.1 Linear representation of IgG antibody molecule. Two heavy (H) chains and two light (L) chains are co-oriented parallel to each other. Interchain disulfide bonds link H chains to each other, and L chains to H chains. Ig fold repeats in the constant (C) region of the H chain are C_H1, C_H2, and C_H3. The constant region of L chain is designated C_L, and variable (V) regions are V_H and V_L of H and L chains, respectively. Based on figure by Burton, D. R. In Calabi, F., and Neuberger, M. S. (Eds.), *Molecular Genetics of Immunoglobulin.* Amsterdam: Elsevier, 1987, 1.

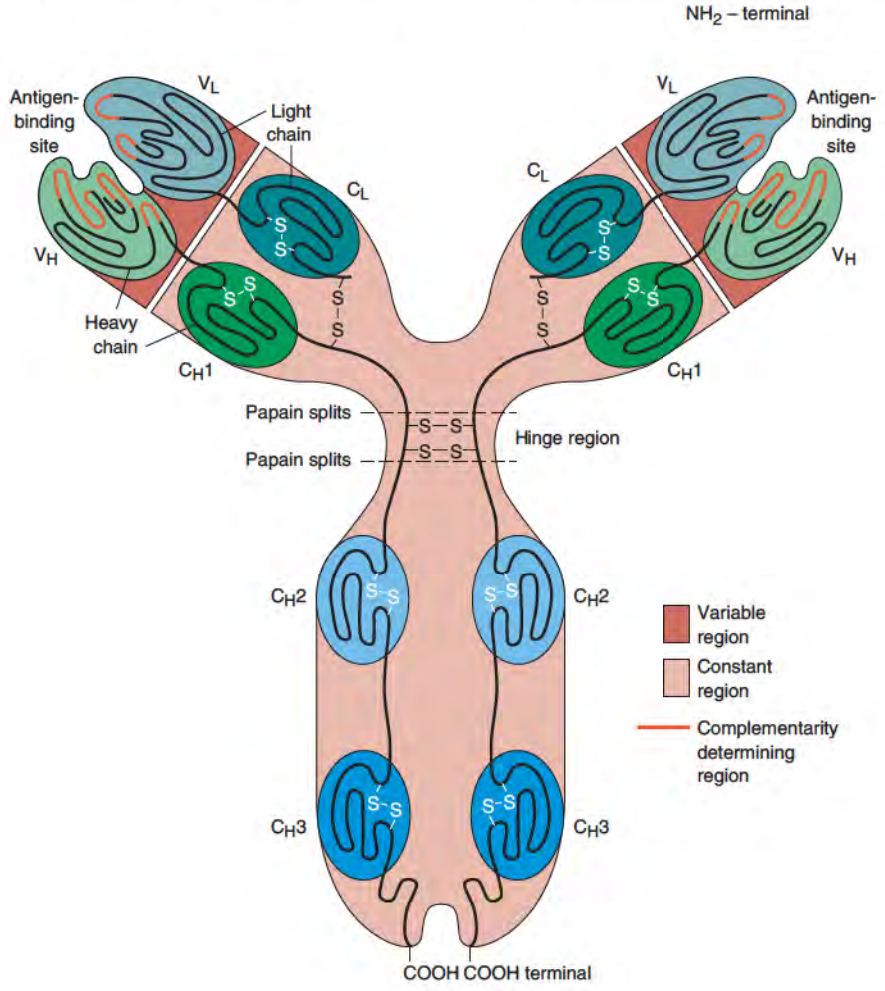

Figure 9.2 Diagrammatic structure of IgG. Light chains (L) are divided into Ig folds V_L (variable amino acid sequence) and C_L (constant amino acid sequence). Heavy chains (H) are divided into V_H and C_H1, C_H2, and C_{H3}. Antigen binding sites are V_H—V_L. "Hinge" polypeptides interconnect domains. Positions of inter- and intrachain cystine bonds are shown. From Cantor, C. R., and Schimmel, P. R. *Biophysical Chemistry*, Part I. San Francisco: Freeman, 1980. TABLE 9.1 • Immunoglobulin Classes

Classes of Immuno-globulin	*Approximate Molecular Mass*	*H-Chain Isotype*	*Carbohydrate by Weight (%)*	*Concentration in Serum (mg 100 mL^{-1})*
IgG	150,000	γ, 53,000	2–3	600–1800
IgA	170,000–720,000[a]	α, 64,000	7–12	90–420
IgD	160,000	δ, 58,000		0.3–40
IgE	190,000	ϵ, 75,000	10–12	0.01–0.10
IgM	950,000[a]	μ, 70,000	10–12	50–190

[a]Forms polymer structures of basic structural unit.

with an L chain such that the NH_2-terminal ends of both chains are near each other. The L chain is half the size of the H chain and only the NH_2-terminal half of the H chain is associated with the L chain.

In the other classes of immunoglobulins (Table 9.1) the H chains are longer than in the IgG class. A variable amount of carbohydrate (2%–12%, depending on class) is attached to the H chain.

Constant and Variable Regions of Primary Structure

Comparison of amino acid sequences of antibody molecules elicited by different antigens shows regions of sequence homology and others of sequence variability. In particular, sequences of the NH_2-terminal half of L chains and the NH_2-terminal quarter of H chains are highly variable. These are the **variable (V) regions** designated V_H and V_L of H and L chains, respectively. Within these V regions certain subregions are hypervariable. Three **hypervariable regions** of between 5 and 7 residues in the V_L and three or four hypervariable regions of between 6 and 17 residues in the V_H domain are common. They are the **complementarity-determining regions** (**CDRs**) as they form the three-dimensional antigen-binding site complementary to the topology of the antigen.

In contrast, the COOH-terminal three-quarters of H chains and the COOH-terminal half of L chains are homologous in sequence with other H or L chains of the same class. These **constant (C) regions** are designated C_H and C_L in the H and L chains, respectively.

The C_H regions determine the antibody class, provide for binding of complement proteins (Clin. Corr. 9.1), and contain the site necessary for antibodies to cross the placental membrane. The V regions determine the antigen specificity of the antibody.

CLINICAL CORRELATION 9.1

The Complement Proteins

The complement system consists of at least 30 distinct complement proteins in plasma (see p. 983 for their designations). These proteins participate in a biochemical cascade that acts to eliminate pathogens and foreign materials from an organism. Three distinct pathways (classical, lectin, and alternative pathways, see figure) utilize different initial signals to activate the complement system. The three pathways converge on factor C3 to form protein fragments C3a and C3b, which cause further activation events.

Many of the complement proteins are inactive precursors or zymogens of serine protease enzymes. On activation, they activate a succeeding protein of the pathway by cleavage of a specific peptide bond in the substrate protein, causing it to become an active serine protease. Activation by hydrolysis of a specific peptide bond is an important method for activation of extracellular proteases. For example, the serine protease enzymes that catalyze blood clot formation, fibrinolysis of blood clots, and digestion of dietary proteins in the gut are mostly activated by specific upstream proteases (pp. 984 and 1033). These pathways of successive protease activations constitute cascades in which amplification of the trigger event occurs.

The classical pathway is initiated by IgG or IgM antibody binding to antigens on the outer surface of invading bacterial cells, protozoa, or tumor cells. On binding to a cellular antigen the complement binding site in the antibody's F_c region becomes exposed as a result of a conformational change. This allows binding of the C1 complement proteins to the cell-surface-bound antibody. The C1 complex is composed of the proteins Clq, Clr, and Cls. Proteins Clr and Cls in the complex undergo a conformational change and become active serine protease enzymes on the cell surface. The activated C1 complex (Cla)

hydrolyzes a peptide bond in C2 and C4, which then also associates on the cell surface. The now proteolytically active C2a—C4b complex is the C3 convertase of the classical pathway (figure, complex 5) and hydrolyzes a peptide bond in C3 to produce products C3a and C3b. C3a is an anaphylatoxin-causing platelet and neutrophil activation, mast cell degranulation, and increased vascular permeability to facilitate inflammatory cell recruitment. C3b binds to the target cell surface and the activated C2—C4—C3b complex proteolytically hydrolyzes C5 to products C5a and C5b. Activated C5b associates with C6, C7, C8, and multiple molecules of C9, which bind to the bacterial cell surface and initiate membrane lysis.

$$\text{IgG or IgM} \xrightarrow{\text{Clq, Clr, Cls}} \overline{\text{Cla}} \xrightarrow{\text{C2, C4}}$$

$$\text{C4b} \cdot \overline{\text{C2a}} \xrightarrow{\text{C3}}$$

$$\text{C4b} \cdot \overline{\text{C2a}} \cdot \text{C3b} \xrightarrow{\text{C5, C6, C7, C8, C9}} \text{lysis}$$

(Line above designates active protease.) In addition, target cell membrane bound C5b has opsonic and immune adherence activities, promoting destruction of the target cell by phagocytic cells. Product C5a with C3a contribute to the inflammation.

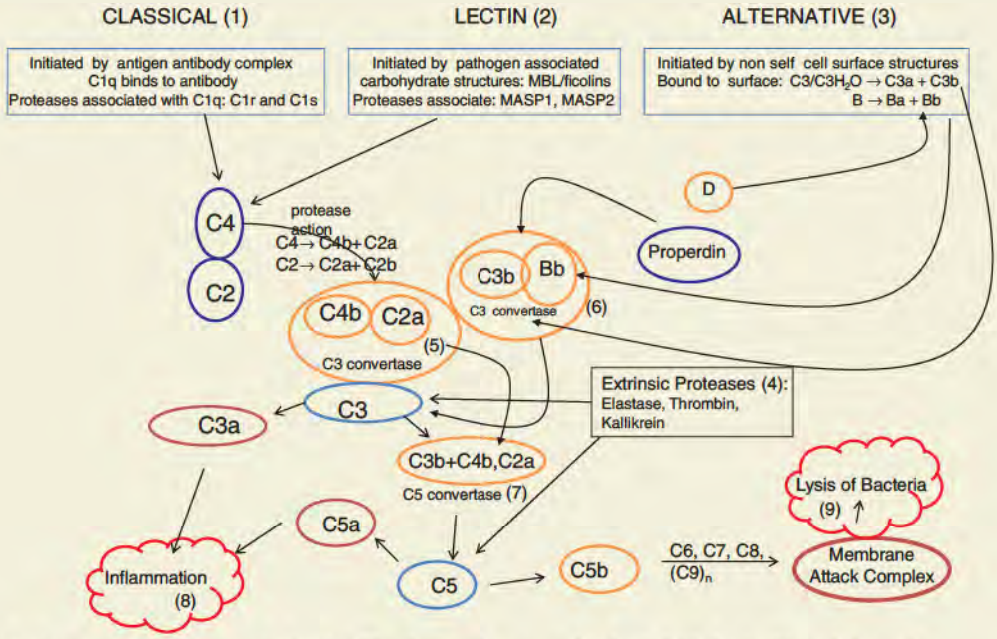
The alternative pathway can be activated by polysaccharides of invading microorganisms, in the absence of a specific antibody, or by aggregates of IgA. The alternative pathway involves properdin and factor D. Factor D proteolytically cleaves B into products Ba and Bb, which on the target cell surface binds C3, and C3 in this complex autocatalytically hydrolyzes a peptide bond to produce C3a and C3b. C3b combines with Bb to produce a C3 convertase, different from the convertase formed in the classical pathway, that further acts on C3 molecules in blood to produce increased amounts of C3a and C3b (see figure, pathway 3).

The lectin pathway is activated by the opsonin, mannose-binding lectin (MBL), which binds mannose polysaccharides on the invading microorganism surface. The MBL on the cell surface then binds the MBL-associated serine proteases MASP-1 and MASP-2. This complex is similar to the C1 complex in the classical pathway and cleaves C4 in the C2—C4 complex to produce C4b that converts C3 to C3a and C3b (figure, pathway 2).

Extrinsic proteases released from leukocytes or activated by other pathways can also activate the complement system independently of the convertase complexes (figure, pathway 4).

Abnormalities in the complement system can result in inflammatory disorders, repeated pathogen infections, autoimmune diseases including rheumatoid arthritis, glomerular injury, and ocular diseases such as uveitis and macular degeneration. Complement has a role in ischemia and cardiovascular diseases, and in organ and tissue transplantation.

Markiewski, M. M., and Lambris, J. D. The role of complement in inflammatory diseases from behind the scenes into the spotlight. *Am. J. Pathology* 171:715, 2007; Okroj, M., Heinegård, D., Holmdahl, R., and Blom, A.M. Rheumatoid arthritis and the complement system. *Ann. Med.* 39:517, 2007; and Zipfel, P.F., Mihlan, M., and Skerka, C. The alternative pathway of complement: a pattern recognition system. *Adv. Exp. Med. Biol.* 598:80, 2007.



Pathways of Complement Activation The three pathways are the classical (1), lectin (2), and alternative (3). In addition, extrinsic proteases (4) can activate the complement system. The classical C3 convertase (5) is generated by both the classical and lectin pathways, while a different C3 convertase complex (6) is formed in the alternative pathway. The C3b product participates in the C5 convertase complex (7). Outcomes of the convertase pathways are inflammation (8) and lysis of invading bacteria ((9). Color scheme: outcomes, red; activators, brown; proteolytic enzymes, orange; and inert protein substrates, blue.
Redrawn from Markiewski, M. M., and Lambris, *J. D. Am. J. Pathol.* 171:715, 2007.

CLINICAL CORRELATION 9.2

Functions of Different Antibody Classes

The IgA class of immunoglobulins is found primarily in mucosal secretions (bronchial, nasal, and intestinal mucous secretions; tears; milk; and colostrum). They are the initial defense against invading viral and bacterial pathogens prior to their entry into plasma or other internal space.

The IgM class is found only in plasma. They are the first antibodies elicited in significant quantity on exposure to a new foreign antigen. They promote phagocytosis of microorganisms by macrophage and polymorphonuclear leukocytes and are also potent activators of complement (see Clin. Corr. 3.1). They occur in many external secretions but at levels lower than those of IgA.

The IgG class occurs in high concentration in plasma. Their synthesis in response to foreign antigens takes a longer period of time than that of IgM. At maximum concentration they are present in significantly higher concentration than IgM. Like IgM, IgG antibodies promote phagocytosis in plasma and activate complement.

The normal biological functions of the IgD and IgE classes are not known; however, the IgE play an important role in allergic responses such as anaphylactic shock, hay fever, and asthma.

Immunoglobulin deficiency usually causes increased susceptibility to infection. X-linked agammaglobulinemia and common variable immunodeficiency are examples. The commonest disorder is selective IgA deficiency, which results in recurrent infection of sinuses and the respiratory tract.

IgA receptors in health and disease. *Tissue Antigens* 68:103, 2006.

Immunoglobulins in a Class Contain Homologous C_H Regions

Differences in sequence of the C_H regions between immunoglobulin classes determine the characteristics of each class. In some classes, the C_H sequence promotes polymerization of molecules of the basic structure $(LH)_2$. Thus antibodies of the IgA class are often present as dimer structures $[(LH)_2]_2$. Similarly, IgM molecules are commonly pentamers $[(LH)_2]_5$. The different H chains, which are identified by their homologous amino acid sequences, are designated γ, α, δ, ϵ, and μ and occur in IgG, IgA, IgM, IgD, and IgE classes, respectively (Table 9.1; Clin. Corr. 9.2). Two types of L chain sequences are synthesized, designated lambda (λ) and kappa (κ), either of which are found combined with each of the five classes of H chains.

IgG is the major immunoglobulin in plasma. Biosynthesis of a specific IgG in significant concentrations takes about 10 days after exposure to a new antigen (Clin. Corr. 9.3). Antibodies of the IgM class are synthesized at a faster rate and are the first line of defense until large quantities of IgG are produced (Figure 9.3).

CLINICAL CORRELATION 9.3

Immunization

An immunizing vaccine consists of killed bacterial cells, inactivated viruses, killed parasites, nonvirulent forms of live bacteria, denatured bacterial toxins, or recombinant protein. The introduction of a vaccine into a human leads to protection against a virulent form of the microorganisms or toxic agents that contain the same antigen. Antigens in nonvirulent material cause differentiation of lymphoid cells so that they produce antibody toward the foreign antigen and differentiation of some lymphoid cells into memory cells. Memory cells do not secrete antibody but place antibodies to the antigen onto their outer surface, where they act as future sensors for the antigen. These memory cells are like long-standing radar for the potentially virulent antigen. On reintroduction of the antigen later, binding of the antigen to the cell surface antibody in the memory cells stimulates the memory cell to divide into antibody-producing cells and new memory cells. Once introduction of an antigen occurs, this reduces the time required for antibody production and increases the initial concentrations of antigen-specific antibody produced. This is the basis for the protection provided by immunization.

Vaccines recently introduced for adults include pneumococcal vaccine (to prevent pneumonia due to *Diplococcus pneumoniae),* hepatitis B vaccine, and influenza vaccine. The composition of the latter is changed each year to account for antigenic variation in the influenza virus.

Repeating Sequences and Homologous Three-Dimensional Domains within an Antibody

Within each chain of an antibody molecule is a repeating pattern of amino acid sequences. For the IgG class, the repetitive pattern contains approximately 110 amino acids within both L and H chains. This homology is far from exact, but clearly a number of amino acids match identically on alignment of these segments. Other residues are matched in the sequence by having similar nonpolar or polar side chains. The repetition occurs four times in the H chains, in the V_H region and three C_H regions (designated C_H1, C_H2, and C_H3) (Figures 9.1 and 9.2). The L chain contains one V_L and one C_L region. Each repeat contains an intrachain disulfide bond (Figure 9.2).

Each 110 amino acid segment has a similar arrangement of antiparallel β-strands known as an **immunoglobulin fold** (Figure 9.4). The fold consists of seven to nine polypeptide strands in two antiparallel β-sheets aligned face-to-face. The association of two immunoglobulin folds from different chains forms globular domains, V_L—V_H, and C_L—C_H1 between the H and L chains, and in the C-terminal half of the H chains the domains C_H2—C_H2 and C_H3—C_H3 (Figure 9.2). A "hinge" region interconnects the two V_H—C_H1 N-terminal domains with the C_H2—C_H2 domain of the H chains. Thus the basic antibody structure exhibits six domains, each domain formed from the interaction of two immunoglobulin folds (Figures 9.2 and 9.5). The NH_2-terminal V_L—V_H domains contain a shallow crevice in the center of a hydrophobic core that binds the antigen. The binding site of the crevice is composed primarily of the **hypervariable sequences** of the V domain that are within loops that come close together and are the complementarity binding site (complementarity

determining regions, CDRs) for the antigen (Figures 9.6 and 9.7). The hypervariable sequences of the domain loops provide a unique three-dimensional conformation for each antibody that makes it specific for its antigenic specificity. The binding of antigen into the V_L–V_H domains may induce small conformational changes in the CDRs inducing functionally important conformational changes between the V_L—V_H domains and the other domains of the antibody molecule leading to the activation of effector sites, such as the binding of complement to the C_H2—C_H2 domain; see C1q site in Figure 9.6. The strength of binding between antibody and antigen is due to noncovalent forces (p. 116). Complementarity of the structures of the antigenic determinant and antigen-binding site results in extremely high equilibrium affinity constants, between 10^5 and 10^{10}/M (strength of 30–60 kJ/mol or 7–14 kcal/mol) for this noncovalent association.

There Are Two Antigen-Binding Sites per Antibody Molecule

There are two NH_2-terminal V_L—V_H domains in the $(LH)_2$ basic antibody structure. The existence of an antigen-binding site in each LH pair is demonstrated by treating antibody molecules with the proteolytic enzyme papain, which hydrolyzes a peptide bond in the hinge region of each of the H chains (see Figures 9.2, p. 335, and 9.8) to release three fragments from the antibody molecule. Two are identical, each consisting of the NH_2-terminal half of an H chain (V_H—C_H1) associated with a full L chain. Each of these fragments binds antigen

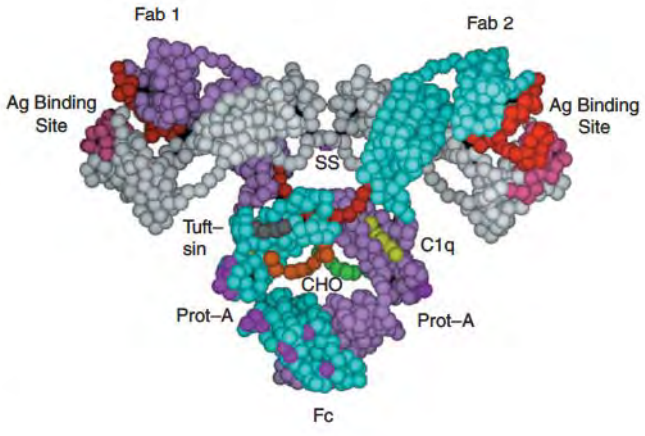

Figure 9.6 Model of an IgG antibody molecule. Only the α-carbons of the structure appear. The two L chains are represented by light gray spheres, and H chains by lavender and blue spheres. Carbohydrates attached to the two C_H2 domains are colored light green and orange. The CDR regions of the V_H—V_L domains are dark red in the H chains and pink in L chains. The interchain disulfide bond between the L and H chains is a magenta ballandstick representation (partially hidden). The heptapeptide hinge between C_H1 and C_H2 domains are dark red. The center of the C1q binding site in the C_H2 domains is yellow, the protein A docking sites at the junction of C_H2 and C_H3 are magenta, and the tuftsin binding site in C_H2 is gray. Tuftsin is a natural tetrapeptide that induces phagocytosis by macrophages and may be transported bound to an immunoglobulin. Protein A is a bacterial protein with a high affinity for immunoglobulins.

(*b*) Redrawn from Branden, C., and Tooze, J. *Introduction to Protein Structure.* New York: Garland, 1991, 189, and attributed to Chothia, C., and Lesk, A. J. *Mol. Biol.* 196:914, 1987.

with a similar affinity to the intact molecule and is designated a $\mathbf{F_{ab}}$ (**antigen binding fragment**). The other fragment is the cystine-linked COOH-terminal halves of the two H chains (C_H2—$C_H3)_2$. This is the $\mathbf{F_c}$ (**crystallizable fragment**), which does not bind the antigen. The V_L—C_L chain can be dissociated from its V_H–C_H1 chain partner within the F_{ab} fragment by reduction of linking disulfide bonds; this eliminates antigen binding. Accordingly, each antigen-binding site must be formed from components of both the L chain and the H chain domains acting together.

The major features of antibody structure and antibody–antigen interactions are: (1) Repeating homologous sequences in the light (L) chains generate two immunoglobulin folds and in the heavy (H) chains four immunoglobulins folds. (2) Immunoglobulin folds on separate chains associate to form the six domains of the basic immunoglobulin structure. (3) The antigen-binding site is generated by hypervariable loops (CDRs) in each V_L—V_H domain, which form a continuous surface topology complementary to the antigenic determinant. (4) The strong interactions between antigen and antibody CDRs are non-covalent and include van der Waals, hydrogen bonding, hydrophobic interactions, and to a smaller extent ionic salt bridges. (5) Small conformational changes occur in the V_L—V_H domain on binding of antigen, indicating an induced fit which induces conformational changes in distant domains of the antibody that alter the binding affinity of effector sites in the

constant domains such as that for binding of complement protein C1q to the C_H2—C_H2 domain (Clin. Corr. 9.1, p. 336).

Genetics of the Immunoglobulins

The V region of the L and H chains are specified by genes distinct from the genes that code for the C region. There are four unique genes that code for the C_H1–C_H2–C_H3 polypeptide segment of the H chain in the IgG antibody class. They are known as gamma (γ) genes, that is, γ_1, γ_2, γ_3, and γ_4, that give rise to **IgG isotypes** IgG_1, IgG_2, IgG_3, and IgG_4. Figure 9.9 presents the sequences of three γ-gene proteins. There is a 95% homology in amino acid sequence among the genes.

It is likely that a primordial gene coded for a single immunoglobulin fold sequence of approximately 110 amino acids and that **gene duplication** events resulted in the three repeating units within the same IgG H γ gene. Mutations modified the individual sequences so that an exact sequence correspondence no longer exists. However, each immunoglobulin fold has a similar length and folding pattern stabilized by a cystine linkage. Later in evolution further gene duplications led to the multiple genes (γ_1, γ_2, γ_3, and γ_4) that code for the constant regions of the IgG classes.

Immunoglobulin Fold Is Found in a Large Family of Proteins with Different Functional Roles

The immunoglobulin fold is present in many nonimmunological proteins, which exhibit widely different functions. On the basis of their structural homology they are grouped into a **protein superfamily** (Figure 9.10). The Class I major histocompatibility complex proteins are in this superfamily; they have immunoglobulin folds like those in antibody molecules consisting of two stacked antiparallel β-sheets enclosing an internal space filled mainly by hydrophobic amino acids. Two cysteines in the structure form a disulfide bond linking the facing β-sheets. Transcription factors Nf-κB and p53 also contain an immunoglobulin fold motif. It has been speculated that gene duplication during evolution led to distribution of the immunoglobulin fold motif in functionally diverse proteins.

9.3 • PROTEINS WITH A COMMON CATALYTIC MECHANISM: SERINE PROTEASES

Serine proteases are a family of enzymes that use a uniquely activated serine residue in their substrate-binding site to catalytically hydrolyze peptide bonds. This serine is characterized by the irreversible reaction of its side chain hydroxyl group with diisopropylfluorophosphate (DFP) (Figure 9.11). Of all the serines in the protein, DFP reacts only with the catalytically active serine to form a phosphate ester.

Proteolytic Enzymes Are Classified by Their Catalytic Mechanism

Proteolytic enzymes are classified according to their catalytic mechanism. Besides serine proteases, other classes utilize cysteine (**cysteine proteases**), aspartate (**aspartate proteases**), or metal ions (**metalloproteases**) to perform their catalytic function. Those which hydrolyze

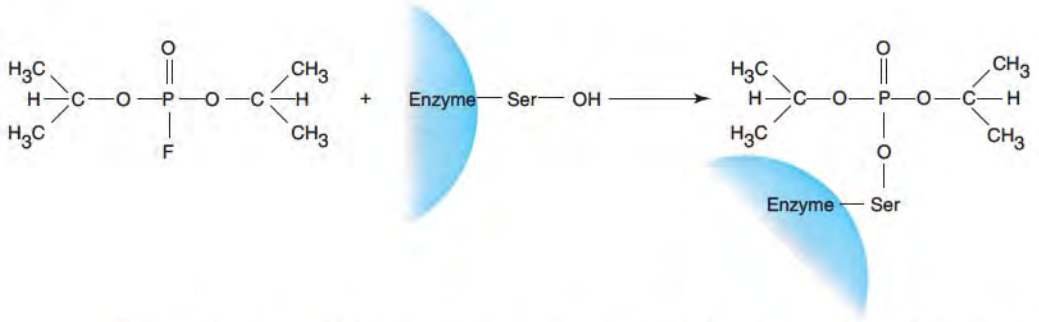

Figure 9.11 Reaction of diisopropylfluorophosphate (DFP) with the active-site serine in a serine protease.

peptide bonds in the interior of a polypeptide are **endopeptidases**, and those which cleave the peptide bond of either the COOH- or NH_2-terminal amino acid in polypeptide substrates are **exopeptidases**.

Serine proteases often activate other serine proteases from their inactive precursor form, termed a **zymogen**, by cleavage of a specific peptide bond. This mechanism of zymogen activation allows serine proteases to participate in carefully controlled physiological processes such as blood coagulation (Clin. Corr. 9.4), fibrinolysis, complement activation (see Clin. Corr. 9.1, p. 336), fertilization, and hormone production (Table 9.2). The serine protease activations are examples of **limited proteolysis** because only one or two specific peptide bonds of the hundreds in the protein substrate are hydrolyzed. Under denaturing conditions, however, these same proteases hydrolyze multiple peptide bonds that lead to digestion of peptides, proteins, and even self-digestion (autolysis). Several diseases, such as emphysema, arthritis, thrombosis, cancer metastasis (Clin. Corr. 9.5), and some forms of hemophilia, are thought to result from the lack of regulation of a specific serine protease.

CLINICAL CORRELATION 9.4

Fibrin Formation in a Myocardial Infarct and Use of Recombinant Tissue Plasminogen Activator (rt-PA)

Blood coagulation results from an enzyme cascade process in which inactive precursor serine proteases (zymogens) are activated by other serine proteases in a stepwise manner (the coagulation pathway is described in Chapter 22). These activation events generate catalytic products producing a dramatic amplification of the initial signal of the pathway. The end product of the coagulation pathway is a cross-linked fibrin clot. The zymogen components include factor II (prothrombin), factor VII (proconvertin), factor IX (Christmas factor), factor X (Stuart factor), factor XI (plasma thromboplastin antecedent), and factor XII (Hageman factor). The Roman numeral designation indicates the order of their discovery and not their order of action within the pathway. On activation, the enzymes are denoted with the suffix "a." Thus, prothrombin is denoted as factor II, and catalytically active thrombin factor as IIa.

The main function of coagulation is to maintain the integrity of the closed circulatory system after blood vessel injury. The process, however, can become dangerously activated in a myocardial infarction, resulting in a decrease blood flow to heart muscle. About 1.2 million individuals suffer heart attacks each year in the United States, which result in approximately 500,000 deaths.

A fibrinolysis pathway in plasma degrades the fibrin clots once formed. The counteracting pathway also utilizes serine proteases activated from zymogens. The end reaction of the fibrinolysis pathway is formation of plasmin, a serine protease, which acts directly on fibrin to degrade the fibrin clot. Tissue plasminogen activator (t-PA) is a plasminogen (plasmin zymogen) activator. Recombinant t-PA (rt-PA) is produced by gene cloning technology (p. 262). Clinical studies show that the administration of rt-PA shortly after a myocardial infarct significantly enhances recovery. Plasminogen activators such as urokinase and streptokinase are also effective.

CLINICAL CORRELATION 9.5

Involvement of Serine Proteases in Tumor Cell Metastasis

The serine protease urokinase plasminogen activator is believed to be required for metastasis of cancer cells. Metastasis is the process by which a cancer cell leaves a primary tumor and migrates through the blood or lymph systems to another tissue or organ, where a secondary tumor grows. Increased synthesis of urokinase-type plasminogen activator (uPA) has been correlated with an increased ability to metastasize in many cancers. uPA activates plasminogen to form plasmin. Plasminogen is ubiquitously located in the extracellular space and its activation to plasmin can cause degradation of proteins in the extracellular matrix through which the metastasizing tumor cells migrate. Plasmin can also convert procollagenase to collagenase, which promotes degradation of collagen in the basement membrane surrounding the capillaries and lymph system. This promotion of proteolytic activity by uPA secreted by tumor cells or stromal cells in the environment of tumor cells allows tumor cells to degrade the extracellular matrix proteins and invade through the matrix to form secondary tumor sites.

Serine Proteases Exhibit Remarkable Specificity in Peptide Bond Hydrolysis

Many serine proteases prefer to hydrolyze peptide bonds next to a particular type of amino acid. Thus trypsin preferentially cleaves on the carboxyl side of the basic amino acids arginine and lysine, and chymotrypsin cleaves on the carboxyl side of large hydrophobic side-chain amino acid residues such as tryptophan, phenylalanine, tyrosine, and leucine. Elastase cleaves on the carboxyl side of small hydrophobic residues such as alanine. A serine protease is trypsin-like, chymotrypsin-like, or elastase-like if it has specificity similar to the named enzymes. The specificity for a certain type of amino acid only indicates an enzyme's relative preference. Trypsin also cleaves peptide bonds following hydrophobic amino acids, but at a much slower rate than the basic amino acids. Thus specificity for hydrolysis of a peptide bond may not be absolute, but may be more accurately described as a range of most likely targets. Each of the identical amino acid hydrolysis sites within a protein substrate is not equally susceptible. Trypsin hydrolyzes each of the arginine peptide bonds in a particular protein at a different catalytic rate, and some may require a conformational change to make them accessible.

The specificity of serine proteases for particular peptide bonds has been determined with synthetic substrates with fewer than 10 amino acids (Table 9.3). Because these are significantly smaller than the natural ones, they interact only with the catalytic site (primary binding site S_1, p. 347) and are said to be **active-site directed**. Studies with small substrates and inhibitors indicate that the site of hydrolysis in polypeptide substrates is flanked by approxi-

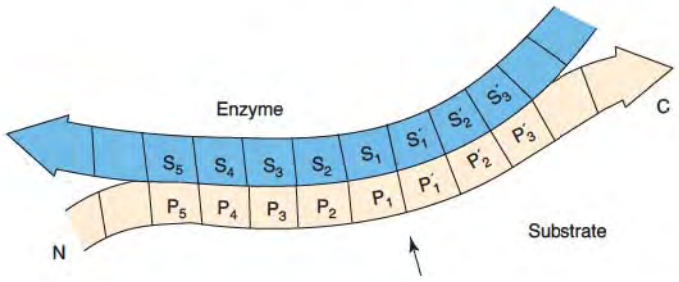

Figure 9.12 Schematic diagram of binding of a polypeptide substrate to binding site in a proteolytic enzyme. P_5—P'_5 are amino acid residues in the substrate that bind to subsites S_5—S'_5 in the enzyme with peptide hydrolysis occurring between P_1—P'_1 (arrow). NH_2-terminal direction of substrate polypeptide chain is indicated by N, and COOH-terminal direction by C. Redrawn from Polgar, L. In Neuberger, A. and Brocklehurst, K. (Eds.), *Hydrolytic Enzymes.* Amsterdam: Elsevier, 1987, 174.

mately four residues in both directions that bind to the enzyme and impact on the reactivity of the bond hydrolyzed. The two residues in the substrate that contribute the hydrolyzable bond are designated **P_1—P'_1**. Thus in trypsin substrates the P_1 residue will be lysine or arginine, and in chymotrypsin substrates P_1 will be a hydrophobic amino acid. The P_1 residue interaction with the S_1 site provides the primary interaction between substrate and enzyme. The other interacting amino acid residues of the protein substrate are labeled P_4—P_2 and P'_2—P'_4 on either end of the scissile bond, respectively. The complementary regions in the enzyme that bind these residues in the substrate are designated subsites **S_4—S'_4** (Figure 9.12). It is the **secondary interactions** with the substrate outside S_1—S'_1 that ultimately determines a protease's specificity toward a particular protein substrate. Thus, the coagulation serine protease factor Xa cleaves only at a particular arginine in prothrombin to produce thrombin. It is the secondary interaction that allows factor Xa to recognize the particular arginine it cleaves in prothrombin. The interactions of P_4—P'_4 with the subsites S_4–S'_4 are noncovalent. The extended binding site in the substrate interacts with the binding site in the enzyme to produce a β-sheet structure between the enzyme and the substrate, which places the scissile peptide bond of the substrate in the S_1–S'_1 position (Figure 9.13).

Serine Proteases Are Synthesized as Zymogens and in Multiple Domain Proteins

Serine proteases are synthesized as **zymogens** that require limited proteolysis to produce the active enzyme. The coagulation zymogens are synthesized in liver cells and are secreted into the blood for subsequent activation following vascular injury by other serine proteases. Zymogens are usually designated by adding the suffix -ogen to the enzyme name; as in trypsin*ogen* and chymotrypsin*ogen*. In some cases the zymogen is referred to as a **proenzyme**; for example, the zymogen of thrombin is prothrombin.

Several plasma serine proteases have zymogen forms that contain **multiple nonsimilar domains**. Protein C, involved in a fibrinolysis pathway in blood, has four distinct domains (Figure 9.14). The NH_2-terminal domain contains the derived amino acid, **γ-carboxyglutamic acid** (Figure 9.15), which is formed by carboxylation of glutamic acid

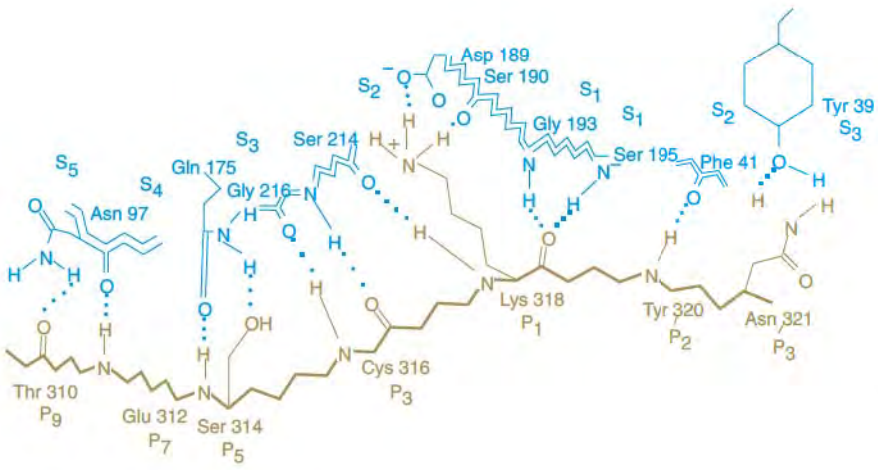

Figure 9.13 Schematic drawing of binding of pancreatic trypsin inhibitor to trypsin. Binding site region of trypsin (blue) shown in complex with region of pancreatic trypsin inhibitor (brown), which models the binding of a polypeptide substrate. Dotted lines are hydrogen bonds. The inhibitor has an extended conformation so that amino acids P_9, P_7, P_5, P_3, and P_1—P'_3 interact with binding subsites S_5—S'_3 in trypsin. Potentially hydrolyzable bond in inhibitor is between P_1—P'_1 (amino acids 318 and 319 of which only Lys318 is visible).

The diagram is based on X-ray diffraction of the complex of pancreatic trypsin inhibitor with trypsinogen. The binding region of trypsinogen in the complex assumes a conformation like that of active trypsin bound to a protein substrate. residues in a vitamin K–dependent reaction (pp. 987 and 994). The γ-carboxyglutamates chelate Ca^{2+} and form part of a site that binds cell membranes. The COOH-terminal region contains the catalytic domains. Activation from the zymogen form requires peptide bond cleavage outside the catalytic domains and is controlled by the binding of the γ-carboxyglutamate-containing NH_2-terminal end through calcium ions to a membrane site.

Tertiary Structures of the Catalytic Domains of Serine Proteases Are Similar

Trypsin-like serine proteases constitute a superfamily of proteins with two distinct closed β-barrel domains of the same fold and equal size (Figure 9.16), which do not penetrate one another. Loop regions protrude from the barrel structures, being almost symmetrically presented by each of the two folded domains. These loops combine to form a surface region that extends outward, above the catalytic site, and are functionally similar to the CDRs of immunoglobulins. Structure determinations by X-ray crystallography have been carried out

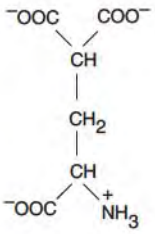

Figure 9.15 Structure of the derived amino acid γ-carboxyglutamic acid (abbreviation Gla), found in NH_2-terminal domain of many coagulation proteins.

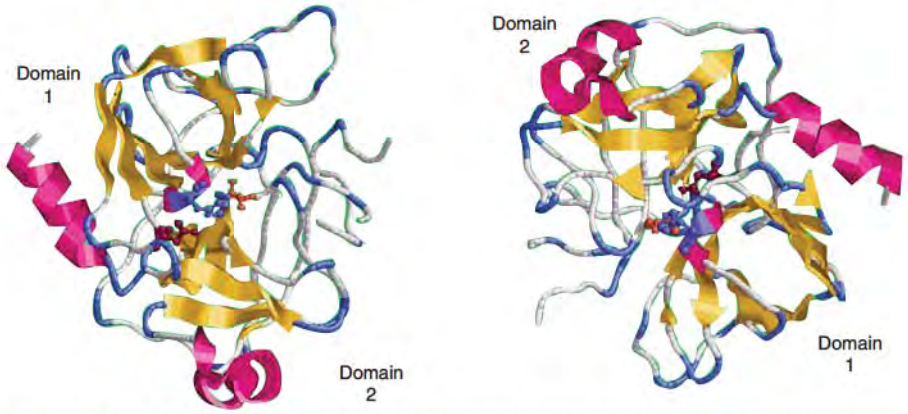

Figure 9.16 Two views of trypsin-like catalytic domains showing β-barrel fold structure of the domains with active site residues at the domain interface. β-strands are yellow arrows, α-helices are magenta, turns are pale blue, and all other residues are white. Active site serine-195 (orange), histidine-57 (blue), and aspartate-102 (reddish-brown) are shown.
B and C chains from human α-chymotrypsin, PDB 6CHA, are visualized with RasMol.

on many members of the trypsin-like serine protease protein family (Table 9.4), including active enzyme forms, zymogens, the same enzyme in multiple species, enzyme-inhibitor complexes, and a particular enzyme at different temperatures and in different solvents.

Alignment of three-dimensional structures can be performed on serine proteases. Table 9.5 shows for sets of two proteases the number of amino acids that are superimposable in the 3-dimensional structures and the number that are chemically identical in comparison of the sequences. Structurally superimposable amino acids, even if they differ chemically, cannot be distinguished from one another at the resolution of the X-ray diffraction. The proteins are more homologous in their structures than in sequence. The regions of greatest difference are in the CDR-like loop regions. Altering these loops changes the **macromolecular-binding specificity** of the protease. The structure of the loop in factor Xa, for example, allows it to bind specifically to prothrombin. Protease inhibitors interact with different proteases through their affinity for the loop structures. Bacterial proteases related to the eukaryotic serine protease family contain the same two domains but lack most of the loops. This agrees with their lack of a requirement for complex interactions and the observation that bacterial proteases are not synthesized as zymogens.

Ser-195 in chymotrypsin reacts with the inhibitor diisopropylfluorophosphate (DFP), with a 1:1 enzyme:DFP stoichiometry (p. 344 and Figure 9.11). The three-dimensional structure of chymotrypsin reveals that the Ser-195 is situated within an internal pocket, with access to the solvent interface. His-57 and Asp-102 are oriented so that they participate with the Ser-195 in the catalytic mechanism. Thus the serine protease family constitutes

TABLE 9.5 • Structural Superposition of Selected Trypsin Family Serine Proteases and the Resultant Amino Acid Sequence Comparison

	Number of Amino Acids in Sequence

Trypsin–*S. griseus* protease	223	180	121	25

a structurally related series of proteins that use a catalytically active serine. During evolution, the basic two-domain structure and the catalytically essential residues have been maintained, but the regions of the secondary interactions (loop regions) have changed to provide for different specificities toward substrates, activators, and inhibitors, related to their diverse physiological roles.

Serine Proteases Have Similar Structure–Function Relationships

The relationships between structure and physiological function of the serine proteases are summarized as follows: (1) Only one serine residue is catalytically active and participates in peptide bond cleavage. Bovine trypsin contains 34 serine residues with only one catalytically active or able to react with the inhibitor DFP (Figure 9.11, p. 344). (2) X-ray diffraction and sequence homology studies demonstrate that a histidine and an aspartate are always associated with the activated serine in the catalytic site. On the basis of their positions in chymotrypsinogen, these three invariant residues are named Ser 195, His 57, and Asp 102 and called the *catalytic triad*. This numbering, based on their sequence number in chymotrypsinogen, is used to identify these residues irrespective of their exact position in any serine protease. (3) Eukaryotic serine proteases exhibit high sequence and structural similarity. (4) Genes that code for serine proteases are organized similarly (Figure 9.17). Their **exon–intron patterns** show that each of the catalytically essential residues (Ser-195, His-57, and Asp-102) is on a different exon. The essential histidine and serine are all almost adjacent to their exon boundary. The cross-species homology in gene structure supports the concept that the serine proteases evolved from a common primordial gene. (5) The catalytic portion of serine proteases comprises two domains, of approximately equal size. The catalytic site is within their interface or the crevice between the two domains. The three-dimensional structure of the catalytic site in serine proteases is complementary to structure of the reaction transition state and contains an oxyanion site to stabilize the transition state of the peptide hydrolysis reaction. (7) Serine proteases that interact with membranes typically have an additional domain to provide for this specific function. (8) Natural protein substrates and inhibitors of serine proteases bind through an extended specificity site. (9) Specificity for natural protein inhibitors is marked by extremely tight binding. The binding constant for trypsin to pancreatic trypsin inhibitor is about 10^{13}/M, reflecting a binding free energy of approximately 75 kJ/mol (18 kcal/mol). (10) Natural protein inhibitors are usually poor substrates with strong inhibition requiring hydrolysis of a peptide bond in the inhibitor by the protease. (11) Serine proteases in eukaryotes are synthesized as zymogens to permit their transport in an inactive state to their sites of action. (12) Zymogen activation frequently involves hydrolysis by another serine protease. (13) Several serine proteases undergo **autolysis** or self-hydrolysis.

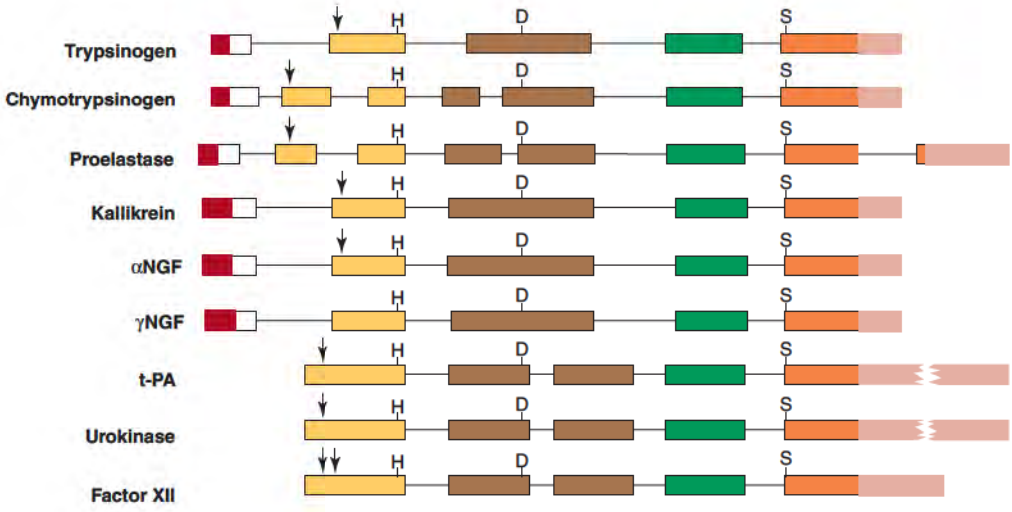

Figure 9.17 Organization of exons and introns in genes for serine proteases. t-PA is tissue plasminogen activator and NGF is nerve growth factor which contain a structure homologous to a serine protease. Exons are shown by boxes and introns by connecting lines. Position of the codons for active-site serine, histidine, and aspartate are denoted by S, H, and D, respectively. Red boxes, on left, show regions that code for NH_2-terminal signal peptide that is cleaved before secretion. Light-colored boxes, on right, represent part of gene sequence transcribed into messenger RNA (mRNA), but not translated into protein. Arrows show codons for residues at which proteolytic activation of zymogen occurs. Redrawn and modified from Irwin, D. M., Roberts, K. A., and MacGillivray, R. T. J. *Mol. Biol.* 200:31, 1988.

Sometimes this leads to specific peptide bond cleavage and further activation of the catalytic activity. At other times autolysis leads to inactivation of the protease.

Sequence Homology in Serine Proteases

Much early knowledge of the serine protease family came from trypsin and chymotrypsin purified from bovine materials. This has yielded a useful but nonintuitive nomenclature, which uses a sequence alignment against the amino acid sequence of chymotrypsin, to name and number residues of other serine proteases. As mentioned previously, the catalytically essential residues are Ser-195, His-57, and Asp-102. Insertions and deletions of the amino acids in another serine protease are compared to the numbering of residues in chymotrypsin. Alignment is made by algorithms that maximize sequence homology, with exact alignment of the essential serine, histidine, and aspartate residues. These three residues are invariant in all serine proteases and the sequences surrounding them are invariant among the serine proteases of the trypsin family (Table 9.6).

Members of the trypsin family also occur in prokaryotes. Thus, bacterial serine proteases from *Streptomyces griseus* and *Myxobacteria* 450 are homologous with trypsin. However, a separate class of serine proteases first discovered in bacteria has no structural homology to the mammalian trypsin family. The serine protease subtilisin, isolated from *Bacillus subtilis,* hydrolyzes peptide bonds and contains an activated serine with a histidine and aspartate in its active site and an active site structure complementary to the hydrolytic reaction transition state, but its active site arises from structural regions of the protein that have no sequence or structural homology with the trypsin family. Serine proteases of the subtilisin family are also found in human cells. This is an example of **convergent evolution** of an enzyme catalytic mechanism. Apparently a completely different gene evolved the same catalytic mechanism for peptide hydrolysis.

Mechanism of Serine Protease Catalysis

All trypsin-like serine proteases catalyze peptide bond hydrolysis by an identical catalytic mechanism with the coordinate actions of an active site Ser-195, His-57, and Asp-102. These residues are in different domains of the two domains that make up the catalytic unit. In the folded protein the three-dimensional structures bring these residues together at the domain interface that comprises the primary site for catalysis (Figure 9.18). The imidazole nitrogens of His-57s form hydrogen bonds to the Ser-195 $^{\gamma}$OH and to the Asp-102 side-chain carboxylate. In protease-catalyzed hydrolysis, the histidine acts as a general base catalyst and the $^{\gamma}$O of the serine forms a transient covalent ester intermediate with a part of the substrate. These mechanisms involving the Ser-195 and His-57 facilitate the breaking of the scissile peptide bond of the substrate bound to the active site.

In addition to the three catalytically essential amino acids of the active site, all active sites have features that stabilize the transition-state structure of the reaction. The transition state is the highest energy structure on the reaction pathway to which the substrate is elevated. The rate of the reaction is dependent on the energy required to reach the structure of the transition state, and enzymes accelerate reaction rates by decreasing the energy required to reach the transition-state structure. One way of decreasing this energy is to stabilize the hydrolytic transition-state structure. All serine protease active sites contain two hydrogen-bond donating groups oriented and poised to donate hydrogen bonds that stabilize the transition-state structure (Figure 9.18). The exact placement of these hydrogen-bond donating groups within the active site is a catalytically critical structural feature of the protease enzymes.

Specific Protein Inhibitors of Serine Proteases

Evolution of the serine protease family for participation in physiological processes promoted a parallel evolution of inhibitors. Specific proteins inhibit the activity of serine proteases when their physiological role has ended (Table 9.7). Thus, coagulation is limited to the site of vascular injury and complementation activation leads to lysis only of cells exhibiting foreign antigens. Inability to control these proteases, such as by a deficiency of a specific inhibitor, can lead to undesirable consequences, such as thrombus formation initiating myocardial infarction and stroke or uncontrolled reactions of complement in autoimmune disease. These natural inhibitors of serine proteases are termed **serpins** for **ser**ine **p**rotease **in**hibitors. They occur in animals that produce the proteases, but surprisingly they are also found in plants that lack proteases.

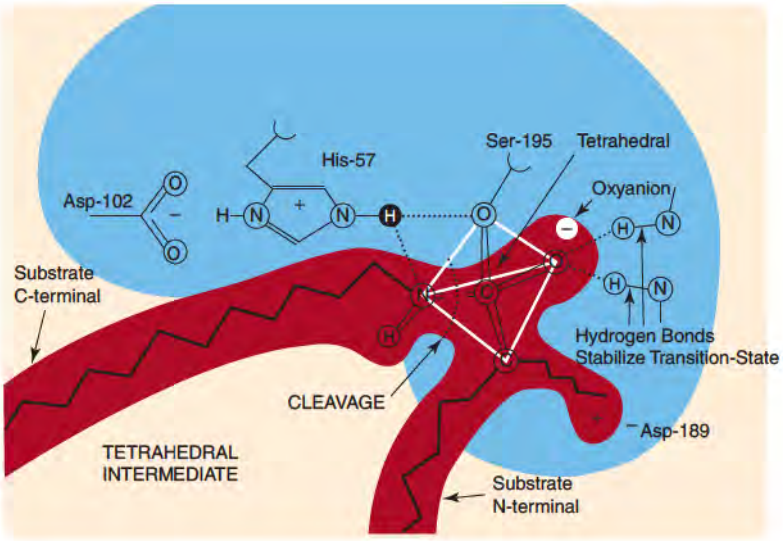

Figure 9.18 Stabilization of peptide hydrolysis reaction transition-state Structure by trypsin. Polypeptide substrate is shown in red with the atoms of the α-carbon, side chain (lysine), and labile peptide bond of the P_1 residue in the substrate. The labile peptide bond is in an intermediate structure like that of the proposed reaction transition state, in which the carbonyl carbon to nitrogen peptide bond is being broken while the bond between the Ser-195 $^{\gamma}$O and carbonyl carbon is being made. In this structure the carbonyl carbon is transiently bonded to four different atoms and the carbonyl oxygen is negatively charged. The enzyme active is in blue and contains the catalytically essential Ser-195, His-57, and Asp-102. The polypeptide chain of the enzyme active site contributes two hydrogen bonds that stabilize the transition-state structure. Modified from figure by Stroud, R. M. *Sci. Am,* 231:74, 1974.

TABLE 9.7 • Some Human Proteins that Inhibit Serine Proteases

Inhibitor	*Action*
α_1-Proteinase inhibitor	Inhibits tissue proteases including neutrophil elastase; deficiency leads to pulmonary emphysema
α_1-Antichymotrypsin	Inhibits proteases of chymotrypsin-like specificity from neutrophils, basophils, and mast cells including cathepsin G and chymase
Inter-α-trypsin inhibitor	Inhibits broad range of serine protease activities in plasma
α_2-Antiplasmin	Inhibits plasmin
Antithrombin III	Inhibits thrombin and other coagulation proteases
C_1 Inhibitor	Inhibits complement reaction
α_2-Macroglobulin	General protease inhibitor
Protease nexin I	Inhibits thrombin, urokinase plasminogen activator, and plasmin
Protease nexin II	Inhibits growth factor-associated serine proteases, identical to NH_2-terminal domain of amyloid protein secreted in Alzheimer's disease
Plasminogen activator inhibitor I	Inhibits plasminogen activators
Plasminogen activator inhibitor II	Inhibits urokinase plasminogen activator

9.4 • HEMOGLOBIN AND MYOGLOBIN

Hemoglobins are globular proteins, present in high concentrations in red blood cells that bind oxygen in the lungs and transport it to cells of the tissues. They also transport CO_2 and H^+ from the tissues to the lungs, and carry and release nitric oxide (NO) in the blood vessels of the tissues. NO is a potent vasodilator and inhibitor of platelet aggregation. The molecular structure and chemistry of the hemoglobins beautifully fit these complex and interrelated physiological roles.

Human Hemoglobin Occurs in Several Forms

A hemoglobin molecule consists of four polypeptide chains, two each of two different sequences. Each chain contains a heme prosthetic group that binds oxygen. On the binding of O_2 to a hemoglobin molecule to form $Hb(O_2)_4$, the four O_2-binding sites act in a cooperative manner. The major form of human adult hemoglobin, **HbA_1**, consists of two α and two β chains ($\alpha_2\beta_2$). The α-polypeptide contains 141, and the β-polypeptide 146 amino acids. The fetal form (**HbF**) (Figure 9.19) contains the same α chains as HbA_1, and γ chains that differ in sequence from the β chain (Table 9.8). Two other hemoglobin forms appear in the first months after conception (embryonic) in which the α chains are substituted by zeta (ζ) chains of different sequence and the ε chains serve as the β chains. A minor adult hemoglobin, **HbA_2**, composes about 2% of normal adult hemoglobin and contains

Embryo	Hb Portland	$\zeta_2\gamma_2$

two α chains and two chains designated delta (δ) (Table 9.8). A discussion of abnormal hemoglobins is presented in Clin. Corr. 9.6.

Myoglobin: A Single Polypeptide with One O_2-Binding Site

Myoglobin (Mb) is an O_2 binding protein that captures and releases O_2 with changes in the O_2 concentration in the sarcoplasm of skeletal muscle cells. In contrast to hemoglobin, which has four chains and four O_2-binding sites, myoglobin contains only a single polypeptide chain and one O_2-binding site. Myoglobin is a model for what occurs when a single protomer molecule acts alone without the interactions exhibited among the four O_2-binding sites in the more complex tetramer molecule of hemoglobin.

CLINICAL CORRELATION 9.6

Hemoglobinopathies

There are well over 800 known mutant human hemoglobins. Mutations cause instability in hemoglobin structure, increased or decreased oxygen affinity, or an increase in the rate of oxidation of the heme ferrous iron (Fe^{+2}) to the ferric state (Fe^{+3}). A nonfunctional ferric hemoglobin is designated methemoglobin and is symbolized HbM.

Unstable hemoglobin can arise by the substitution of proline for an amino acid within an α-helical region of the globin fold. Prolines do not participate in α-helical structure and the breaking of an α-helical segment causes an unstable hemoglobin (examples are $Hb_{Saki}^{\beta Leu14\rightarrow Pro}$ and $Hb_{Genova}^{\beta 28Leu\rightarrow Pro}$). Other unstable hemoglobins arise from substitution by an amino acid that is either too large or too small to make appropriate contacts or by placement of a charged or polar group on the inside of a domain. Unstable hemoglobins easily denature and may precipitate to form Heinz bodies, which damage the erythrocyte membrane. Patients with unstable hemoglobins develop anemia, reticulocytosis, splenomegaly, and urobilinuria.

Some mutant hemoglobins have an increased oxygen affinity (lower P_{50}). An interesting example is $Hb_{Cowtown}^{\beta His146\rightarrow Leu}$, in which the histidine that dissociates 50% of the Bohr-effect protons is lost. This mutation impedes the regulation of oxygen dissociation by hydrogen ion concentration and destabilizes the T conformation relative to the R conformation, causing an increase in oxygen affinity and decreased release of O_2 to the tissues. Hemoglobin mutations that impair BPG binding also increase oxygen affinity. Hemoglobinopathies of increased oxygen affinity are often characterized by hemolytic anemia and Heinz body formation.

Mutant hemoglobins that form methemoglobin include $HbM_{Iwate}^{\alpha 87His\rightarrow Tyr}$ and $HbM_{Hyde\ Park}^{\beta 92His\rightarrow Tyr}$ where the proximal histidines F8 in the α and β chains, respectively, are mutated. In $HbM_{Boston}^{\alpha 58His\rightarrow Tyr}$ and $HbM_{Saskatoon}^{\beta 63His\rightarrow Tyr}$ the distal E7 histidines are mutated. Mutations of amino acids that pack against the heme or form the oxygen-binding site often lead to methemoglobinemia. Patients with high concentrations of methemoglobin show cyanosis (bluish color of the skin).

Two of the most prevalent mutations occur at the same amino acid position, the β6Glu. When this glutamate is replaced by valine, the result is $HbS^{\beta 6Glu\rightarrow Val}$, whereas replacement by lysine yields $HbC^{\beta 6Glu\rightarrow Lys}$. Homozygotes with HbS have sickle-cell anemia in which the hemoglobin molecules precipitate as tactoids or long arrays, which produce the sickle shape of the erythrocyte. HbC forms a different aggregate structure consisting of blunt-ended crystalloids. This reduces the survival time of the red blood cells but produces less hemolysis than HbS. This form of hemoglobinopathy exhibits more limited pathological effects. As both HbS and HbC are commonly found among certain black African populations, it is not unusual to find individuals heterozygous for both mutant genes among this population. Individuals with HbSC will have an intermediate anemia between that observed of homozygotes for HbS and HbC.

The Heme Prosthetic Group Is Site of O_2 Binding

The four globin subunits in hemoglobin and the one of myoglobin each contain a heme prosthetic group. A **prosthetic group** is a nonpolypeptide moiety that forms a functional part of a protein. Without its prosthetic group, a protein is designated an **apoprotein**. With its prosthetic group it is a **holoprotein**.

In hemoglobins and myoglobin the heme is protoporphyrin IX (p. 791) with an iron atom in its center (Figure 9.20). The iron is in the ferrous (+2 charge) state in functional hemoglobin and myoglobin where it can form five or six covalent bonds, depending on whether or not O_2 is bound. Four bonds are to the pyrrole nitrogen atoms of the porphyrin. As the pyrrole rings and connecting carbons are part of the same aromatic system, these atoms lie in a common plane. The porphyrin bonded Fe^{+2} will tend to lie in this same porphyrin plane. The fifth and the potentially sixth bonds to Fe^{+2} are directed along an axis perpendicular to the plane of the porphyrin ring (Figure 9.21). The fifth bond is to a nitrogen of a histidine imidazole. This is designated the **proximal histidine** in globin structures (Figures 9.21 and 9.22). In oxy-globins, O_2 forms the sixth bond, the O_2 being between the ferrous atom and a second histidine imidazole, designated the **distal histidine**. In deoxy-globins, the sixth position is unoccupied.

The heme is positioned within a hydrophobic pocket of each globin subunit. In the pocket about 18 amino acid residues, mostly between apolar side chains and the apolar regions of the porphyrin, provide approximately 80 interactions. The driving force for the interaction is the expulsion of water of solvation on association of the hydrophobic heme with the apolar side chains in the heme pocket (see hydrophobic forces, p. 116). Additional interactions in myoglobin are made between the negatively charged propionate groups of the heme and positively charged arginine and histidine side chains. In hemoglobin chains a difference in the amino acid sequence in this region of the heme binding site leads to stabilization of the porphyrin propionates by interaction with an uncharged histidine imidazole and with water molecules of solvent toward the outer surface of the molecule.

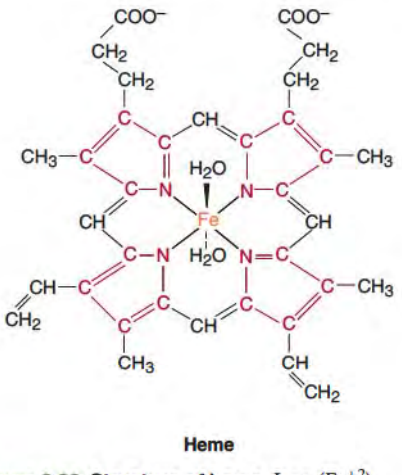

Figure 9.20 Structure of heme. Iron (Fe^{+2}) has four bonds to the pyrrole nitrogens in planar porphyrin. The fifth and six bonds are perpendicular to porphyrin plane. Porphyrin structure is protoporphyrin type IX.

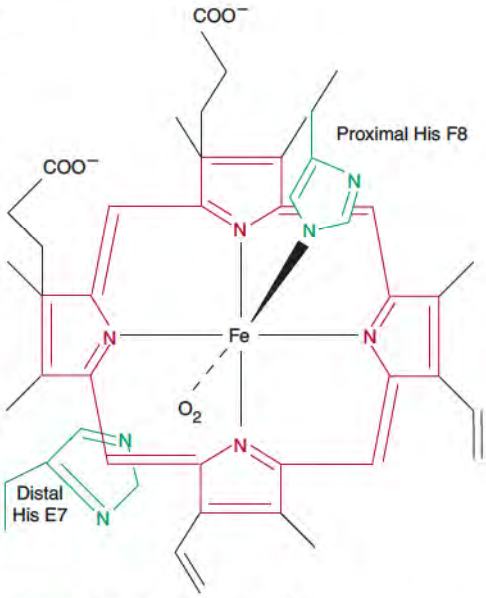

Figure 9.21 Ligand bonds to ferrous atom in oxyhemoglobin.

X-Ray Crystallography Has Defined the Structures of Hemoglobin and Myoglobin

The structures of deoxy and oxy forms of hemoglobin and myoglobin have been resolved by X-ray crystallography. In fact, sperm whale myoglobin was the first protein whose structure was determined by this technique, followed by horse hemoglobin. These structures show that

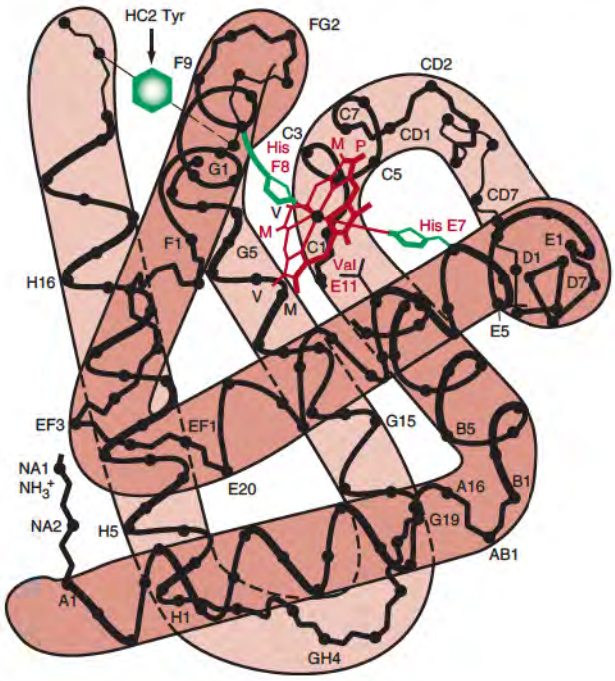

Figure 9.22 Secondary and tertiary structure characteristics of globins of hemoglobin. Proximal His F8, distal His E7, Tyr HC2, and Val E11 side chains are shown. Other amino acids of polypeptide chain are represented by α-carbon positions only; the letters M, V, and P refer to the methyl, vinyl, and propionate side chains of the heme.

each globin consists of multiple α-helical regions connected by turns that allow folding into a spheroidal shape characteristic of the globin fold (Figure 9.22 and Figure 3.37, p. 101).

Primary, Secondary, and Tertiary Structures of Myoglobin and Hemoglobin Chains

Comparison of the amino acid sequences of myoglobin from many animal species shows all myoglobin chains contain 153 amino acids, of which 83 are invariant. Only 15 invariant residues are identical to the invariant residues of the globin chains in mammalian hemoglobins. While there is surprising variability in sequences, the secondary and tertiary structures are almost identical (Figure 9.23). In addition, all the globin chains function to reversibly bind oxygen. However, when comparing the myoglobin sequences to the sequences of the globin chains in hemoglobin, the changes are mostly conservative and preserve the physical properties of the residues (Table 9.9). Changes in the sequence between the myoglobin and hemoglobin sequences are partially explained by myoglobin acting as a monomer; hence many of its surface positions interact with water and prevent another molecule of myoglobin from associating. In contrast, surface residues of the individual subunits in hemoglobin provide hydrogen bonds and nonpolar contacts with other subunits in the quaternary structure. The proximal and distal histidines to the heme iron are preserved in all the globin chains, as are the hydrophobic heme pockets that form essential nonpolar contacts with the heme.

Any significant differences in the physiological properties between α, β, γ, and δ chains of hemoglobins and the chain of myoglobin are due to rather small specific changes in their structures. The similarity in tertiary structure shows that the same fold structure of a polypeptide can be arrived at by different sequences.

Approximately 70% of the residues participate in the α-helices of the globin fold, generating seven α-helices in the α chain and eight in the β chain. These latter eight helical regions are commonly labeled A–H, starting from the NH_2-terminal end. The interhelical regions are designated as AB, BC, CD, . . . , GH, respectively. The nonhelical region at the NH_2-terminal end is designated NA, and that at the COOH-terminal end is HC (Figure 9.22). Amino

[a]Myoglobin from sperm whale. Residues that are identical are enclosed in box. A, B, C, . . . designate different helices of tertiary structure (see text).

acid residues are sequentially numbered from 1 in each of the lettered helices and interhelical regions. This numbering system allows discussion of particular regions and residues that have similar functional and structural roles in hemoglobin and myoglobin.

A Simple Equilibrium Defines O_2 Binding to Myoglobin

The association of oxygen with myoglobin is characterized by a simple equilibrium constant (Eqs, 9.1 and 9.2). [MbO_2] is the solution concentration of oxymyoglobin, [Mb] is deoxymyoglobin, and [O_2] is oxygen, all in units of moles/liter. The equilibrium constant,

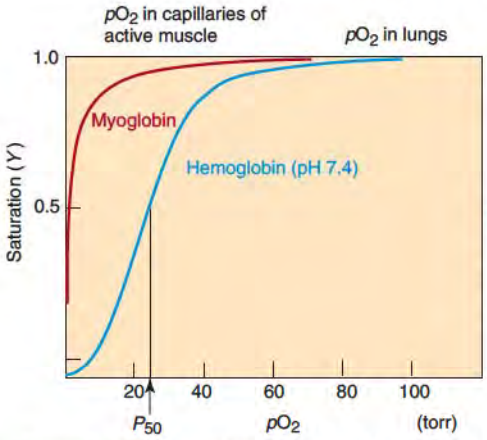

Figure 9.24 Oxygen-binding curves for myoglobin and hemoglobin. The plots place the myoglobin curve near the zero pO_2 value in this coordinate system. If the pO_2-axis was expanded around the region of the myoglobin P_{50}, the lower sensitivity of the change in Y in myoglobin to fold-change in oxygen concentration to that of hemoglobin (see Cooperativity Index, Table 9.10) would be demonstrated. The index, based on the observed Hill coefficients, shows that myoglobin changes from $Y = 0.1$ to $Y = 0.9$ over a 81-fold change in oxygen concentration while hemoglobin takes only a 4.8-fold change in oxygen concentration.

K_{eq}, has units of moles/liter. The value of K_{eq} is dependent on pH, ionic strength, and temperature.

$$Mb + O_2 \overset{K_{eq}}{\rightleftharpoons} MbO_2 \tag{9.1}$$

$$K_{eq} = \frac{[Mb][O_2]}{[MbO_2]} \tag{9.2}$$

Since oxygen is a gas, it is convenient to express its concentration as the pressure of oxygen in torr (1 torr equals the pressure of 1 mm Hg at 0°C and standard gravity). In Eq. 9.3 this conversion of units has been made as shown by the change in symbols: P_{50}, the equilibrium constant, and pO_2, the concentration of oxygen, being expressed in torr.

$$P_{50} = \frac{[Mb] \cdot pO_2}{[MbO_2]} \tag{9.3}$$

In an oxygen binding or saturation curve the fraction of oxygen-binding sites that contain oxygen (Y, Eq. 9.4) is plotted on the ordinate *versus* pO_2 (oxygen concentration) on the abscissa. The Y-value is defined for myoglobin by Eq. 9.5. Substitution into Eq. 9.5 of the value of $[MbO_2]$ obtained from Eq. 9.3, and dividing through by [Mb] results in Eq, 9.6, which shows the dependence of Y on the value of the equilibrium constant, P_{50}, and on pO_2. From Eqs. 9.3 and 9.6, the value of P_{50} is equal to pO_2 when $Y = 0.5$ (50% of the available sites occupied), hence the designation of the equilibrium constant as P_{50}.

$$Y = \frac{\text{number of binding sites occupied}}{\text{total number of binding sites in solution}} \tag{9.4}$$

$$Y = \frac{[MbO_2]}{[Mb] + [MbO_2]} \tag{9.5}$$

$$Y = \frac{pO_2}{P_{50} + pO_2} \tag{9.6}$$

A plot of Eq. 9.6 for Y versus pO_2 generates an oxygen-saturation curve for myoglobin and has the form of a rectangular hyperbola (Figure 9.24).

A simple algebraic manipulation of Eq. 9.6 leads to Eq. 9.7. Taking the logarithm of both sides of Eq. 9.7 results in Eq. 9.8, the **Hill equation**. A plot of $\log[Y/(1 - Y)]$ versus $\log pO_2$, according to Eq. 9.8, yields a straight line with a slope equal to 1 for myoglobin (Figure 9.25). This is the Hill plot, and the slope (n_H) is the **Hill coefficient** (Eq. 9.9).

$$\frac{Y}{1 - Y} = \frac{pO_2}{P_{50}} \tag{9.7}$$

$$\log \frac{Y}{1 - Y} = \log pO_2 - \log P_{50} \tag{9.8}$$

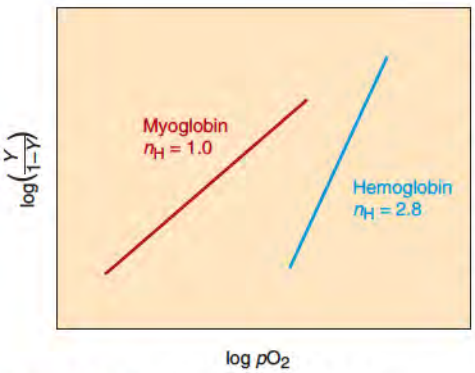

Figure 9.25 Hill plots for myoglobin and hemoglobin A_1.

Binding of O_2 to Hemoglobin Involves Cooperativity between Subunits

Binding of four O_2 to hemoglobin manifests as **positive cooperativity**, since binding of the first O_2 facilitates binding of O_2 to the other subunits. Conversely, dissociation of the first O_2 from $Hb(O_2)_4$ will make dissociation of O_2 from the other subunits easier.

Because of this cooperativity, the oxygen-saturation curve for hemoglobin differs from that for myoglobin. A plot of Y versus pO_2 for hemoglobin is sigmoidal, indicating cooperativity in oxygen association (Figure 9.24). A plot of the Hill equation (Eq. 9.9) gives a slope (n_H) equal to 2.8 (Figure 9.25). Values of $n_H = 1.0$ show no cooperativity in substrate binding to multiactive site proteins. Values of $n_H > 1.0$ show positive cooperativity with higher values correlating with greater positive cooperativity in binding. Values of n_H greater than 0 and less than 1.0 show negative cooperativity, with values closer to 0 having higher negative cooperativity.

$$\log \frac{Y}{1-Y} = n_H \log pO_2 - \text{constant} \qquad (9.9)$$

The meaning of the Hill coefficient to cooperative O_2 association is evaluated quantitatively as presented in Table 9.10. A **cooperativity index**, *Rx*, is calculated, which shows the fold change of pO_2 required to change Y from a value of $Y = 0.1$ (10% of sites filled) to a value of $Y = 0.9$ (90% of sites filled) for Hill coefficient values found experimentally. For myoglobin $n_H = 1$ and an 81-fold change in oxygen concentration is required to change from $Y = 0.1$ to $Y = 0.9$. For hemoglobin, $n_H = 2.8$, and only a 4.8-fold change in oxygen concentration is required for the same change in Y.

TABLE 9.10 • Relationship between Hill Coefficient (n_H) and Cooperativity Index (R_x)

n_H	R_x	*Observation*
0.5	6560	Negative substrate cooperativity
0.6	1520	
0.7	533	
0.8	243	
0.9	132	
1.0	81.0	Noncooperativity
1.5	18.7	Positive substrate cooperativity
2.0	9.0	
2.8	4.8	
3.5	3.5	
6.0	2.1

Molecular Mechanism of Cooperativity in O_2 Binding

X-ray diffraction data on deoxyhemoglobin show that the ferrous atoms actually sit out of the plane of their porphyrins by about 0.4–0.6 Å. The electronic configuration of the five-coordinated ferrous atom in deoxyhemoglobin has a slightly larger radius than the distance from the center of the porphyrin to each of the pyrrole nitrogen atoms. Accordingly, the iron can be placed in the center of the porphyrin only with some distortion of the porphyrin conformation. Probably more important is that if the iron atom sits in the plane of the porphyrin, the proximal His F8 imidazole will interact unfavorably with the porphyrin. This unfavorable steric interaction is due, in part, to conformational constraints on the His F8 and the porphyrin in the deoxyhemoglobin conformation that forces the approach of the His F8 toward the porphyrin to a particular path (Figure 9.26). These constraints become less significant in oxyhemoglobin. With the iron atom out of the plane of the porphyrin, the conformation is unstrained and energetically favored for the five-coordinated ferrous atom. When O_2 forms the sixth bond of the iron, however, this conformation becomes strained. A more energetically favorable conformation for the O_2-bonded iron is that in which the iron atom is within the plane of the porphyrin.

The binding energy of O_2 overcomes the repulsive interaction between His F8 and porphyrin, and the ferrous atom moves into the plane of the porphyrin. This is the most thermodynamically stable position for the oxy-heme, the six-bonded iron atom having one axial ligand on either side of the plane of the porphyrin, and the steric repulsion of one axial ligand is balanced by the repulsion of the second axial ligand on the opposite side when the ferrous atom is in the center. Also, the radius of the iron atom with six bonds is reduced

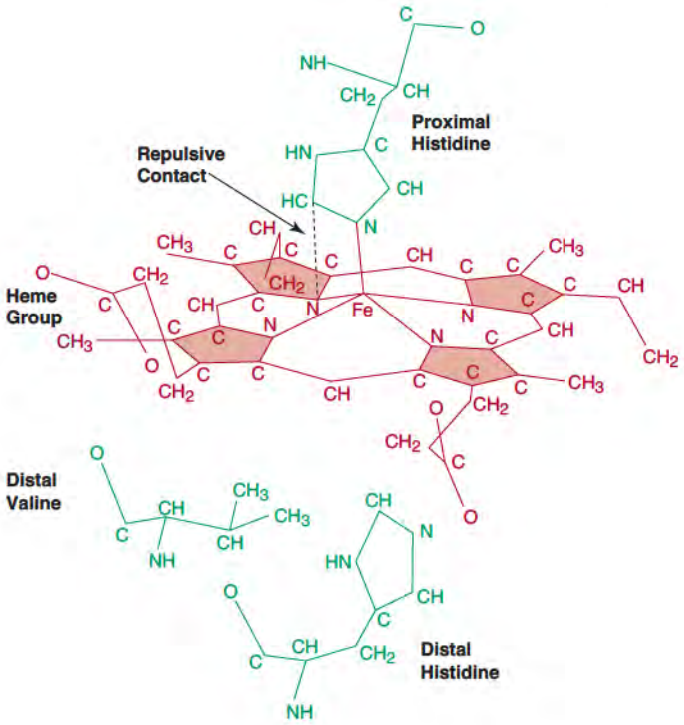

Figure 9.26 Steric hindrance between proximal histidine and porphyrin in deoxyhemoglobin. Redrawn from Perutz, M. *Sci. Am.* 239:92, 1978. Copyright (1978) by Scientific American, Inc. All rights reserved.

so that it just fits into the center of the porphyrin without distortion of the porphyrin conformation.

Since steric repulsion between porphyrin and His F8 in the deoxy-conformation must be overcome on O_2 association, binding of the first O_2 is characterized by a relatively low affinity constant. However, on binding of O_2 to the first heme, the movement of the iron into the center of the porphyrin triggers a conformational change in other subunits of the hemoglobin molecule. This change results in a greater affinity of O_2 to other empty heme sites.

The conformation change involves the following interconnected sequential events: (1) The binding of O_2 pulls the Fe^{2+} into the porphyrin plane. (2) The movement of the Fe^{+2} moves the bonded proximal His F8 toward the porphyrin. (3) The position of the covalently connected F-helix of which the His F8 is a part consequently changes. (4) The interconnected FG corner of the subunit changes position; this destabilizes the FG corner's noncovalent interaction with the C-helix of the adjacent subunit at $\alpha_1\beta_2$ or $\alpha_2\beta_1$ subunit interfaces (Figures 9.27 and 9.28). (5) The adjacent globin structure changes to a conformation that allows O_2 to bind to its heme with high affinity.

Thus, the FG to C inter-subunit contacts act as a *switch* between two different arrangements between the FG corner of one subunit and the C-helix of the adjacent subunit. The new conformation allows the His F8 residues in the deoxy globin chains to approach their porphyrins on O_2 association with less steric repulsion (Figure 9.28). O_2 binds to the empty hemes in the modified conformation with higher affinity. In addition, ionic interactions that stabilize the deoxy-conformation (Figure 9.29) are broken by the conformation change induced by the binding of O_2 to one of the hemes, allowing the oxy-conformation in other subunits to more easily form.

The deoxy-conformation of hemoglobin is the *tense*, or **T conformational state**. The oxy form with higher O_2 affinity is the *relaxed*, or **R conformational state**. The allosteric mechanism describes how initial binding of the O_2 to one of the heme subunits of the tetrameric molecule pushes the molecular conformation from the T to R conformational state. The affinity constant for O_2 is greater in the R state by a factor of 150–300, depending on the solution conditions.

Hemoglobin Facilitates Transport of CO_2 and NO

The survival of cells relies on the ability of hemoglobin in red blood cells to deliver O_2 for cellular metabolism and to facilitate the transport of CO_2 away from the cells to the lung. Hemoglobin also binds the vasodilator, NO, and delivers it to the blood vessel walls in the tissues. The T to R conformational equilibrium of the hemoglobin molecule controls the delivery of O_2, CO_2, and NO to their appropriate sites. Due to changes in the p*Ka* of side-chain acid groups between the T and R conformations, the T ⇆ R equilibrium is regulated by the hydrogen ion concentration. The changes in pH link the delivery of O_2 and NO to the tissues with the transport of CO_2 away from the tissues.

Decrease in pK_a of Acid Groups with Change from T to R Conformation Releases Protons

Equation 9.10 shows the release of protons as the T conformation is converted to the R conformation. This release of protons at blood pH is the alkaline **Bohr effect** and is of physiological importance.

$$\underset{T}{Hb} + 4O_2 \rightleftharpoons \underset{R}{Hb(O_2)_4} + nH^+ \qquad (9.10)$$

The value of n in Eq. 9.10 (equivalents of protons released when one molecule of deoxy-Hb is converted to oxy-Hb) varies between 1.2 and 2.7 depending on solution conditions and the concentration of chloride ion and 2,3-bisphosphoglycerate. According to the law of mass action, increasing the hydrogen ion concentration on the right side of Eq. 9.10 forces the equilibrium to the left, toward increasing concentrations of deoxy-Hb and free O_2. Increased cellular metabolic activity increases release of both carbonic acid from CO_2 and lactic acid (p. 601), and thereby increases the hydrogen ion concentration (acidity) of

the blood in the cellular environment. The increase in acidity forces oxy-Hb to deoxy-Hb with the dissociation of O_2, which is delivered to the metabolizing cells. This is a feedback loop in which the cellular metabolic acid waste signals an increase in the dissociation of O_2 required for the continuation of cellular metabolism. The increase in hydrogen ion concentration induces O_2 delivery through its effect on the equilibrium between the R and T conformations of the hemoglobin molecule.

Why do protons dissociate from hemoglobin as the T conformation converts to the R conformation? Protons dissociate when acid side chains of hemoglobin are more acidic in the R conformation than in the T conformation. This requires the pK_a of these groups to be lower in the R conformation.

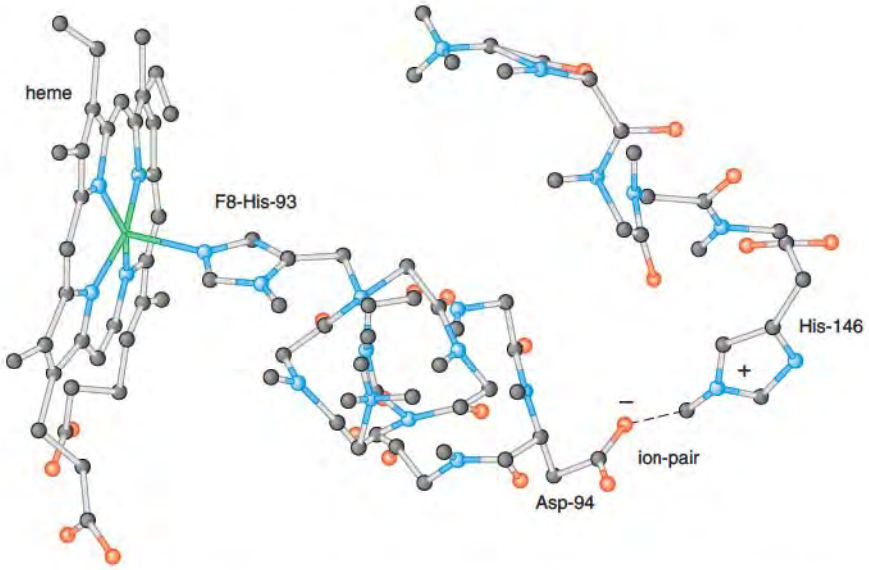

Figure 9.30 Ion pair between the βHis-146 imidazolium and the βAsp-94 carboxylate side-chain groups in the deoxy(T)-conformation of hemoglobin. A partial structure of the β-chain showing the backbone polypeptide chain for amino acids 87 through 95 and 142 through 146 of the β-chain in the deoxy-conformation. Only the side chains of Asp-94, His-146, and the F8 His-92 liganded to the β-subunit heme are shown. Oxygen atoms are colored red, nitrogen atoms are blue, and carbon and hydrogen atoms are black. The hydrogen bond (broken line) is shown between the positively charged imidazolium N-H of βHis-146 and negatively charged carboxylate oxygen of βAsp-94.

Drawing made with the Swiss-PdbViewer using PDB structure 1A3N.

His-146(β) is the major contributor to this proton dissociation on conversion of the T to R conformation. In the T conformation, the positive charge on the His-146(β) side-chain imidazolium is in an ion pair with the negative charge of the carboxylate side chain of the Asp-94(β) (Figure 9.30). The negatively charged carboxylate stabilizes the positively charged imidazolium. The stabilized imidazolium tends to retain its positive charge and has a higher than normal pK_a (approximately 7.7). Conversion of hemoglobin to the R conformation breaks this ion pair, placing the Asp and His side chains at new positions in the R conformation where the oppositely charged groups no longer strongly interact, and this loss of opposite charge interaction reverts the His-146(β) imidazolium to a more normal pK_a of approximately 7.3. The change in the His-146(β) pK_a to a more acidic value on conversion to the R conformation results in the dissociation of protons at the pH of blood (7.4). Approximately 50% of the protons that dissociate come from the β-His-146 midazolium. The rest come from other acid groups that similarly change their p*Ka* from higher to lower values as the conformation changes from T to R.

Figure 9.31 shows the plot of the fractional saturation of O_2 binding sites in hemoglobin versus O_2 concentration for Hb at different values of pH. At more acidic pH (higher $[H^+]$), hemoglobin dissociates its O_2 more easily (Eq. 9.10) and the curve is shifted to the right. Accordingly, the P_{50} value at more acidic pH is higher. The higher P_{50} represents a poorer O_2 affinity as oxygen-binding sites are 50% saturated at a higher $p(O_2)$ concentration. At higher pH, the curve is shifted to the left and the P_{50} value decreases reflecting a higher affinity of O_2.

CO_2 and O_2 Transport Are Linked by Bohr-Effect Protons

Metabolizing cells utilize O_2 and produce CO_2. The CO_2 produced by the cells diffuses into the surrounding blood and enters the red blood cell. There the CO_2 is rapidly converted by the action of the enzyme carbonic anhydrase to carbonic acid by a hydration reaction (Eq. 9.11).

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \qquad (9.11)$$

$$H_2CO_3 \rightleftharpoons HCO_3^- + H^+ \qquad (9.12)$$

Subsequently, the carbonic acid spontaneously dissociates to HCO_3^- and a H^+ (Eq. 9.12). The HCO_3^- diffuses out of the red blood cell and is carried to the lung by the plasma (Figure 9.32). This transport of CO_2 from tissues to lung in plasma as bicarbonate (HCO_3^-) is known as **isohydric transport**. Approximately 70%–80% of CO_2 produced by cells is transported to the lung by this mechanism.

The hydrogen ions that dissociate from the carbonic acid bind to hemoglobin, according to Eq. 9.10, and force $Hb(O_2)_4$ to dissociate its O_2, which diffuses out of the red blood cell to the cells of the tissue. Hemoglobin thus acts as a buffer of blood pH by binding the hydrogen ions produced by the metabolizing cells and preventing the blood pH from

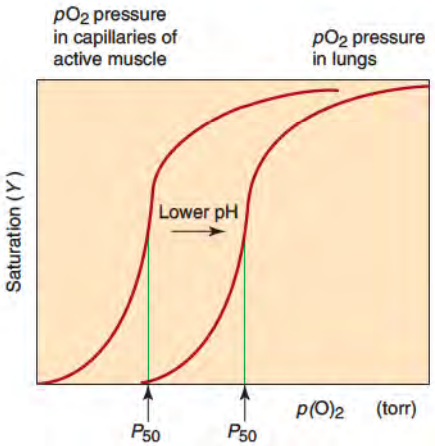

Figure 9.31 Change in oxygen–hemoglobin saturation curve to higher P_{50} value with decrease in pH (increase in $[H^+]$).

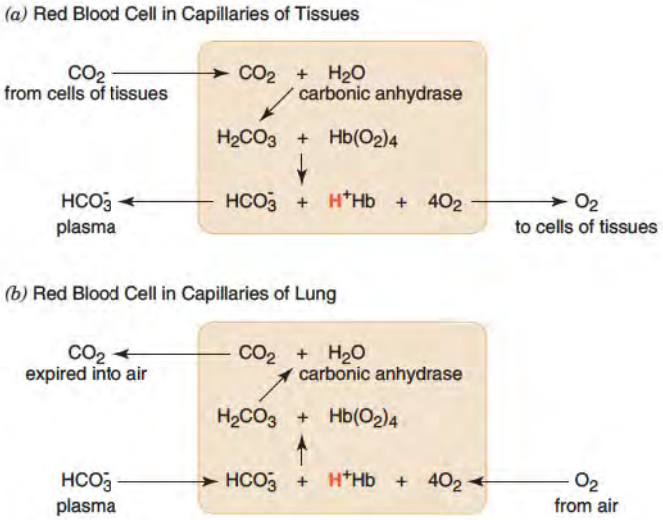

Figure 9.32 The isohydric transport of CO_2 as bicarbonate. (*a*) Reactions in the red blood cell at the tissues. CO_2 diffuses into red blood cell from tissues and is converted into carbonic acid by carbon anhydrase (Eq. 9.11). The carbonic acid spontaneously dissociates into H^+ and HCO_3^- (Eq. 9.12). The proton that dissociates from carbonic acid (boldface H^+) binds to deoxy-Hb forcing the O_2–Hb equilibrium from oxyhemoglobin to deoxy-hemoglobin (Eq. 9.10) with the dissociation of O_2, which diffuses out of the red blood cell to the tissues. The HCO_3^- diffuses out of the red blood cell and is transported in plasma to the lung (outside of cell). (*b*) Reactions in the red blood at the level of the lung. In the lung, the high O_2 pressure forces the reactions in the opposite direction. Reactions are the reverse of those in the capillaries.

becoming too acidic. The protons bind side chains such as the imidazole of the His-146(β) in the two β chains. The deoxy H^+·Hb is transported to the lungs in the red blood cell.

In the lungs the same reactions that occurred at the tissues are now forced in the reverse direction by the high concentration of O_2 in the lung. The high pO_2 concentration converts $H^+Hb(T)$ to $Hb(O_2)_4(R)$ conformation, the protons dissociate (Eq. 9.10), and combine with HCO_3^- molecules that diffuse back into the red blood cells from the plasma to form carbonic acid (H_2CO_3, reverse reaction of Eq. 9.12). The carbonic anhydrase of the red blood cell converts H_2CO_3 to CO_2 and H_2O (reverse of Eq. 9.11). The CO_2 diffuses into the lung alveoli and is expired into air (Figure 9.32).

A second mechanism of CO_2 transport, which accounts for 15%–20% of the CO_2 transported from tissues to lungs, is through **carbamino-hemoglobin**, formed by the nonenzymatic reaction of CO_2 with the NH_2-terminal amino groups of Hb polypeptide chains (Eq. 9.13). This reaction producing carbamino-Hb also produces a H^+.

$$HbNH_2 + CO_2 \rightleftharpoons HbNHCO_2^- + H^+ \qquad (9.13)$$

The excess H^+ produced by carbamino-Hb formation then binds to hemoglobin and stabilizes the deoxy form, promoting the release and delivery of O_2 to the actively metabolizing cells (Eq. 9.10 and Figure 9.33).

In the lung, the high pO_2 concentration generates $Hb(O_2)_4$ with dissociation of H^+ (Eq. 9.10). This increase in H^+ forces dissociation of the carbamino group with release of CO_2 (reverse of Eq. 9.13), which is expired from the lung (Figure 9.33).

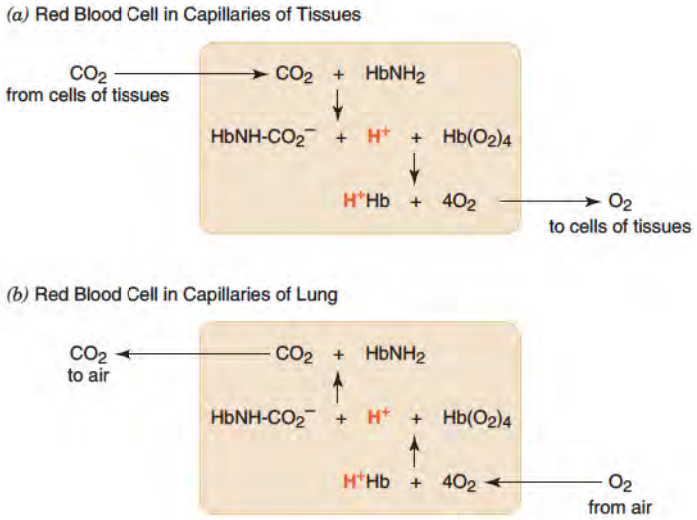

Figure 9.33 Transport of CO_2 as carbamino-hemoglobin. (*a*) Reactions in the red blood cell at the tissues. CO_2 diffuses into red blood cell and reacts with the NH_2-terminal amino group of hemoglobin chains to form carbamino-hemoglobin (Eq. 9.13). The reaction releases a proton (boldface H^+), which promotes the dissociation of O_2 from hemoglobin. The O_2 diffuses out of the red blood cell to the tissues. (*b*) Reactions in the red blood cell at the level of the lung. In the lung, the high O_2 pressure forces the reactions in the opposite direction leading to the expiration of CO_2 from the lung. Reactions are the reverse of those in the capillaries.

2,3-Bisphosphoglycerate (BPG) in Red Blood Cells Modulates Oxygen Release from Hemoglobin

An important modulator of the hemoglobin equilibrium is **2,3-bisphosphoglycerate (BPG)** or **2,3-diphosphoglycerate (DPG)** (Figure 9.34). BPG is formed in a minor pathway for glucose metabolism and is present in small amounts in all cells. However, in the red blood cell this pathway is highly active, and BPG concentrations are approximately equimolar to that of hemoglobin. BPG binds to the deoxy (T) but not the oxy (R) conformation. Binding of BPG to Hb stabilizes the T conformation and increases its concentration relative to the R conformation. BPG dissociates as deoxy-Hb is converted to oxy-Hb (Eq. 9.14).

$$H^+BPG \cdot Hb + 4O_2 \rightleftharpoons Hb(C_2)_4 + BPG + nH^+ \qquad (9.14)$$

Increased concentrations of BPG force the equilibrium (Eq. 9.14) to the left, and correspondingly shift the saturation plot to the right with an increase in P_{50} (Figure 9.35). In contrast, lowered concentrations of BPG force this equilibrium to the right, and correspondingly shift the saturation plot to the left with a lower P_{50}.

A single BPG molecule binds within a pocket formed at the β_1–β_2-subunit interface in the T conformation. This site contains eight positively charged groups [the His-143(β), Lys-82(β), His-2(β), and NH_2-terminal ammonium residues from both β chains] (Figure 9.36). The BPG has a charge of minus 5 (Figure 9.34) and is strongly attracted to the positive charges of the β–β-interface binding site. In the R conformation, the size of the binding pocket is decreased making the BPG unable to fit easily into the binding pocket. Hence the conversion of T to R leads to the dissociation of bound BPG.

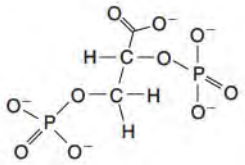

Figure 9.34 Structure of 2,3-bisphosphoglycerate (BPG). Molecule has a charge of –5 at pH 7.4.

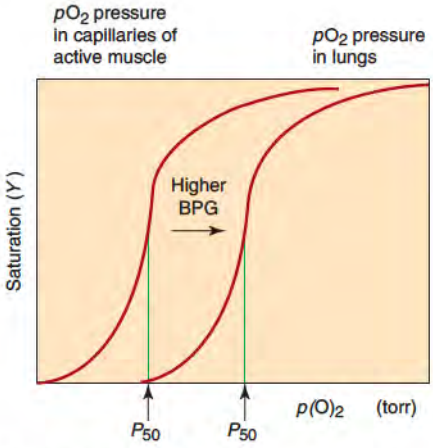

Figure 9.35 Change in oxygen–hemoglobin saturation curve to higher P_{50} value with increase in BPG concentration.

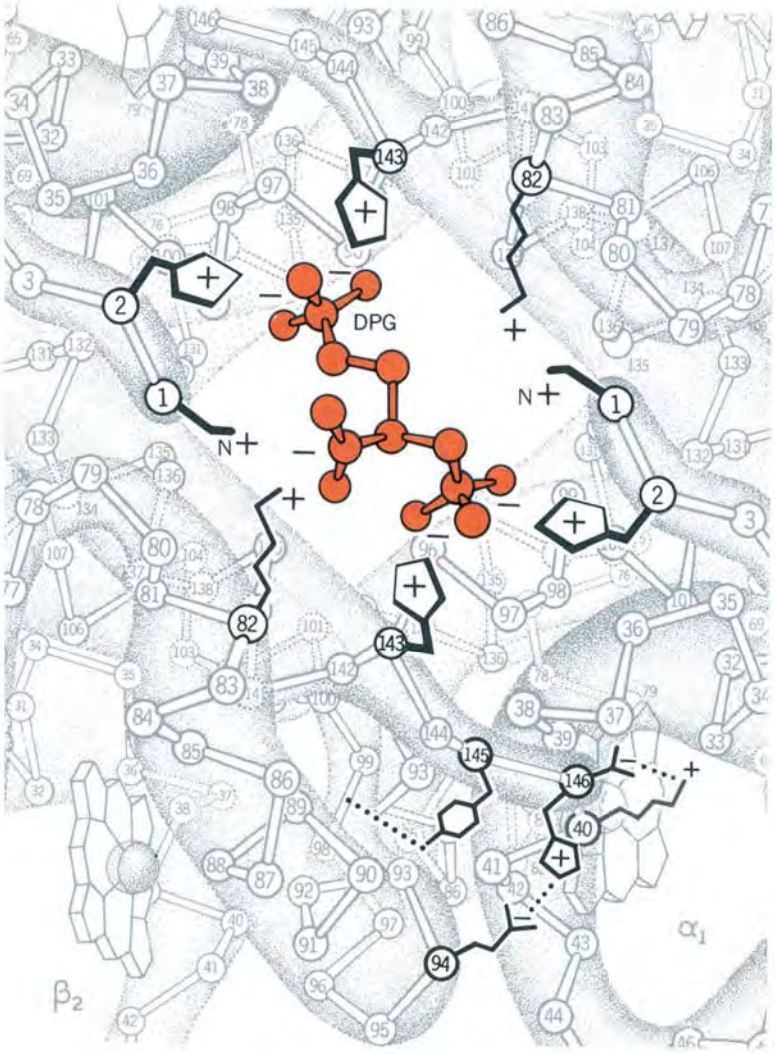

Figure 9.36 2,3- Bisphosphoglycerate binding site at the β–β interface of deoxy-hemoglobin. Shown are the positively charged side chains of two βVal-1 amino terminus ammonium, βHis-2 imidazolium, βLys-82 ε-ammonium, and β143-His imidazolium. The negatively charged 2,3-bisphosphoglycerate binds in the middle of the ring of positively charged groups. Reproduced with permission from Dickerson, R. E., and Geis, I. *Hemoglobin: Structure, Function, Evolution, and Pathology.* Menlo Park, CA: Benjamin/Cummings, 1983. Illustration by Irving Geis. Figure 9.37 The X-S-NO Transporter. Glutathione (γ-glutamyl-cysteinyl-glycine) transports NO bound to the sulfhydryl side chain of its cysteine.

Conditions that cause hypoxia (deficiency of oxygen) such as anemia, smoking, and high altitude increase BPG levels in the red blood cells. In turn, conditions leading to hyperoxia result in lower levels of BPG. Changes in red blood cell levels of BPG are slow and occur over hours and days to compensate for chronic changes in pO_2 levels.

Hemoglobin Delivers Nitric Oxide (NO) to the Capillary Wall of Tissues Where It Promotes O_2 Delivery

Hemoglobin reversibly binds nitric oxide (NO) a potent vasodilator, with a very short lifetime in blood. By binding NO, hemoglobin sequesters it from rapid destruction. Hb releases NO by transferring it to small sulfhydryl (X-SH) molecules as hemoglobin changes from oxy(R)- to the deoxy(T)-conformation. A common X-SH molecule is glutathione (Figure 9.37). The X-S-NO compound continues to stabilize NO against degradation and allows efficient delivery of a bioactive NO equivalent (X-S-NO) to the NO receptors in cells of the blood vessel wall, promoting relaxation of the vascular wall. The relaxation facilitates the transfer of gases between the blood and the cells of the tissues. The molar concentration of NO in blood is 1/70th the concentration of Hb. However, this low concentration is physiologically significant because of the potent biological activity of X-S-NO.

NO is first captured by the Fe^{+2} at the heme and then transferred to the sulfhydryl of the β-chain cysteine-93 (βCys^{93}) residues. The heme iron preferentially binds NO when in the T conformation. The NO is transferred to βCys^{93} when hemoglobin is in the R conformation. Then when the R changes again to the T conformation to deliver O_2 to the tissues, the NO is transferred from the βCys^{93} to small S-XH molecules such as glutathione (Figures 9.37 and 9.38). The net effect is the conversion by hemoglobin of unstable free plasma NO to stable X-S-NO.

Figure 9.39 shows the region of hemoglobin that contains βCys^{93}-S-NO. In the T conformation the S-NO is on the outside and accessible to glutathione molecules. This allows *trans*-nitrosylation to occur. In contrast, in the R conformation the βCys^{93}-SH is pointed toward the heme iron and inaccessible to the outside solvent. The distance in the R conformation between the heme iron and βCys^{93} is optimal for transfer of NO from the heme to the βCys^{93}-SH.

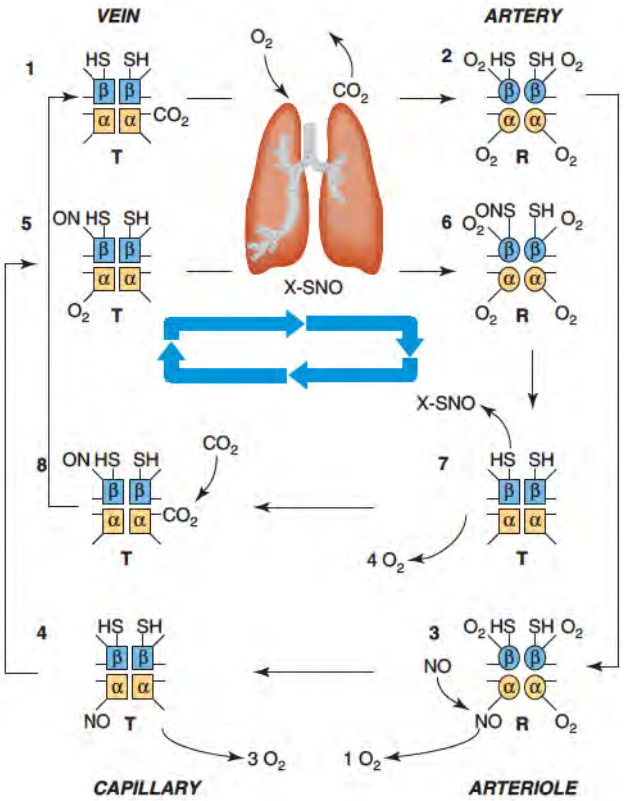

Figure 9.38 Binding and release of NO by hemoglobin during the respiratory cycle. The model shows the binding and dissociation of NO, O_2, and CO_2 as a hemoglobin molecule makes two complete cycles through the circulation. The first cycle involves intermediates 1–4, and the second cycle intermediates 5–8. The T and R conformations are shown, and the SH groups are from the side chain of βCys^{93}. The NO is either directly bound to a heme iron or to the βCys^{93} SH.

The key steps in the NO transport are its initial binding to a heme in intermediate 3 and transfer from a β-subunit heme to βCys^{93} in intermediate 6 (R conformation), and its transfer to a small molecular thiol X-SH in intermediate 7 (T conformation) when hemoglobin is converted from R to T. The hemoglobin molecule depicted may be only 1 in 1000 hemoglobin molecules that are cycling, due to the low relative molar concentration of NO in blood.

Redrawn from Gross, S. S., and Lane, P. *Proc. Natl. Acad. Sci. USA* 96: 9967, 1999.

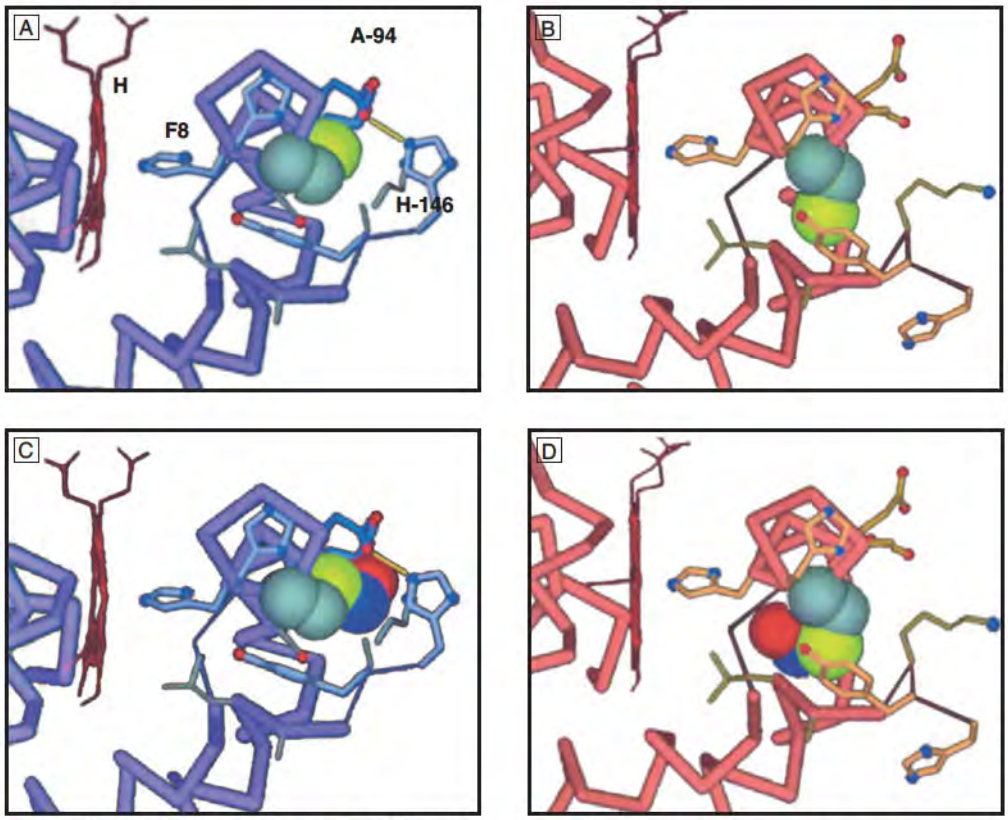

Figure 9.39 Structure of βCys^{93} and βCys^{93}-S-NO in the T and R conformations. In all structures the heme (H, red) edge is pointed toward reader and is shown to be bonded to proximal histidine imidazole (F8). The two carbons (grey) and sulfur (yellow-green) of the Cys-93 side chain are shown with space filling models. In panels C and D, NO is bonded to the sulfur of βCys^{93} with the N atom colored blue and the O atom colored red.

A. The deoxy(T) conformation with the βCys^{93} side chain ($—CH_2—SH$) is on the surface of the molecule away from the heme. The cysteine side chain is prevented from entering the heme binding site by the βHis^{146}-imidazolium to βAsp^{94}-carboxylate hydrogen bonded ion pair (H bond between groups shown in yellow) on the upper right and behind the βCys^{93}-SH side chain.

B. The oxy(R) conformation with the βCys^{93} side chain pointed toward the heme and away from the solvent on the outside of the molecule. The βHis^{146} to βAsp^{94} salt bridge is broken in the R conformation, which allows the folding of the βCys-SH toward the heme pocket.

C. Model of βCys^{93}-SNO in the deoxy(T) conformation. SNO is positioned on the outside accessible to react with X-SH small molecules in the solvent. As in A, the cysteine side chain is prevented from entering heme site by the βHis^{146}–βAsp^{94} ion pair.

D. Model of βCys^{93}-SNO in oxy(R) conformation. SNO is buried near the heme and away from the outside solvent. This conformation facilitates the transfer of NO from the heme iron to the cysteine SH and prevents the reaction of the βCys^{93}-SNO with X-SH molecules in the solvent.
From Stamler, J. S., Jia, L., Eu, J. P., McMahon, T. J., et al. *Science* 276: 2034, 1997. Reprinted with permission from AAAS.

Thus the conformational changes in the hemoglobin molecule, induced by changes in oxygen pressure between the lungs and tissues, regulate NO uptake and release from the βCys^{93}. The net effect is delivery of bioactive NO to the tissue capillaries under low oxygen tension.

9.5 • THE BASAL LAMINA PROTEIN COMPLEX

A **basal lamina** is a highly structured complex of extracellular matrix proteins observed microscopically as an amorphous densely packed region of about 50–100 nm thickness surrounding tissues or cells (Figure 9.40). The term **basement membrane** is used to describe both the basal lamina and connecting fibrillar collagens attached to its outside. The basement membrane gives support to tissues and regulates access of cells to the interstitial stroma. It also participates in determining the properties of the cells that are attached to it, including the critical processes of cell division, death (apoptosis), differentiation, and migration. All cells produce constituents of basement membrane, and each basement membrane has characteristics of the cell type from which it is synthesized. A basement membrane underlies sheets of epithelial and endothelial cells and surrounds other cell types (Figure 9.40). A basement membrane separates two sheets of cells in the kidney glomerulus, where it acts as a selective filter.

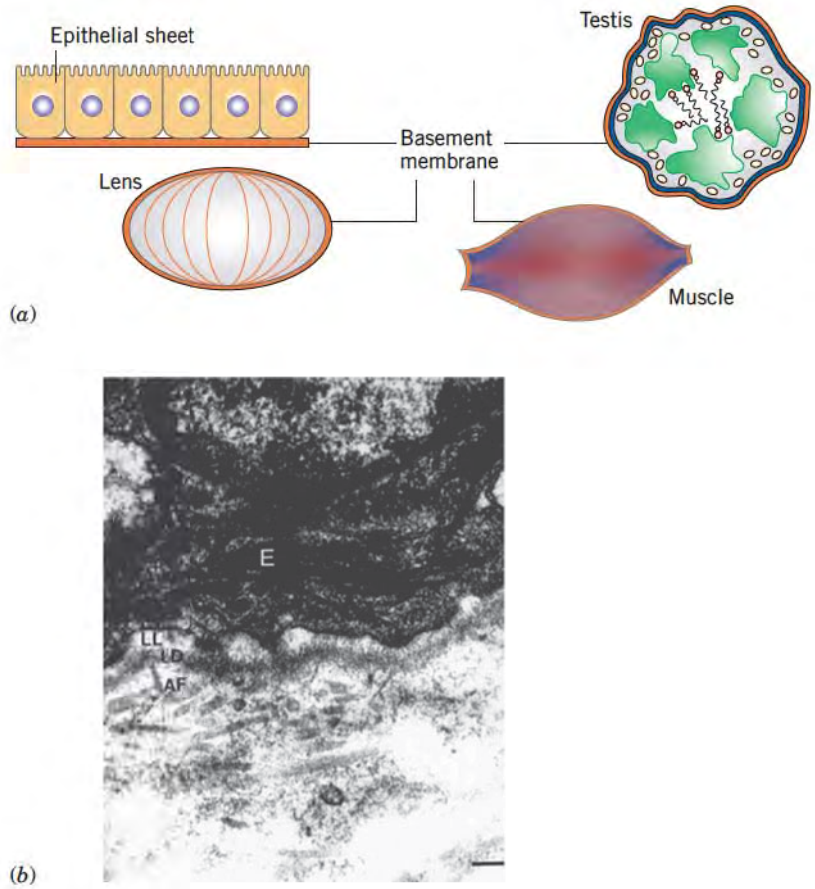

Figure 9.40 Basement membranes. (*a*). Diagram of the basement membranes surrounding various tissues and cell types. (*b*) Electron micrograph showing ultrastructure of extracellular matrix with basement membrane adjacent to epithelial cell (E). The lamina lucida (LL) and lamina densa (LD), or basal lamina of the basement membrane is shown. Below lamina densa is stroma of extracellular matrix. Bar represents 100 nm. (*a*) Reproduced with permission from Kalluri, R. *Nature Rev. Cancer* 3:422–433, 2003. (*b*) Reproduced with permission from Bosman, F. T., and Stamenkovic, I. J. *Pathol.* 200:423, 2003.

The basal lamina is formed by the non-covalent associations between specific sites located in binding domains of the associated proteins. Many basement membrane proteins also bind to cells through cellular binding domains in the proteins and cell receptor proteins in the outer cell membrane. The structure of many of the proteins is composed of module units with sequence and fold homology to common superfolds, such as the immunoglobulin (Ig) and the epidermal growth factor (EGF) folds. These folds are found repetitively and are the building blocks of extracellular matrix proteins. While the EGF modules within these proteins do not appear to have a growth factor function, growth factor and cytokine proteins are found within the basal lamina, particularly in association with the carbohydrate parts of the proteoglycan components. During turnover of the basement membrane induced by proteases and heparanases, these growth factors and cytokines are freed to act on nearby cells. In addition, many basal lamina proteins hide cryptic activities that are activated when cleaved out of the full sequence by action of proteases (see endostatin, p. 1020). The pro-protease plasminogen is ubiquitously present within extracellular matrix and is activated by cellular secretions of plasminogen activators (p. 994).

Protein Composition of the Basal Lamina

The basal lamina is composed of type IV collagen, laminin, nidogen (also referred to as entactin), and perlecan, a heparin sulfate proteoglycan. In addition, minor amounts of perhaps 50 other proteins may be present including osteopontin (also referred to as BM-40 or SPARC), fibulin, type XV collagen, type XVIII collagen, and the proteoglycan agrin. The diversity and tissue specificity of a basement membrane is determined by the isoforms of type IV collagen and laminin and the types of minor proteins present. Type IV collagen isoforms are produced by seven different type IV collagen genes. These isoforms share domain structure homology, but differ by 30%–50% in their amino acid sequences. There are at least 12 different laminin isoforms. The isoforms of type IV collagen and laminin expressed are characteristic of the cell type and tissue that synthesizes the associated basement membrane.

The Molecular Structure of Basal Lamina Is Formed from Networks of Laminin and Type IV Collagen

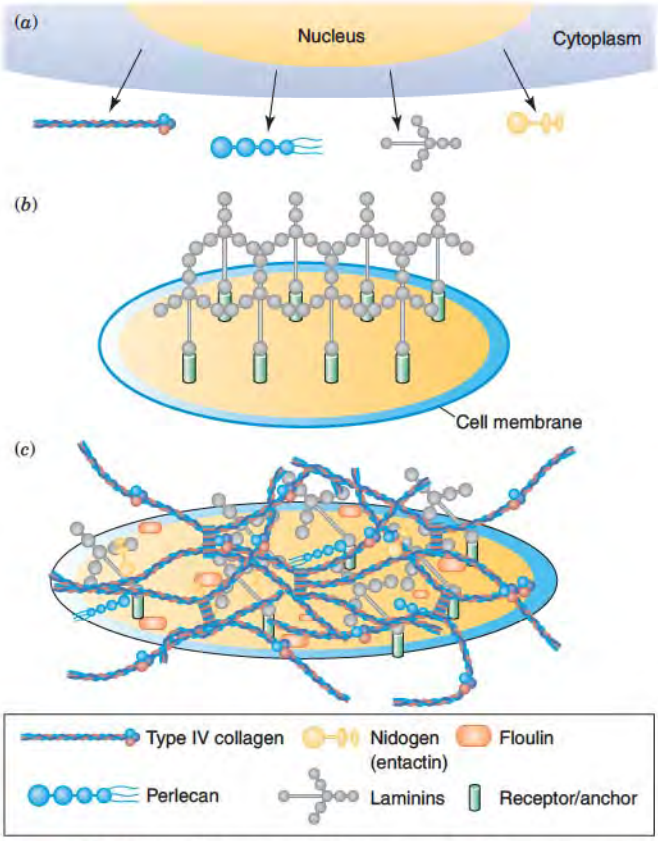
The structure of the basal lamina protein complex is produced by the connecting of planar networks of laminin and of type IV collagen. Nidogen/entactin and perlecan proteoglycan molecules link these networks. The laminin polymer structure initiates formation of the basement membrane, facilitated by its attachment to cellular receptors (Figure 9.41).

Laminin Network

Laminin is composed of three-polypeptide chains (α, β, and γ) cross-linked by disulfide bonds. Each chain contains about 1500 amino acids, and the molecular weight of the laminin-1 isoform is approximately 800 kD. The overall structure appears as an asymmetric cross (Figure 9.42). The cruciform structure contains three short arms, each formed by a different chain, and a long arm composed of all three chains. There are five distinct genes that code for an α chain and three each for the β and γ chains, which combine to form at least 12 distinct $\alpha\beta\gamma$ isoforms. Different domains in the structure bind to perlecan and nidogen, and at least two domains contain binding sites for cell surface receptors. Near the cell surface, the laminin molecules self-associate to form a sheetlike network structure through interactions between binding sites in the domains of the short arms of the cruciform structure (Figure 9.43).

Type IV Collagen Network

Collagen molecules contain three polypeptide chains that initially associate through noncovalent interactions (p. 103). Fibrillar forming collagens, such as type I collagen, contain long



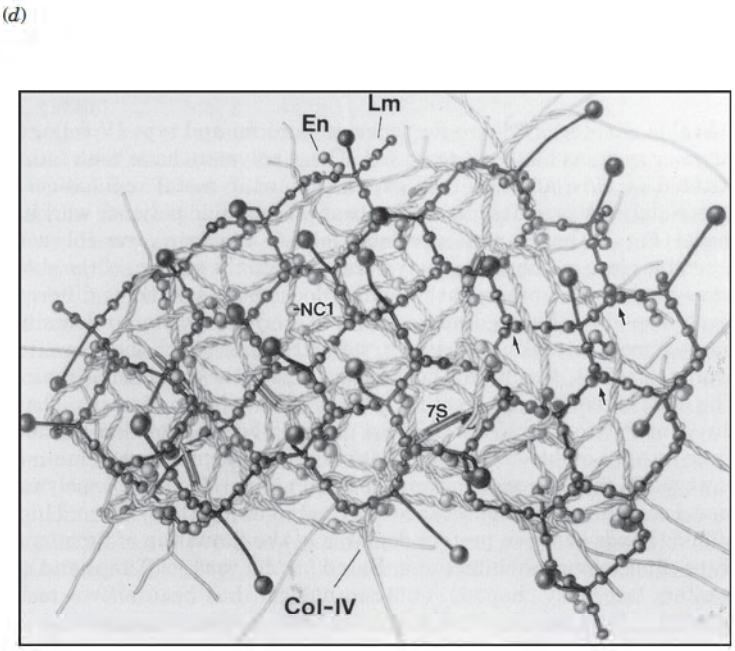


Figure 9.41 Molecular structure of basal lamina. stretches of the repeating sequences (Gly-Pro-X)*n*/(Gly-Y-HyPro)*n* containing a proline or hydroxyproline (HyPro) and a glycine approximately every third residue (p. 106). Hydroxyproline is a derived amino acid formed by proline hydroxylase in the endoplasmic reticulum on proline residues within the nascent procollagen chain. The high content of proline and hydroxyproline generates a helical conformation for this sequence known as the polyproline type II helix (p. 106). This helix is characterized by three residues per helix turn ($n = 3$), with a Gly every third residue forming a longitudinal glycine edge along one side of the helix that promotes self-association of three polypeptides, each in a polyproline helical conformation, into a triple helical or superhelical structure. This three-chain molecule composes the collagen protomer unit.

Type IV collagen does not form fibrillar structures as type I, but a laminar sheetlike network. Type IV collagen polypeptides contain regions of $(Gly\text{-}X\text{-}Pro)_n/(Gly\text{-}HyPro\text{-}Y)_n$ sequence

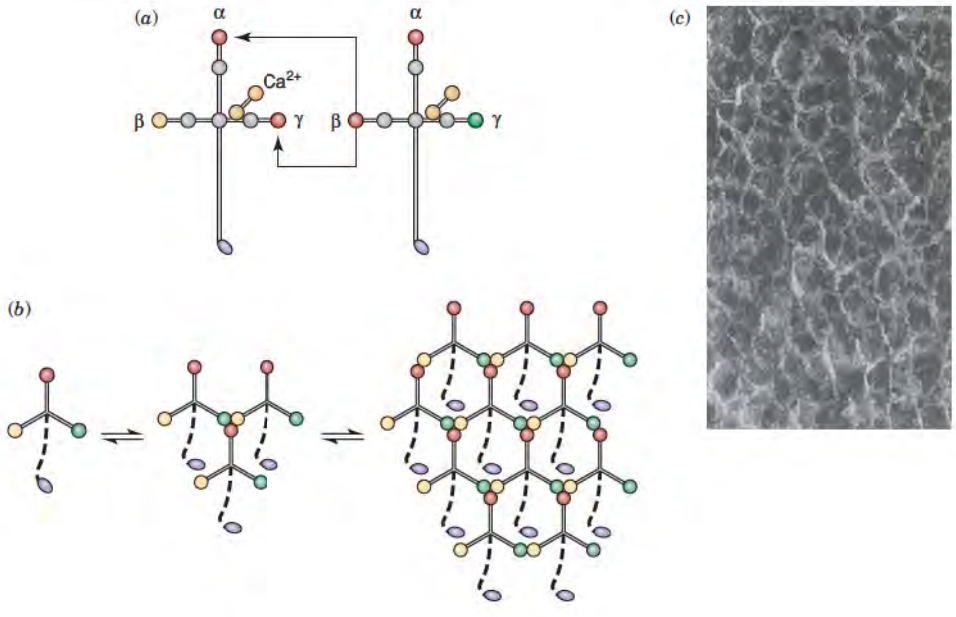

Figure 9.43 Formation of laminin network structure. (*a*) and (*b*) Binding interactions between short arms of different laminin molecules lead to sheet-like network structure. Entactin is shown bound to a short arm of laminin, but is not required for laminin network polymerization. Long arm is believed to be free to participate in other interactions. that form rod-shaped triple-helical regions, but different from type I these regions are interspersed by linker and globular domains that break up the superhelical regions (Figure 9.44). The globular domain at the C-terminal end of the protomer is called the NC1 (*n*on-collagenous 1) domain. This C-terminal domain is preceded by a triple-helical (TH) central region and a hinge connecting to a smaller triple-helical (7S) region at the N-terminal end.

In assembling the type IV collagen network, each protomer binds to another through a NC1 to NC1 head-to-head interaction (Figure 9.45). Then the dimers interact through their 7S regions to form tetramers, which further self-aggregate to form the planar network. The 7S interactions are the nodes of the collagen network structure.

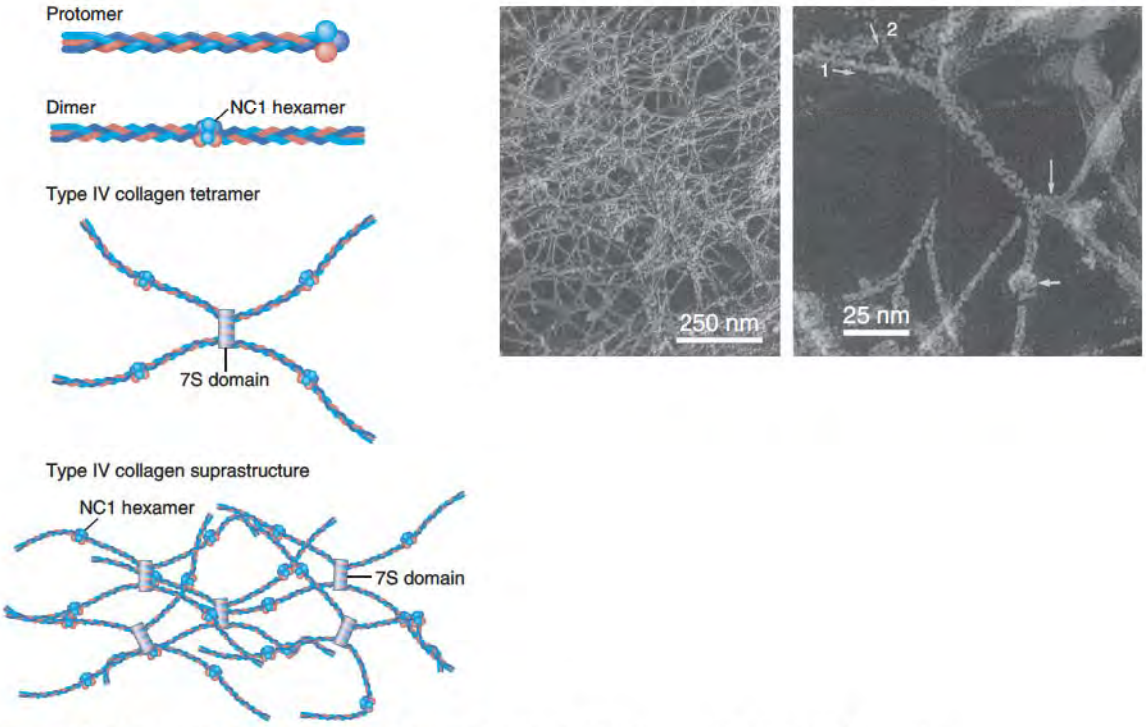

Figure 9.45 Formation of type IV collagen network structure. A. Diagrammatic depiction of network formation. (*a*) Protomer type IV collagen molecule is formed from three polypeptide chains (red, purple, and blue) in the endoplasmic reticulum and golgi of cell. Collagen chains are aligned with their NH_2-terminal 7S regions on one end and COOH-terminal NC1 regions at other end. (*b*) Two protomers are joined by their NC1 domains to form a dimer of protomers (each protomer has three chains so that interaction is between NC1 domains of six chains). (*c*) Two protomer dimers bind through 7S regions. (*d*) Polymerization of tetramers of protomers forms type IV collagen network. B. Nidogen/Entactin Interconnects Laminin and Type IV Collagen Networks.

The two isoforms, nidogen-1 and nidogen-2, have a 46% homology. Both forms are composed of three globular domains (G1, G2, and G3) separated by a link region between G1 and G2 and a longer rod region between G2 and G3 (Figure 9.46). Domain G3 is a β propeller fold composed of antiparallel β strands that appear as blades of an airplane propeller. It is similar to a fold of the LDL receptor protein. Nidogens bind to laminin by interaction of the β-propeller interface with laminin domains III and IV (Figure 9.47). Other sites in nidogen form complexes with type IV collagen and perlecan (Figure 9.48).

Heparan Sulfate Proteoglycan Perlecan Interconnects Laminin and Type IV Collagen Networks

Perlecan (MW 600 kDa) is a major proteoglycan of the *basal lamina*. Proteoglycans have a polypeptide core attached by serine side chains through a tetrasaccharide to a glycosaminoglycan (GAG) chain, composed of a disaccharide of an amino sugar (*N*-acetylglucosamine or *N*-acetylgalactosamine) and a uronic acid (glucuronic or iduronic). In perlecan the GAG is the heavily sulfated heparin sulfate (Figure 9.49). Each perlecan contains 2–15 heparin sulfate (**GAG**) chains (Figure 9.50). The sulfated GAG chains are highly negatively charged and bind cations and water to form gels. This provides a swelling pressure that enables the basement membrane to withstand compressive forces. Perlecan interacts with the other three major components of basement membrane through either its core protein to type IV collagen or through its heparan sulfate chains to bind laminin. Other sites in the heparin sulfate bind to cellular receptors and still others to growth factors such as TGF-β.

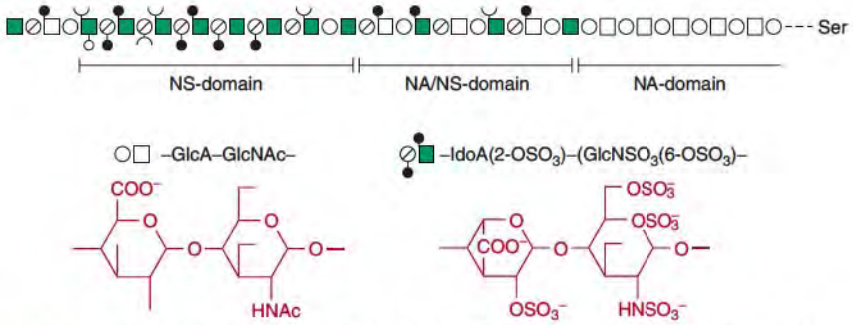

Figure 9.49 Structure of a heparan sulfate chain. The GAG disaccharide polymers contain alternating hexuronic acid (D-glucuronic acid (GlcA) or L-iduronic acid (IdoA)) and D-glucosamine (GlcN) units. The GlcN is *N*-acetylated in regions of the chain (NA region). In further processed regions of the heparan polymer the *N*-acetyl groups have been partially replaced by *N*-sulfate (NA/NS regions) or the *N*-acetyl groups have been completely replaced by *N*-sulfate (NS regions). Open circle is 3-*O*-sulfate.

The polymers are further modified by C-5 epimerization of GlcA to IdoA residues, and, finally incorporation of *O*-sulfate groups at various positions. The heparan chain is joined to the protein core by forming a bond to a serine side chain.

Focal Contact in Cell Membrane Interconnects Extracellular Matrix with Cytoskeleton

The basement membrane is an extracellular protein complex that is connected to the intracellular cytoskeletal protein complex, as both complexes are connected to the same receptor proteins present in the focal contact regions of cellular membranes. These protein–protein binding interactions connect the extracellular matrix to the cellular cytoskeleton and are critical for the regulation of intracellular processes, such as cell motility, cell division, and cell death. In most cancer cells, this binding of the membrane receptor protein complex to both the extracellular *basal lamina* and the cytoskeletal protein complexes is broken.

Key Terms

ANTIBODY MOLECULES

constant and variable regions
F_{ab} fragment
F_c fragment
H chains
hapten
hypervariable region
immunoglobulin class
immunoglobulin fold
L chains

SERINE PROTEASES

active-site directed
β-barrel domain
catalytic residues
convergent evolution
endopeptidase
exopeptidase
γ-carboxyglutamic acid
proenzyme

reaction transition-state stabilization
sequence homology
serine proteases
serpin
zymogen

HEMOGLOBIN

2,3-bisphosphoglycerate
allosteric mechanism
Bohr effect
carbamino-hemoglobin
CO_2 transport
distal histidine
HbA_1
HbF
Hill coefficient
isohydric effect
myoglobin
NO transport
O_2 transport
P_{50}
pK_a perturbation
positive cooperativity
proximal histidine
R and T conformations

BASAL LAMINA

basement membrane
collagen network
focal contact
laminin network
nidogen
perlecan

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. Haptens
- **A.** can function as antigens.
- **B.** strongly bind to antibodies specific for them.
- **C.** may be macromolecules.
- **D.** never act as antigenic determinants.
- **E.** can directly elicit the production of specific antibodies.

2. In the three-dimensional structure of immunoglobulins,
- **A.** β-sheets align edge to edge.
- **B.** in each chain (H and L) the C and V regions fold onto one another, forming CV associations.
- **C.** C_L–V_L associations form the complementary sites for binding antigens.
- **D.** free-SH groups are preserved to function in forming tight covalent bonds to antigens.
- **E.** hinge domains connect globular domains.

3. In immunoglobulins all of the following are true except
- **A.** there are four polypeptide chains.
- **B.** there are two copies of each type of chain.
- **C.** all chains are linked by disulfide bonds.
- **D.** carbohydrate is covalently bound to the protein.
- **E.** immunoglobulin class is determined by the C_L regions.

4. Hemoglobin and myoglobin both have, are, can, or do all of the following except
- **A.** subunits that provide hydrogen bonds to and nonpolar interaction with other subunits.
- **B.** highly α helical.
- **C.** bind one molecule of heme per globin chain.
- **D.** bind heme in a hydrophobic pocket.
- **E.** bind one O_2 per heme.

5. Isohydric transport of carbon dioxide from tissues to lung refers to
- **A.** free CO_2 dissolved in plasma.
- **B.** HCO_3^- in plasma.
- **C.** carbamino compounds.
- **D.** the Bohr effect.
- **E.** the presence of carbonic anhydrase in plasma.

6. Myoglobin has a Hill coefficient of 1.0 and hemoglobin has a Hill coefficient of 2.8. This indicates that
- **A.** an oxygen saturation curve for myoglobin would be sigmoidal.
- **B.** hemoglobin exhibits a simple equilibrium binding of oxygen.
- **C.** myoglobin shows negative cooperativity in its binding of oxygen.
- **D.** hemoglobin shows positive cooperativity in its binding of oxygen.
- **E.** only myoglobin would yield a straight line in a Hill plot.

Questions 7 and 8: A serine protease is believed to be required for metastasis of cancer cells. Tumor cells secrete urokinase-type plasminogen activator (uPA), a serine protease, which activates plasminogen to plasmin. Plasmin causes hydrolysis of proteins in the extracellular matrix. It also activates procollagenase to collagenase; this degrades collagen. The destruction of extracellular matrix proteins allows tumor cells to invade through the matrix to form secondary tumor sites.

7. Basal lamina structure is produced by connecting planar networks of laminins and type IV collagen. Which of the following statements about these is/are correct?
- **A.** Both laminin and type IV collagen are composed of three polypeptide chains.
- **B.** Laminin has a cruciform structure.
- **C.** Laminin and type IV collagen are interconnected by a heparin sulfate proteoglycan.
- **D.** Type IV collagen contains repeating sequences of $(Gly\text{-}HyPro\text{-}Y)_n$.
- **E.** All of the above.

8. In addition to serine, the other two essential residues at the catalytic site of the serine proteases are
- **A.** proline and hydroxyproline.
- **B.** histidine and aspartate.
- **C.** proximal and distal histidines.
- **D.** the C-terminal and N-terminal amino acids.
- **E.** aspartate and glutamate.

Questions 9 and 10: When a blood vessel is injured, the coagulation process is initiated to prevent loss of blood and maintain the integrity of the circulatory system. Coagulation is a process in which zymogens are converted to active serine proteases in a stepwise, cascade process with the final result the production of a cross-linked fibrin clot. In a myocardial infarction, the process can be activated to such an extent that blood flow to the heart muscle is decreased. The fibrinolysis pathway to dissolve fibrin clots also involves activating zymogens to active serine proteases, the final step being the activation of plasminogen to plasmin, which acts directly on the fibrin clot. One of the current treatments for myocardial infarctions is rapid administration of t-PA (tissue plasminogen activator). Actually recombinant t-PA, produced by gene cloning technology, is used.

9. Serine proteases
- **A.** hydrolyze peptide bonds involving the carboxyl groups of serine residues.
- **B.** are characterized by having several active sites per molecule, each containing a serine residue.
- **C.** are inactivated by reacting with one molecule of diisopropylfluorophosphate per molecule of protein.
- **D.** are exopeptidases.
- **E.** recognize only the amino acids that contribute to the bond to be broken.

10. All of the following are characteristic of serine proteases as a class except
- **A.** only one serine residue is catalytically active.
- **B.** natural protein substrates and inhibitors bind very tightly to the protease.
- **C.** the genes that code for serine proteases are organized in a similar fashion.
- **D.** catalytic units exhibit two structural domains of dramatically different size.
- **E.** conversion of zymogen to active enzyme usually involves one or more hydrolytic reactions.

Questions 11 and 12: There are over 800 mutant human hemoglobins. Mutations may cause instability leading to rapid degradation, alterations in oxygen affinity, or more rapid oxidation of heme Fe^{2+} to Fe^{3+}. All of these alter hemoglobin's ability to carry out its physiological functions. In the mutation $Hb_{Cowtown}$, histidine 146, which contributes to 50% of the Bohr effect, is lost. Regulation of oxygen dissociation by protons is impeded, the T confirmation is destabilized relative to the R conformation, and oxygen affinity is increased.

11. All of the following are believed to contribute to the stability of the deoxy or T conformation of hemoglobin except
- **A.** a larger ionic radius of six-coordinated ferrous ion as compared to five-coordinated ion.
- **B.** unstrained steric interaction of His F8 with the porphyrin ring when iron is above the plane.
- **C.** interactions between the FG corner of one subunit and the C helix of the adjacent subunit.
- **D.** ionic interactions.

12. When hemoglobin is converted from the deoxy (T) form to oxyhemoglobin (R),
- **A.** it becomes more acidic and releases protons.
- **B.** carbamino formation is promoted.
- **C.** binding of 2,3-bisphosphoglycerate (BPG) is favored.
- **D.** bound NO is transferred to glutathione.
- **E.** all of the above.

Problems

13. One of the adaptations to high altitude is an increase in the concentration of BPG. What effect does this have on a saturation versus pO_2 curve? Why does increasing [BPG] increase the delivery of O_2 to tissues?

14. What would be the likely order of appearance of various immunoglobulins in response to a viral pathogen introduced via the nasal passages and subsequently into the blood?

Answers

1. B Haptens are small molecules and cannot alone elicit antibody production; thus they are not antigens. They can act as antigenic determinants if covalently bound to a larger molecule, and free haptens may bind strongly to the antibodies thereby produced.

2. E See Figure 9.2. A: The β-sheets align face-to-face. B: The V and C regions are adjacent to each other. C: The complementarity regions are the variable regions of both the heavy and light chains (V(H)—V(L). D: Antigen binding is noncovalent.

3. E The C_H regions determine class. A: There are two copies of each of two types of polypeptide chain.

4. A Hemoglobin has four chains and four oxygen-binding sites, whereas myoglobin has one chain and one oxygen-binding site. Each oxygen-binding site is a heme.

5. B Protons released as H_2CO_3 dissociates to HCO_3^- and H^+ bind to oxyhemoglobin, facilitating release of O_2 to tissues. A: Very little CO_2 is in this form. C: This is another way to carry CO_2. D: Bohr effect releases H^+ as deoxy Hb picks up O_2. E: Carbonic anhydrase is in red cells.

6. D A Hill coefficient greater than 1 indicates positive cooperativity which hemoglobin has. A: A coefficient of 1.0 indicates non-cooperativity; this would give a hyperbolic oxygen saturation curve. B: This coefficient indicates a simple equilibrium, which is what myoglobin shows. C: The coefficient is between 0 and 1 for negative cooperativity. Myoglobin is a single polypeptide and does not show cooperativity. E: The Hill plot is the log of each value for a normal saturation curve and gives a straight line. The slopes, which are the Hill coefficients, differ.

7. E All of these contribute to the basil lamina, which with connecting fibrillar collagen attached to the outside, is called the basement membrane.

8. B They are designated Ser-195, His-57, and Asp-102, on the basis of the numbering of chymotrypsin, regardless of the actual numbers in the individual proteases. A: These are found in collagen. C: These are important residues in hemoglobin. D and E: These are not involved.

9. C This is the distinguishing characteristic of the serine proteases, and of the serine hydrolases in general. A: They have various specificities. B: There is only one active site per molecule. D: They are all endopeptidases. E: An "extended active site" containing the hydrolyzable bond and about four amino acids on either side is responsible for specificity.

10. D The domains are of about equal size.

11. A Six-coordinated ferrous ion has a smaller ionic radius than the five-coordinated species and just fits into the center of the porphyrin ring without distortion.

12. A Positively charged histidine is no longer stabilized by close proximity to an aspartate carboxylate group. This is the Bohr effect. B: Increased H^+ favors dissociation of carbamino groups; this is what happens in the lung. C: DPG does not bind effectively to oxyhemoglobin because the binding pocket is too small. D: In oxyhemoglobin, NO is bound to cysteine and it gets transferred to glutathione when O_2 is released (R form reverts to T form).

13. Binding of BPG to hemoglobin stabilizes the T conformation, so for any given amount of O_2, less O_2 will be bound to hemoglobin. This shifts the saturation curve to the right and increases P_{50}. The equilibrium shown illustrates that increasing BPG causes the release of O_2, which must happen in order for O_2 to enter tissues.

$$H^+BPG{\cdot}Hb + 4O_2 \rightleftarrows Hb(O_2)_4 + BPG + nH^+ \text{ (Eq. 9.14 from text)}$$

14. The initial defense against pathogens in the nasal mucus is immunoglobulins of the IgA class. If the organism invades the plasma, IgM immunoglobulins are the first antibodies elicited. With time, the IgG class antibodies are synthesized and will reach higher concentrations than IgM antibodies.

Key Concepts

- Enzymes are proteins that catalyze chemical reactions by increasing the rate of conversion of a specific-substrate to a specific product.
- Enzymes lower-the energy of activation of reactions by stabilizing the substrate in a form that allows formation of product. This is referred to as the transition state.
- Coenzymes, most derived from vitamins, are essential participants in many enzyme-reactions; some are chemically altered and others unchanged during the reaction. Some are covalently bound to the enzyme. Metal ions are required for the activity of some enzymes; they are often bound to the protein or a cofactor.
- The chemistry of enzymatic transformations is related to general chemical principles such as acid-base catalysis and nucleophilic attack. Enzyme catalysis is more efficient because groups that protonate (general acids) or deprotonate (general bases) and nucleophilic amino acids are part of the enzyme.
- Rates of enzyme catalyzed reactions are related to concentration of enzyme and substrate and are described by the Michaelis–Menten equation, in which one term, K_m, is related to how well the substrate binds to the enzyme. Another kinetic term, k_{cat}, indicates how fast the enzyme converts the substrate to product.
- Specific chemicals inhibit the binding of substrate and the rate of catalysis. Many drugs are enzyme inhibitors by binding to the substrate-binding site or to a different domain of the protein.
- In addition to the substrate- and coenzyme-binding sites on the enzyme, some enzymes possess additional binding sites (allosteric sites) such that when a compound (ligand) binds, it regulates the catalytic activity. These ligands (allosteric modifiers or effectors) usually induce a change in the structure of the enzyme. The catalytic properties of some enzymes are modified by covalent modification.
- Tissue-specific enzymes released into blood from damaged cells are measured to determine the clinical condition. Enzymes are also used in treatment of some medical conditions.

10.1 • INTRODUCTION

Enzymes are specialized proteins that catalyze biological reactions. Virtually every reaction that occurs within a cell requires the action of an enzyme because most reactions will not occur at a detectible rate under physiological conditions (pH, temperature, and ionic milieu) of the cell. Enzymes are efficient catalysts not only increasing the rate of conversion of substrate to product but also recognizing a specific chemical structure in the presence of similar structures to produce a specific product.

Not all biological catalysts, however, are enzymes. Catalytic RNAs (p. 68) have been identified that participate in processing introns and tRNA, while others perform a self-processing step by hydrolyzing a phosphodiester bond within its own nucleotide chain. Artificial enzymes, termed **abzymes**, have been synthesized by making antibodies against chemicals that are transition-state analogs. Abzymes have been designed to catalyze over 100 different chemical reactions.

10.2 • CLASSIFICATIONS OF ENZYMES

With the advent of genomic sequences, many enzymes have been identified. In mid-2004, information was available for over 83,000 different enzymes from 9800 different organisms; by 2008 the number of entries doubled. All enzymes are classified as belonging to one of six classes, defined by the chemical reaction they catalyze. A numbering system, consisting of four numbers for each enzyme, has been developed by the International Union of Biochemistry and Molecular Biology (IUBMB) to characterize each enzyme. The first number defines the type of reaction that is catalyzed, followed by numbers to define details of the reaction. It is interesting that the entire chemistry of life can be reduced to six different types of chemical reactions. The classes of enzymes are listed in Table 10.1.

The systematic names for enzymes include the substrate and the type of reaction; the enzyme name often ends in "ase." Alcohol dehydrogenase, an enzyme that oxidizes an alcohol to an aldehyde, has the IUBMB number 1.1.1.1. This indicates (1) that the enzyme is involved in an oxidation–reduction reaction (first number), (2) it removes hydrogen as a hydride ion with NAD^+ as the electron acceptor (second number), and (3) substrates for the enzyme can be most primary alcohols (third number). (4) The last number is reserved

TABLE 10.1 • Summary of the Enzyme Classes and Major Subclasses

1. Oxidoreductases	2. Transferases
Dehydrogenases	Transaldolase and transketolase

Epimerases	
Isomerases	
Mutases (not all)	

to differentiate each enzyme that catalyzes the same overall reaction but with different substrates. Lactate dehydrogenase (1.1.1.27) catalyzes an identical reaction as alcohol dehydrogenase, but the substrate is lactate. Enzymes are often named for the direction of the reaction of importance in the cell.

Arbitrary names are frequently given to enzymes; for example, aldolase was the name given and still used for the enzyme that catalyzes an aldol-condensation reaction between glyceraldehyde-3-phosphate and dihydroxyacetone phosphate (p. 597), and lysozyme for an enzyme that breaks down bacterial cell walls. There has been an effort to drop the trivial in favor of the systematic name of many enzymes but the literature continues to contain references to both names for many enzymes.

Isozymes are different structural forms of a protein that catalyze the same reaction. They are products of different genes, possess different degrees of sequence identity, and can have different kinetic properties. There are two isozymes of lactate dehydrogenase, a heart form (H) and a muscle form (M), which have slightly different amino acid sequences. Lactate dehydrogenase is a tetrameric protein, consisting of the M and H monomers, and can have five different tetrameric structures (Table 10.2).

Class 1: Oxidoreductases

Class 1 enzymes catalyze oxidation–reduction reactions and are referred to as oxidoreductase. Oxidation means the loss of electrons, and reduction means the addition of electrons.

TABLE 10.2 • Lactate Dehydrogenase Isozymes

Type	*Composition*	*Location*
LDH_1	HHHH	Myocardium and RBC
LDH_2	HHHM	Myocardium and RBC
LDH_3	HHMM	Brain and kidney
LDH_4	HMMM	
LDH_5	MMMM	Liver and skeletal muscle

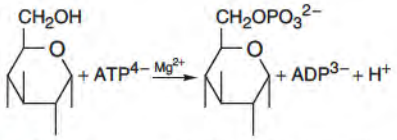

Figure 10.2 Phosphorylation reaction. Phosphorylation of glucose by ATP catalyzed by hexokinase.

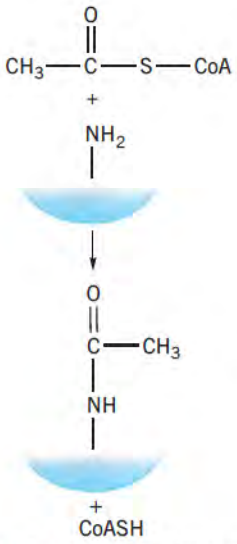

Figure 10.3 Acetylation of amino acid residues in a protein.

Electrons are removed from one substrate (donor or reductant) that is oxidized and added to a second substrate (acceptor or oxidant) that is reduced. Many different electron acceptors are used in biological systems (p. 561). Dehydrogenases are typically named in the oxidizing direction. Examples are lactate dehydrogenase rather than pyruvate reductase and glyceraldehyde-3-phoshpate dehydrogenase rather than 1,3-bisphosphoglyerate reductase.

Oxidations and reduction reactions include the following pairs of donors–acceptors: saturated–unsaturated carbon–carbon bonds, alcohols–aldehydes, aldehydes–acids, and amines–imines. Molecular oxygen (O_2) as an electron acceptor is involved in a variety of irreversible oxidation–reduction reactions. Monooxygenases catalyze the insertion of a hydroxy group into the substrate with the other atom of oxygen ending up in water (Figure 10.1) whereas dioxygenases incorporate both atoms of O_2 into a substrate. Cytochromes P450 (p. 426) are an important group of enzymes that use oxygen in the metabolism of xenobiotics such as drugs and toxins; these enzymes convert a saturated compound into an alcohol, a hydroxylation reaction using one of the oxygen atoms in O_2 for the hydroxyl group.

Class 2: Transferases

Members of this large family transfer a chemical group from one molecule to another; thus they have two substrates and produce two products. Hexokinase transfers a phosphate group from ATP to an acceptor such as glucose (Figure 10.2). An enzyme that transfers phosphate to another molecule using a nucleotide triphosphate as the donor is referred to as a **kinase**; the acceptor can be a small molecule or a protein. Another example of a transferase is acyltransferase that catalyzes the transfer of an acetyl group from acetylCoA to an acceptor such as lysine in a histone or a serine in other proteins (Figure 10.3).

An important amine transfer reaction occurs between an amino acid and a carbonyl-containing compound. These enzymes, **aminotransferases**, transfer the amino group and convert the amino acid to a keto acid; the accepting substrate, a keto acid, is transformed in to an amino acid (Figure 10.4). Aminotransferases require pyridoxal phosphate, derived from vitamin B_6, as a coenzyme (p. 755).

Class 3: Hydrolases

Hydrolases catalyze hydrolysis reactions, which are the addition of water to a chemical bond (Figure 10.5). This is essentially a transfer of an –OH from water to the substrate, but the enzymes are not classified as transferases. Hydrolysis is essentially an irreversible reaction. The substrate is typically an ester or an amide, for example, an ester between an alcohol and a carboxylic acid. Such a reaction is the hydrolysis of a cholesterol ester to produce cholesterol and a fatty acid. The acid need not be a carboxylic acid; sulfuric acid, phosphoric acid, or any acid can form an ester bond. RNases and DNases are enzymes that hydrolyze the phospho–ester bond. The clinical use of a hydrolase is presented in Clin. Corr. 10.1.

Class 4: Lyases

Lyase implies a breaking apart. These enzymes usually catalyze a carbon–carbon bond cleavage. Other enzymes in this class can form or break a carbon–nitrogen bond or release a CO_2 from a β-keto acid. Some of the reactions are reversible so a carbon–carbon bond can form, as illustrated by the reaction catalyzed by aldolase (Figure 10.6). Some lyases require pyridoxal phosphate as the cofactor. Important neurochemical reactions including the formation of dopamine (Figure 10.7) and serotonin are examples of this reaction. If a nucleotide triphosphate is not involved in forming the new bond, the enzyme is called

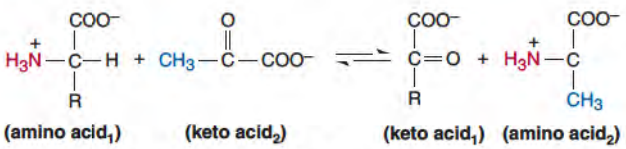

Figure 10.4 Example of a reaction catalyzed by an aminotransferase. Aminotransferase reactions require pyridoxal phosphate (PLP).

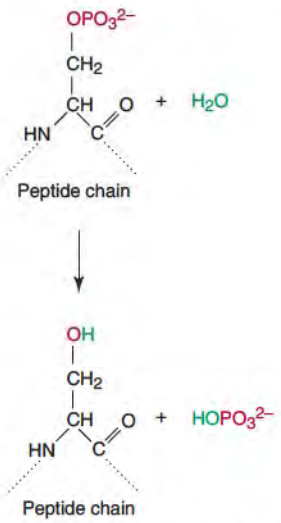

Figure 10.5 Hydrolysis of a phosphorylated protein by a protein phosphatase.

a **synthase**, but if the energy released when ATP is hydrolyzed is required, the enzyme is referred to as a **synthetase** (see Class 6: Ligases).

Class 5: Isomerases

The enzymes in this class are involved with moving a group or a double bond within the same molecule. These include exchanging the position of a hydroxyl and a carbonyl, such as found when glucose-6-phosphate is converted to fructose-6-phosphate (p. 596), and moving of a double bond from one position to the adjacent one, as found in fatty acid metabolism (p. 695). The enzyme is called a mutase when a phosphate is moved from one carbon to another within the same molecule such as occurs with phosphoglycerate mutase that converts 2-phosphoglycerate to 3-phosphoglycerate (Figure 10.8). Isomerases and epim-erases may change the stereochemistry at a carbon atom. The conversion of D-lactate to L-lactate is an example of an isomerase and D-xylulose 5-phosphate to D-ribulose 5-phosphate an epimerase (Figure 10.9). The UDP-glucose 4-epimerase-catalyzed reaction requires the involvement of NAD, so it is assumed that an oxidation–reduction reaction occurs during the reaction but there is no net oxidation–reduction of the coenzyme.

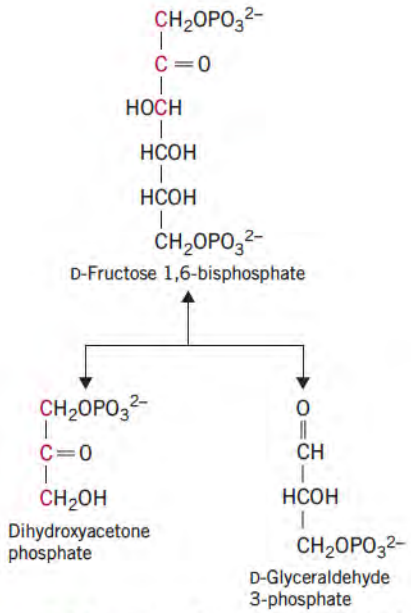

Figure 10.6 Lyase reaction catalyzed by aldolase.

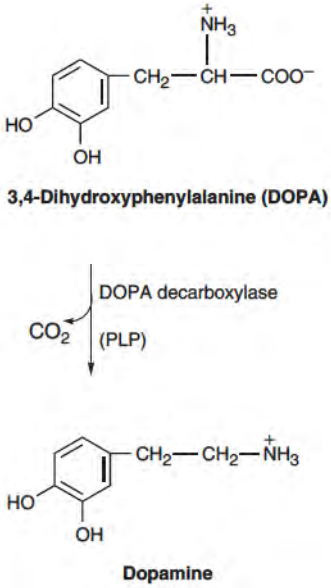

Figure 10.7 Dopamine synthesis involves a lyase reaction. Synthesis of dopamine requires pyridoxal phosphate (PLP).

CLINICAL CORRELATION 10.1

Hydrolysis of Asparaginase and Leukemia

Some forms of juvenile leukemia require the nonessential amino acid asparagine. Early investigators immobilized bacterially derived asparaginase, a hydrolase enzyme that converts asparagine into aspartic acid, and passed the patient's blood over a column of immobilized enzyme. This placed the patient afflicted with acute lymphoblastic leukemia into remission. Later investigators found that they could inject the enzyme into the patient where it would hydrolyze the substrate circulating in blood. More recently the enzyme was encoded in polyethlenglycol as some patients had a reaction to the bacterial enzyme even though it was purified to complete homogeneity. The encoded enzyme functioned well in children and helped clear their blood of asparagine. This form of the enzyme is commercially available and is approved for human treatment.

Appel, I. M., Kazemier, K. M., Boos, J., Lanvers, C., et al. Pharmacokinetic, pharmacodynamic, and intracellular effects of PEG-asparaginase in newly diagnosed childhood acute lymphoblastic leukemia: Results from a single agent window study. *Leukemia* 22:1665, 2008.

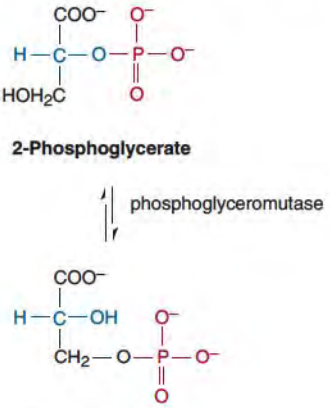

Figure 10.8 **Interconversion of 2- and 3-phosphoglycerates.**

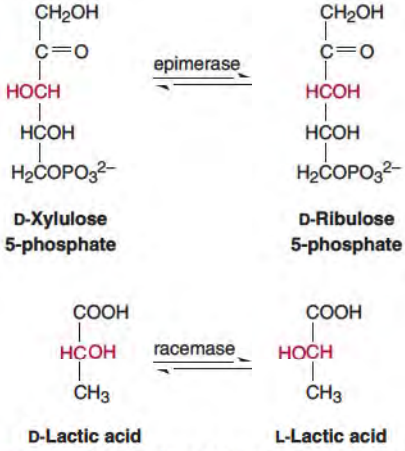

Figure 10.9 **Examples of reactions catalyzed by an epimerase and a racemase.**

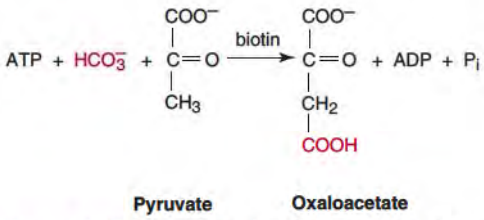

Figure 10.10 **Pyruvate carboxylase reaction.** See page 622 for details of biotins role.

Class 6: Ligases

Ligases join carbon atoms together but unlike lyases, Class 4, they require energy for the reaction. They are referred to as **synthetases**. Typically, the energy comes from the involvement of ATP. For example, to add CO_2 to pyruvate, CO_2 is incorporated into the coenzyme biotin, which requires hydrolysis of ATP (Figure 10.10). The CO_2 is transferred to pyruvate by the same enzyme. The addition of an amino acid to tRNA is another example of an enzyme in this class (p. 216). There must be some interaction between the components of the reaction to utilize the energy released from ATP hydrolysis for synthesis of the new bond.

10.3 • GENERAL CONCEPTS OF ENZYME MECHANISMS

Thermodynamic Considerations

Energy is required to form the starting material of a reaction and to form the product of a reaction. This energy is referred to as the **heats of formation**. There is a **thermodynamic relationship** between the difference in energy needed to form the starting material (reactants) and to form the products. The energy difference is ΔG_o, and the units can be expressed as either kilojoules/mole (kJ/mol) or kilocalories/mole (kcal/mol) (A Closer Look 10.1). When the equilibrium of the reaction is established, the concentration of each is related as indicated in Eq. 10.1.

$$\Delta G_0 = -2.3RT \times \log[\text{Products}]/[\text{Reactants}] \qquad (10.1)$$

R is the universal gas constant (8.31 joule/mole/°K, or 1.99cal/mole/°K) and T is the temperature in °K.

When added to a reaction, a catalyst increases the rate of reaching equilibrium between the starting material and the product. The ratio of [Products]/[Reactants] at equilibrium is the equilibrium constant, K_{eq}. This implies that the difference in the free energy (heats of formation) of the products and reactants will determine the amount of each that is present when equilibrium is reached. It does not dictate the rate at which equilibrium is reached. A catalyst increases the rate of the reaction to reach equilibrium but does not change the equilibrium. K_{eq} is governed by the heats of formation, which is a constant for any reaction.

Many reactions are considered irreversible; it is not possible for products of irreversible reactions to be reconverted to starting material even in the presence of an enzyme because essentially 100% of the starting material will become product. This statement is not completely valid, for even with essentially irreversible reactions, the ratio of starting material to products might be 1:200,000 or even 1:1,000,000. The reaction reaches equilibrium but

A CLOSER LOOK 10.1

Units of Energy

Two different conventions exist for describing the units of energy released or required for a chemical reaction. One is calories and the other is joules with the latter now being used in the scientific literature. Calories are still used to describe how much energy is available in food. For example, a typical glass of beer contains approximately 125 Cal (125 kilocal) of energy when metabolized. To convert calories to joules, one multiplies the caloric value by 4.184. Thus, the universal gas constant (R) in Eq. 10.1 is 1.987 cal/mol/°K, or 8.31 J/mol/°K. This book will use kilojoules (kJ) to describe the energetics of biological transformations, but it will also present the values in kilocalories (kcal or Cal). Nutritional discussions will use calories (Cal).

the amount of starting material present at equilibrium is lower than the level of detection, so the reaction is considered essentially irreversible.

Binding of Substrate by an Enzyme

For an enzyme to function as a catalyst it must first bind the substrate(s), and then lower the energy of activation so that the reaction will proceed at a faster rate than it would in the absence of the catalyst. Two prevalent theories exist to explain how substrate binds to the enzyme. The classical one is the **lock-and-key theory**, which proposes that the binding site for substrate on the enzyme is a rigid entity and only a compound with a particular shape will fit, analogous to how a lock (enzyme) allows only one key (substrate) to make the proper contact. An alternative theory is the **induced-fit theory**. This assumes that the enzyme is flexible, and after substrates bind to the enzyme, the conformation of the protein changes so that a stable binary complex forms. Both of the theories were presented prior to knowledge of the actual structure of any protein. Now that three-dimensional structures of many enzymes are known, it is found that substrate binding causes a small movement of the peptide bonds supporting the induced-fit hypothesis. A large conformational change is illustrated in Figure 3.33, p. 97. Figure 10.11 illustrates a change in conformation.

The altered structure of an enzyme after a substrate binds allows for complementary interactions between substrate and enzyme to take place. That is, a hydrophilic portion of the substrate will lie near amino acid residues that allow a hydrogen bond to be shared, and a charged portion of the substrate will interact such that either its charge is neutralized by an opposite charge or it is stabilized by forming a hydrogen bond. Hydrophobic portions of the substrate bind such that they are in a hydrophobic portion of the protein, referred to as a **hydrophobic pocket**.

Transition State

The theory to describe how a chemical reaction occurs is based on the transition-state model. The basic concept is that the starting material (substrate) has certain structural and chemical properties, and a product has others. The transition state is a structure where the bond(s) undergoing a transformation are such that they are not like either the starting material or the product.

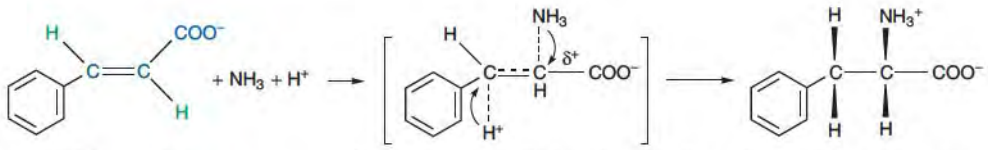

Figure 10.12 Transition state. The transition-state structure shows electrons in the double bond moving to accommodate the incoming proton, which makes the other carbon positive so the pair of electrons on the nitrogen can attack.

This can be illustrated in the reaction of ammonia adding to *trans*-cinnamic acid to produce phenylalanine (Figure 10.12), where the double bond in the starting material is planar. The product has the amine attached so the carbon that was part of the double bond (planar) is now tetrahedral in structure. The transition state is where the bond is starting to form and the geometry is changing. It takes energy to change the shape of the substrate so it will resemble the transition state, and the velocity of a reaction is inversely proportional to the energy needed to reach the transition state. A reaction energy plot is presented in Figure 10.13 and used to depict the energy change necessary to convert a substrate to the transition state. At the transition state, an entity exists that has never been observed or isolated. The transition-state entity can proceed to produce product, or it can return to the starting material. A catalyst simply lowers the energy of the transition state (ΔE^*), thus speeding up the rate of its formation from the starting material.

Enzymes stabilize the transition state by lowering the energy of activation, hence speeding up the reaction. This is accomplished by having residues in the enzyme interact with the substrate while in the transition state.

The hydrolysis of a peptide bond to produce a carboxylic acid and a free amino group illustrates how it might be possible for the enzyme to stabilize the transition state (Figure 10.14). As water adds to the peptide bond, the carbonyl group becomes tetrahedral and hence has to change its bond angle and shape. The transition state is not the tetrahedral intermediate but is the conformation that would lead to it should the covalent

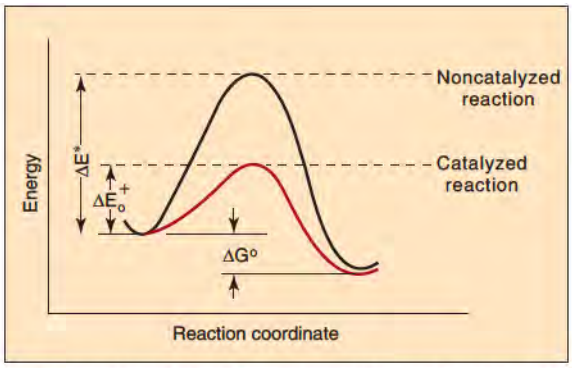

Figure 10.13 Energy diagrams for catalyzed versus noncatalyzed reactions. Diagrammatic representation of the energy differences between the reactant and product. The ground state is indicated by ΔG_0 and the transition state by ΔE^*. The velocity of the reaction is inversely proportional to ΔE^* while K_{eq} is related to the difference in ΔG_0. ΔE^* is the energy required to raise the ground state to the hypothetical transition state.

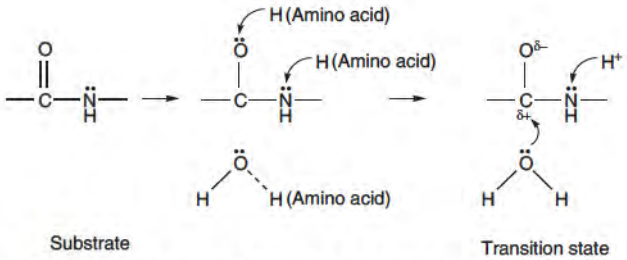

Figure 10.14 Transition state for the hydrolysis of a peptide bond. The carbonyl group in the planar peptide bond becomes tetrahedral as water (or OH^-) attacks and the nitrogen is protonated, followed by hydrolysis of the peptide bond. Amino acids in the active site furnish an H^+ to stabilize the developing negative charge on the carbonyl oxygen atom and protonate the nitrogen so it will leave as an amine. A different amino acid in the protein removes a proton from water, producing the more reactive OH^-.

bond actually form. During the reaction not only does the carbon–oxygen bond of the carbonyl group on the substrate change from being planar to being tetrahedral, but a negative charge develops on the oxygen that needs to be stabilized.

Tight Binding in the Transition State

An enzyme binds tightly the transition-state structure but not the substrate or final product. If it binds substrate tightly, then it takes more energy to reach the transition state. Similarly, the enzyme cannot bind the product too tightly, for if it did, it would become too difficult for the product to dissociate from the enzyme. The enzyme needs to release product so it can again interact with another molecule of substrate. These concepts are illustrated in Figure 10.15.

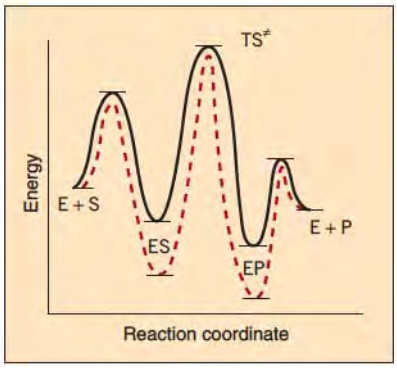

Figure 10.15 Energy diagrams for transition state of tightly bound substrate. Red line indicates tight binding of substrate in comparison to a less tightly bound substrate. More energy is required if the substrate is tightly bound, hence a slower reaction to reach the transition state. A similar condition occurs if the product is bound too tightly; more energy would be required to reach the transition state for releasing product. There is a transition state for each step in the reaction.

Ionic Reactions Need Not Involve Ions

The majority of reactions found in nature can be explained using ionic models. That is, most cellular reactions require positive and negative charges within the molecules to allow the components to interact. The enzyme can add or remove protons from the substrate, changing its charge, or a neutral group of the enzyme becomes ionic. The removal of a proton makes a group more nucleophilic, which is a group (nucleophile) that will attack a positive center. For example, OH^- is more nucleophilic than is water and ionized cysteine is more nucleophilic than is the unionized sulfur atom. Similarly, enzymes can protonate a group to make it positive so it will be more susceptible to nucleophilic attack. In the hydrolysis of a peptide bond the more nucleophilic $-OH^-$ group attacks the bond rather than water. In addition, the attack will be on a polarized carbonyl group, where the carbon atom would have a partial positive charge, rather than on an unpolarized carbonyl group (Figure 10.14). The addition and removal of protons is referred to as **general acid** and **general base catalysis**, respectively. The advantage of enzymes using general acid and general base catalysis is that at a physiological neutral pH, they can catalyse a reaction even though the concentration of OH^- and H^+ is very low.

Partially Charged Bonds

A common way for forming a carbon–carbon bond is to have a carbanion attack a carbonyl group, as illustrated with the formation of fructose-1,6-bisphosphate from two three-carbon compounds (Figure 10.16*a*). The presence of the carbonyl group in dihydroxyacetone phosphate allows the hydrogen atoms on the carbon adjacent to be more acidic. The enzyme removes a proton, leaving a negative charge on the carbon. Electrons of a carbonyl group reside closer to the oxygen; thus the carbon carries a partial positive charge. This stabilizes the carbanion since the electrons are delocalized and not just associated with one carbon. The carbanion then can attack the carbonyl group to form the new bond. The enzyme both holds the two substrates near to each other increasing the likelihood of favorable collision and is involved in polarizing the carbonyl bond and removing a proton.

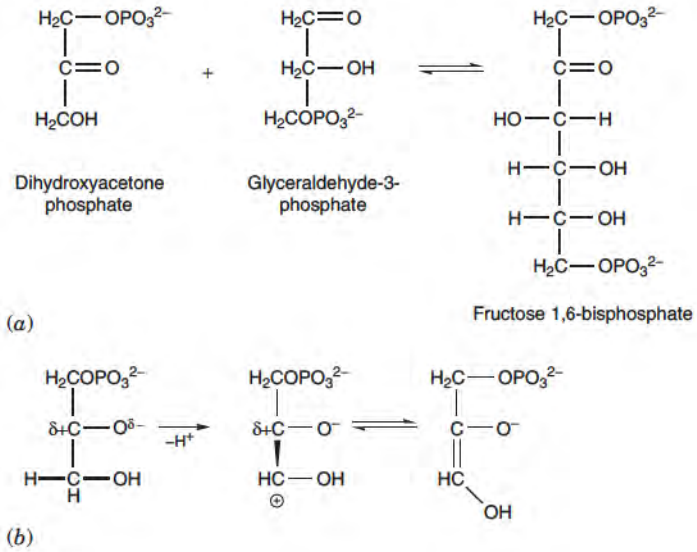

Figure 10.16 A carbonyl group stabilizes a negative charge on the adjacent carbon. (*a*) Reaction of dihydroxyacetone phosphate and glyceraldehydes-3-phosphate to form fructose 1,6-bisphosphate. (*b*) Dihydroxyacetone phosphate transition states. The partial positive charge on the carbon can be attacked by a carbanion to form a new carbon–carbon bond. The presence of the carbonyl group will allow a proton to be removed from the adjacent carbon atom so the carbanion can be produced.

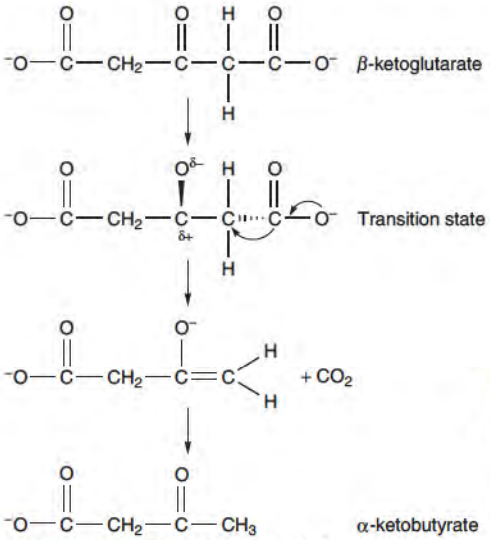

Figure 10.17 Decarboxylation of β-ketoglutarate. The decarboxylation of β-ketoglutarate occurs because the partial positive charge on the carbon of the carbonyl group stabilizes the developing negative charge that forms as the bond to the carboxyl group starts to break. A carbonyl adjacent to the leaving CO_2 cannot stabilize the charge.

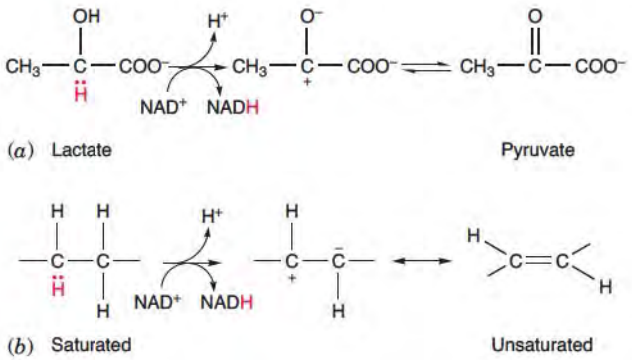

Figure 10.18 Oxidation of lactate and a saturated carbon bond. (*a*) Lactate to pyruvate. (*b*) Saturated bond to an unsaturated bond. These reactions undergo an ionic-type reaction even though a hydride ion (H^-) is involved.

Importance of the Carbonyl Group

Many metabolic transformations are based on the special nature of the carbonyl group and its ability to stabilize a negative charge on the carbon adjacent to it. For example, β-keto acids such as β-ketoglutarate (Figure 10.17) can be decarboxylated but it is energetically more difficult for an α-keto acid such as pyruvate to be decarboxylated. As the —CH_2—COO^- bond breaks, the electrons in the bond are left behind on the β-carbon. The developing negative charge on what was the β-carbon can be stabilized by the partial positive charge on the carbonyl carbon. The enzyme stabilizes the transition state by having a proton interact with the carbonyl oxygen that is partially negative due to the resonance of the carbonyl carbon and the developing negative charge on the β-carbon.

In contrast, pyruvate cannot undergo a simple decarboxylation reaction, as there would be no way to stabilize the negative charge that would result from the pair of electrons being left as the CO_2 group departs. For decarboxylation of α-keto acids, coenzymes are required.

Oxidations

Even oxidation reactions have an ionic component. During the oxidation of an alcohol to an aldehyde/ketone or a carbon–carbon saturated bond to an unsaturated bond, the electrons are moved not as free electrons but as a hydride ion, that is, a proton with two electrons carrying a negative charge (Figure 10.18). The hydride ion does not go into the solvent as does a proton but to an acceptor such as NAD(P) or FAD.

Addition and Removal of Protons

Most enzymes efficiently add and remove protons but often in a unique way. Proteases can polarize the carbonyl group of the peptide bond so that the bond is more easily hydrolyzed, catalyzing general base catalysis, or acid catalysis, or metal ion catalysis (p. 393).

Phosphorylation of proteins, especially on the hydroxyl group of a serine, threonine, or tyrosine residues by ATP or GTP, proceeds by having the —OH group attack phosphate (Figure 10.19). It is necessary to make the —OH more nucleophilic by having it lose a proton while the phosphate–oxygen bond is being polarized so the phosphorous atom is partially positive and is more susceptible to nucleophilic attack. Nearly every enzyme (kinases) catalyzing this type of reaction uses Mg^{2+}. Divalent ions can bind to two or three of the phosphates. The presence of the positive ion causes the electrons in the P═O bond to reside closer to the oxygen atom thus leaving the phosphate ion with a slightly positive charge.

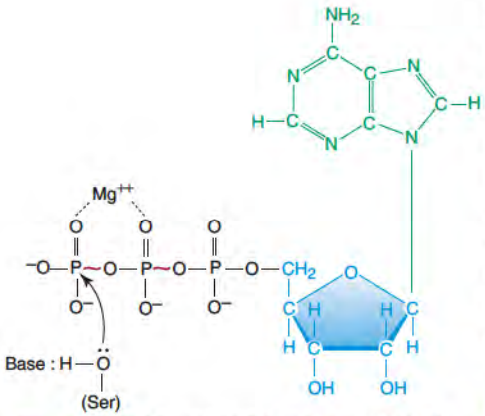

Figure 10.19 Phosphorylation is an attack of a nucleophile on a nucleoside triphosphate (NTP). ATP or another NTP is attacked by the pair of electrons on the oxygen of an alcohol such as serine, threonine, or tyrosine. A Mg^{2+} ion when bound by the NTP serves to pull electrons away from the phosphorous group making it more susceptible to attack by the nucleophile.

Covalent Binding of Substrate to Enzyme

Enzymes not only function in performing general acid and base catalysis, but in some cases the substrate forms a covalent bond with the enzyme. Both chymotrypsin and glyceraldehyde 3-phosphate dehydrogenase are examples of such enzymes (Figure 10.20). In each case, a nucleophilic amino acid attacks a carbonyl group. Even some kinases function with covalent catalysis; ATP initially binds to the enzyme, and the phosphate is transferred to a nucleophilic residue forming a phosphorylated enzyme; in this case a hydroxyl group on a serine or threonine is

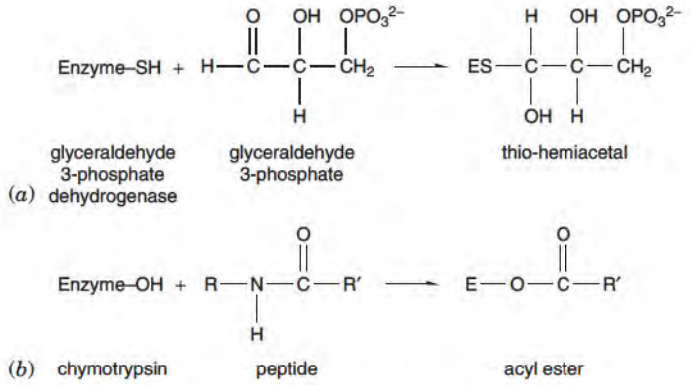

Figure 10.20 Some substrates form a covalent bond with an enzyme.
(*a*) Glyceraldehyde-3-phosphate dehydrogenase and (*b*) chymotrypsin function by first forming a covalent intermediate with substrate.

activated and does the initial attacking. Substrate then enters, and it is activated by the general base on the enzyme; the base attacks the phosphate group forming the final product.

pH Alters a Reaction by Affecting General Acids and Bases

Nearly all enzymes involve general acid/base catalysis, and it is not unexpected that reaction rates would be affected by pH. An enzyme requiring a histidine to donate a proton in a reaction will not proceed at pHs above 8, where most of the imidazole groups of histidine are unprotonated. The pK_a of the imidazole is near 7 (Figure 10.21). All enzymes have a pH versus rate profile (p. 405), which in some cases gives an insight as to the groups involved in the active site. Since the overall structure of a protein is important in the catalytic activity, if a change in pH alters the overall protein conformation, then the activity will also be changed. In some disease states, the intracellular pH is not normal; this will affect cellular enzyme activity.

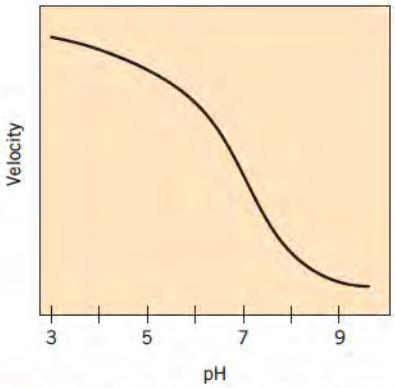

Figure 10.21 Velocity of an enzyme-catalyzed reaction can be affected by pH if a group dissociates a H^+. If an imidazole of histidine needs to be protonated for catalytic activity of an enzyme, the velocity of the reaction will decrease as the pH increases above the pK_a (assume 7) of the residue. If the group needed to be unprotonated for the enzyme to function, then the curve would have the reverse shape, with maximum activity above pH8. Half maximal activity would be found at the pK_a of the group because 50% of the molecules will be ionized and 50% unionized.

10.4 • ACTIVE SITE OF AN ENZYME

The active site of an enzyme is small compared to the overall size of the protein molecule. Most of the amino acid residues are not in contact with the substrate (Figure 10.22). The distances and angles between the catalytic residues of the enzyme and the substrate must be exact to permit catalysis to occur. Most of the amino acids in the protein serve as a large scaffold to allow for the proper alignment of the functional groups of the substrates. A mutation of a residue distant from the active site can cause the enzyme to have altered activity. This is illustrated in Figure 10.23 for a point mutation in human liver aldehyde dehydrogenase.

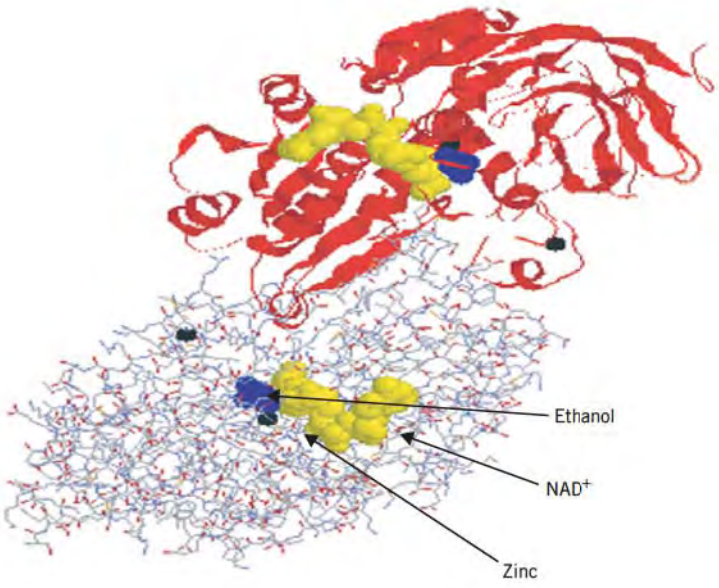

Figure 10.22 Enzymes are much larger than their substrates. Alcohol dehydrogenase with ethanol bound to a Zn^{2+} and an NAD^+ at the active site. Most of the amino acids of the protein are not in contact with the substrate. One subunit of the dimer is shown as ribbons and the other as atoms.

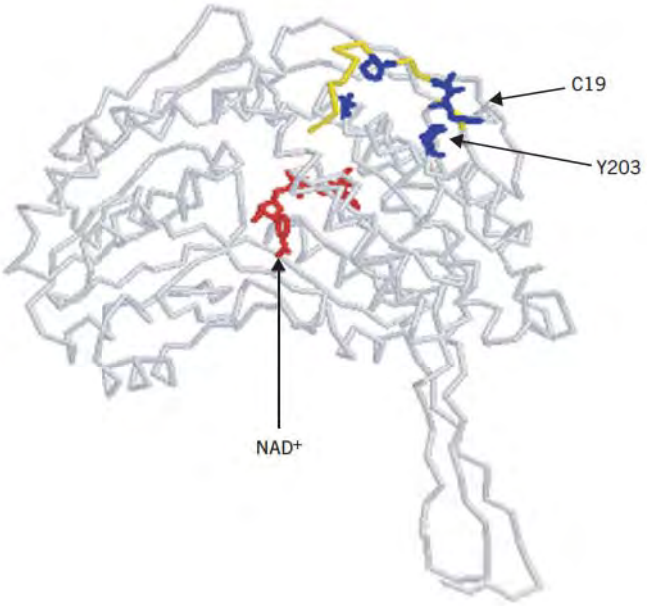

Figure 10.23 Amino acids at a distance from the active site are critical. An amino acid residue on the surface of an enzyme might be necessary to keep the enzyme in its proper shape. Residue 19, a cysteine, of a subunit of aldehyde dehydrogenase (500 amino acids) was changed to tyrosine. The resulting mutant was insoluble. Residue 19 normally bonds to residue 203, which is apparently necessary to maintain the proper three-dimensional structure.

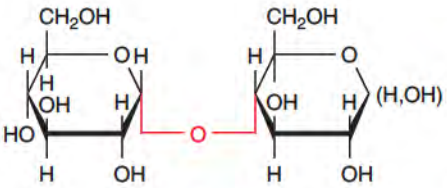

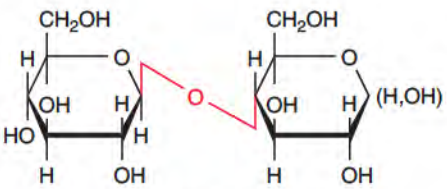

Figure 10.24 Enzymes can differentiate between α and β linkages. An enzyme that hydrolyzes maltose does not hydrolyze cellobiose.

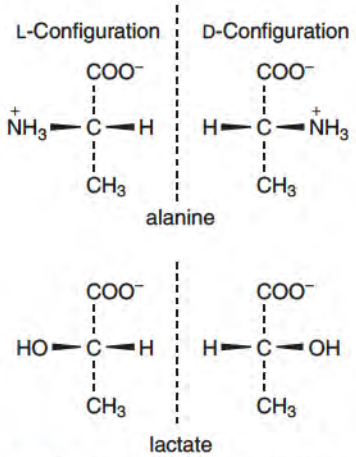

Figure 10.25 Enzymes can differentiate between optical isomers.

Stereochemistry of Active Site

The active site is specific for the substrate. As an example, subtle geometric constraints prevent an enzyme from hydrolyzing a β-glycosidic linkage between two glucose molecules while allowing the enzyme to hydrolyze the α-linkage (Figure 10.24). Enzymes also differentiate between optical isomers; though both the D and L forms of many compounds exist, mammalian cells utilize only one stereoisomer. D-Lactate is hardly recognized by mammalian lactate dehydrogenase, which is specific for the L-isomer (Figure 10.25). The binding can also react with pro-chiral centers to produce an optically active compound. A chiral carbon has four different groups attached and is optically active; a **pro-chiral center** is a carbon that is not optically active but becomes optically active on a stereo-specific addition of a group. The non-optically active compound binds to the enzyme in just one orientation, forcing the chemical reaction to produce an optically pure product. Glycerol, a non-optically active compound, is phosphorylated by glycerol kinase; only the L-product is produced. The enzyme binds the compound such that just one of the primary alcohols is near ATP. This occurs because the surface of the enzyme is asymmetric since the amino acids are all L configuration and the helices are all right handed (p. 93). Though perhaps an over simplification, it is often stated that if there were a three-point attachment of the substrate to the enzyme, then an optically pure product would be formed from a pro-chiral center (Figure 10.26). See A Closer Look 10.2 for a discussion on how stereochemistry explains some enzyme mechanisms.

Influence of Groups on the Substrate Distal to the Bond Being Modified

The chemistry at the active site in some cases involves a limited portion of the substrate, but adjoining portions of the substrate can be necessary for the reaction to occur. For example, the mitochondrial-processing protein peptidase requires at least 12 residues before the site of hydrolysis in order to function. Lysozyme, an enzyme that hydrolyzes bacterial cell walls, involves sugar residues located on both sides of the bond to be split (Figure 10.27). The binding of adjacent sugar moieties helps create a change in the conformation of the sugar at the bond being broken. Thus, the active site is more than just the amino acid residues involved in the bond breakage or formation; it is a complex region on the enzyme that can adjust its structure to accommodate the proper substrate and stabilize the transition state.

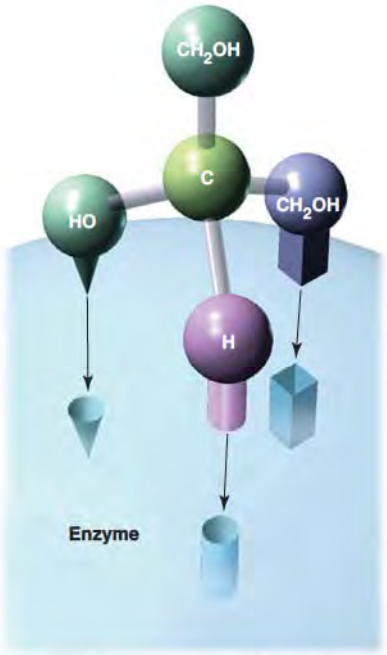

Figure 10.26 Three-point attachment of a symmetrical substrate to an asymmetric substrate-binding site. Glycerol kinase by virtue of dissimilar binding sites for the —H and —OH group of glycerol binds only the α'-hydroxymethyl group to the active site. One stereoisomer results from the kinase reaction, L-glycerol 3-phosphate. Active site is box on the right.

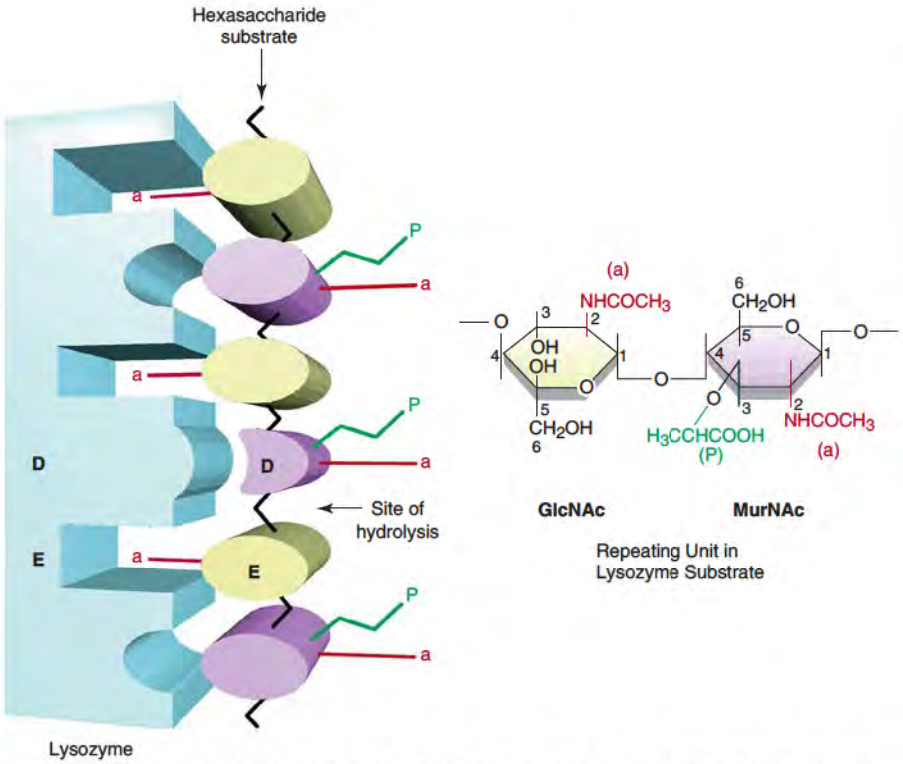

Figure 10.27 Hexasaccharide binding at active site of lysozyme. In the model substrate pictured, the ovals represent individual pyranose rings of the repeating units of the lysozyme substrate shown to the right. Ring D is strained by the enzyme to the half-chair conformation, and hydrolysis occurs between the D and E rings. Six subsites on the enzyme bind the substrate. Alternative sites are specific for acetamido groups (*a*) but are unable to accept the lactyl (P) side chains, which occur on the *N*-acetylmuramic acid residues. Thus the substrate can bind to the enzyme in only one orientation.
Redrawn based on model proposed by Imoto, T., et al. In Boyer, P. (Ed.), *The Enzymes*, 3d ed., Vol. 7. New York: Academic Press, 1972, 713.

A CLOSER LOOK 10.2

Stereochemistry Helps Explain the Mechanism of Enzyme-Catalyzed Reactions

Many naturally occurring substrates are optically active. The stereochemistry of the product can give a clue to the mechanism the enzyme employs. For example, if the reaction produces a carbonium ion, one would expect the product to be racemic. However, an enzyme-catalyzed carbonium ion reaction will produce a product with retention of stereochemical configuration. The carbonium ion would not be free in solution but would be associated with the enzyme, so the incoming nucleophilic attack could come only from the same direction as the leaving group. Retention of configuration can also be achieved by an enzyme that functions with covalent catalysis. Reactions catalyzed by a ping-pong mechanism (p. 405) involve two inversion steps that produce a product with retention of configuration. As an example, the phosphorolysis of a disaccharide starts with the sugar in the β conformation and ends with a phosphorylated product that is also β. The attachment of the substrate to the enzyme causes inversion to an α configuration, but phosphate attacks to give another inversion resulting in retention of configuration. If the reaction occurred by a direct attack of the phosphate on the substrate, then the product would have been inverted. Inversion of configuration at an optically active carbon usually occurs when there is a ternary complex and the nucleophile attacks the substrate.

TABLE 10.3 • Coenzymes

Coenzyme	*Vitamin*	*Reaction Mediated*

CLINICAL CORRELATION 10.2

Mutation of a Coenzyme-Binding Site Results in Clinical Disease

Cystathioninuria is a genetic disease in which γ-cystathionase is either deficient or inactive. Cystathionase catalyzes the reaction

$$\text{Cystathionine} \rightarrow \text{cysteine} + \alpha\text{-ketobutyrate}$$

Deficiency of the enzyme leads to accumulation of cystathionine in the plasma. Since cystathionase is a pyridoxal phosphate-dependent enzyme, vitamin B_6 was administered to patients whose fibroblasts contained material that cross-reacted with antibodies against cystathionase. Many responded to B_6 therapy with a fall in plasma levels of cystathionine. These patients produce the apoenzyme that reacted with the antibody. In one patient the enzyme activity was undetectable in fibroblast homogenates but increased to 31% of normal with the addition of 1 mM of pyridoxal phosphate to the assay mixture. It is thought that the K_m for pyridoxal phosphate binding to the enzyme was increased because of a mutation in the binding site. Activity is partially restored by increasing the concentration of coenzyme. Apparently these patients require a higher steady-state concentration of coenzyme to maintain γ-cystathionase activity.

Pascal, T. A., Gaull, G. E., Beratis, N. G., Gillam, B. M., et al. Vitamin B_6-responsive and unresponsive cystathionuria: two variant molecular forms. *Science* 190:1209, 1975.

10.5 • COENZYMES, CO-SUBSTRATES, AND COFACTORS

Many enzymes require the participation of a nonprotein molecule during the enzymatic reaction. **Coenzymes** are small organic molecules; most are derivatives of vitamins (Chapter 26) Coenzymes are involved in many different reactions and may or may not be modified in the reaction. Those that are altered are also referred to as **co-substrates**. For some reactions the energy from hydrolysis of ATP is required without incorporation of phosphate in the product; in this case ATP is a co-substrate. Metal ions are required for many enzyme reactions and are termed **cofactors**.

Coenzymes

Table 10.3 lists the coenzymes and the vitamins from which they are derived. Coenzymes participate in enzyme-catalyzed reactions, but they are not the primary compounds being modified. Some coenzymes participate in the action of many different enzymes whereas others only in a limited number of reactions. They have affinities for specific enzymes and may be tightly bound or covalently attached. Some are modified during the course of a reaction but are in their original state at the end of the reaction whereas others remain modified at the end. If they are modified at the end, they must participate in another reaction to be returned to their original state. Coenzymes are present in cells in a reasonably constant concentration and play a dynamic role in metabolism. The term *apoenzyme* is used to refer to an enzyme that does not have the coenzyme bound to it, and *holoenzyme* refers to an enzyme with its cofactor bound. The importance of the coenzyme-binding site and how alterations in this site cause metabolic dysfunction are discussed in Clin. Corr. 10.2.

NAD and NADP Are Coenzyme Forms of Niacin

Nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP) (Figure 10.28) are derived from niacin (p. 1077) and are involved in oxidation–reduction reactions catalyzed by dehydrogenases. The difference between NAD^+ and $NADP^+$ is the presence of a phosphate group on the 2′ carbon of the adenine ribose. The nomenclature for the abbreviations for these coenzymes is described in A Closer Look 10.3. A generalized dehydrogenase reaction involving NAD^+ is presented in Figure 10.29. Though most dehydrogenases are specific for one or the other coenzyme, some can use either form. Most dehydrogenases catalyze reversible reactions.

The functional portion of the oxidized coenzyme is the nicotinamide ring that has a nitrogen atom at position 1 and carries a positive charge due to the attachment to a ribose ring. The positive charge makes it possible for the nicotinamide to accept a hydride ion, transferring two electrons (Figure 10.30). A ternary complex between enzyme, coenzyme, and substrate forms and a hydride ion is transferred from substrate to $NAD(P)^+$. A proton from the substrate is released to the medium. For the reverse

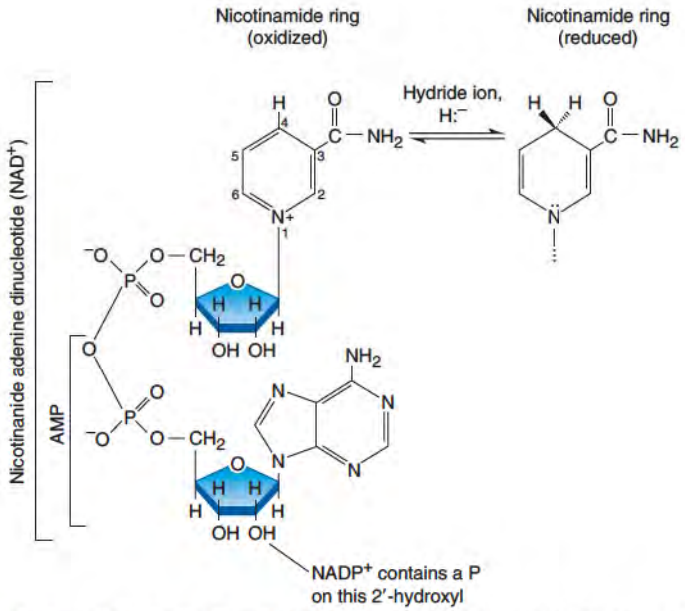

Figure 10.28 Nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP).

reaction, the reduced nicotinamide ring is involved and the ring does not have the positive charge until the hydride is transferred to an oxidized substrate. The reactions in which NAD(P) participate can be considered as ionic though the ion they transfer is a hydride ion that carries a negative charge. Hydride ions do not exist in the free state; the ion is transferred directly between substrate and coenzyme. After accepting or donating the hydride ion, the coenzyme dissociates from the enzyme and enters the cellular pools of NAD^+ or $NADP^+$ and is available for other reactions. The ratios of NAD^+/NADH and $NADP^+$/ NADPH are independent of a specific dehydrogenase but are measures of the oxidation–reduction state of the cellular compartment (p. 561). NAD-dependent dehydrogenases are more often involved in catabolism whereas NADP-dependent ones in anabolism.

Nearly all NAD(P)-dependent dehydrogenases possess a similar structural motif (**Rossmann fold**) involved in the coenzyme binding domain; the motif for alcohol dehydrogenase is presented in Figure 10.31.

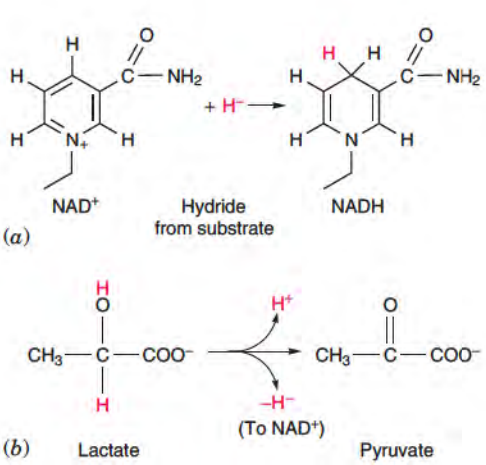

Figure 10.30 NAD is involved in oxidation–reduction reactions. (*a*) Nicotinamide group in NAD^+ accepts a hydride ion (H^-) while oxidizing substrate. (*b*) Lactate donates the hydride ion when oxidized to pyruvate.

A CLOSER LOOK 10.3

Abbreviations for NAD and NADP

The notation NAD and NADP are used generically to indicate the coenzymes whether oxidized or reduced. NAD^+ and $NADP^+$ specify the oxidized forms, and NADH and NADPH the reduced forms. Some enzymes use either NAD or NADP, so they are referred to as NAD(P)-dependent enzymes.

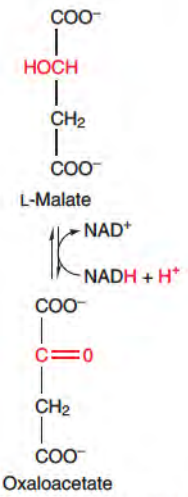

Figure 10.29 Reaction catalyzed by malate dehydrogenase. The enzyme forms a ternary complex by binding both NAD^+ and malate before the hydride ion is passed to NAD^+.

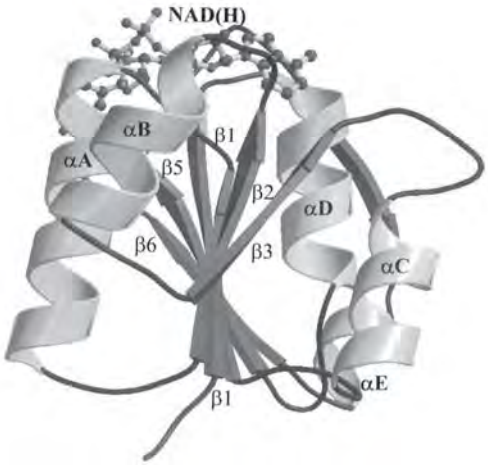

Figure 10.31 The Rossmann fold in liver alcohol dehydrogenase. NAD(H) binds to the Rossmann fold in most dehydrogenases.

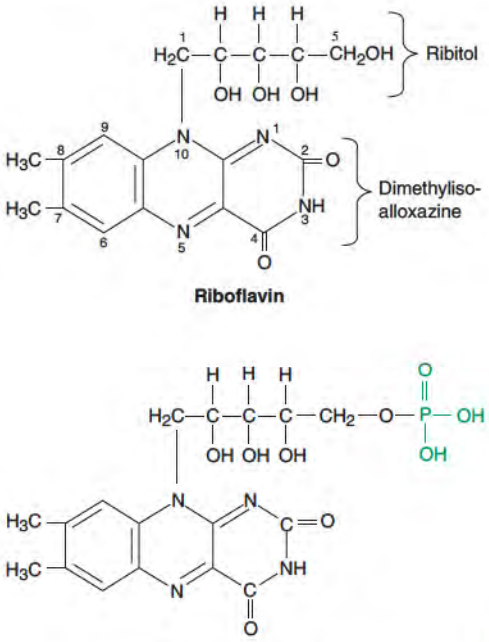

Figure 10.32 **Riboflavin and flavin mononucleotide.**

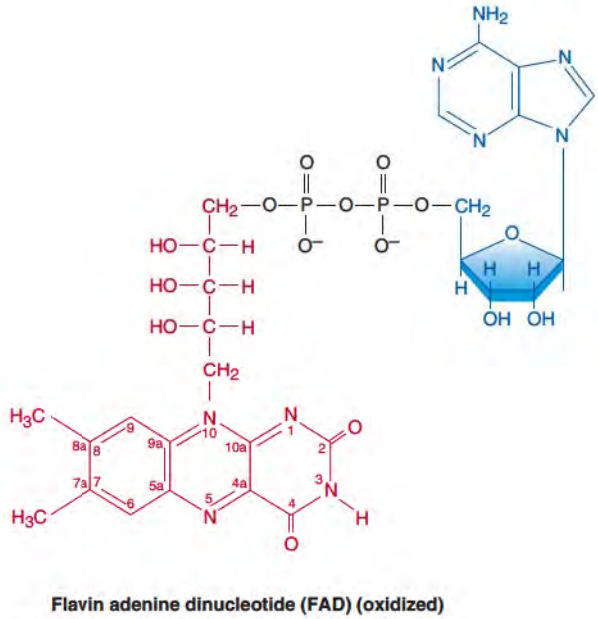

Figure 10.33 **Flavin adenine dinucleotide (FAD).**

FMN and FAD Are Coenzyme Forms of Riboflavin

The two coenzyme forms of riboflavin are **FMN** (**flavin mononucleotide**) and **FAD** (**flavin adenine dinucleotide**). The vitamin riboflavin consists of the heterocyclic ring, isoalloxazine (flavin) connected through N-10 to the alcohol ribitol (Figure 10.32). FMN has a phosphate esterified to the 5′-OH group of ribitol. FAD is structurally analogous to NAD in having adenosine linked by a pyrophosphate linkage to sugar of a flavin mononucleoside (Figure 10.33). Both FAD and FMN function in oxidoreduction reactions by accepting and donating $2e^-$ in the isoalloxazine ring in the form of a hydride. In some cases, these coenzymes are $1e^-$ acceptors, which lead to flavin semiquinone formation (a free radical). Flavin coenzymes are not found free in solution but are bound either very tightly or covalently. They are considered a **prosthetic group** in the latter case. This requires that an enzyme involved in an oxidation reaction generating reduced bound flavin must also carry out the reduction of another substrate so that oxidized flavin will be regenerated.

The oxidation of a saturated carbon–carbon bonds, such as in oxidation of succinic acid to fumaric acid (Figure 10.34) or a saturated to an unsaturated fatty acid, involves flavin-dependent dehydrogenase reactions. In the case of monoamine oxidase, a flavin-containing enzyme, a hydride ion is removed from the amine but the terminal acceptor of electrons is molecular oxygen, leading to formation of hydrogen peroxide.

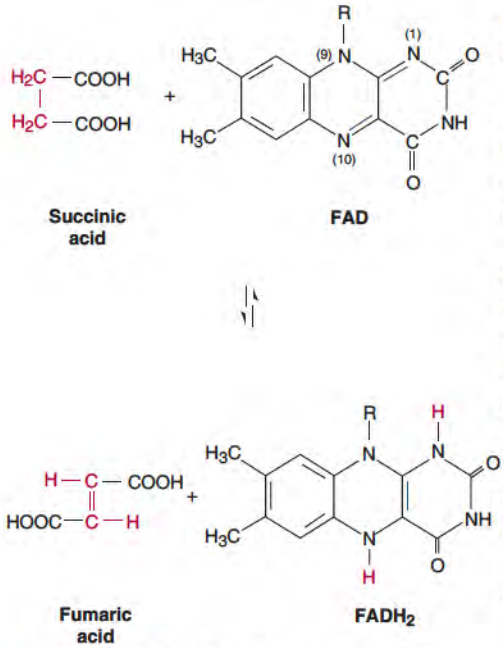

Figure 10.34 **FAD is the coenzyme in the succinic dehydrogenase reaction.**

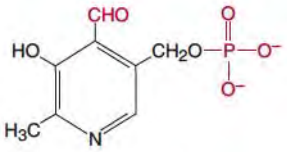
Pyridoxal Phosphate Is the Coenzyme Form of Pyridoxal

Pyridoxal phosphate (Figure10.35) is involved primarily in reactions involving amino acids. A major reaction utilizing pyridoxal phosphate is transamination, a reaction (see Figure 10.4, p. 380) that introduces an amino group into a compound. The acceptor is a carbonyl group such as an α-keto acid and the donor is an amino acid such as glutamate or aspartate (see Figure 19.3, p. 753). The amino acid bound to pyridoxal phosphate transfers the amino group to it making an enzyme-bound pyridoxamine. After the substrate which donated the amino group leaves the enzyme, a different α-keto acid enters and there is a transfer of the amine from pyridoxamine. Pyridoxal is thus regenerated. This is an example of the modification of a coenzyme during the reaction but returning to its original state at the end.

Resonance in the pyridine ring of the coenzyme stabilizes a negative charge at what was the α-carbon. The basis of the reaction is that the aldehyde in the pyridoxal moiety binds with the amino acid making a Schiff base. It is on this covalent intermediate that the

enzyme catalyzes the removal of the group. A pair of electrons is left on the carbon, and their charge is stabilized by resonance with the pyridoxal ring. The formation of dopamine and serotonin, important neurotransmitters, involves a pyridoxal phosphate enzyme.



Pyridoxal phosphate

Figure 10.35 Pyridoxal phosphate. Pyridoxal phosphate binds to the amino group of an amino acid and assists in the removal of the R group, the H or the CO_2 of the amino acid.

Adenosine Triphosphate May Be a Second Substrate or a Modulator of Activity

Adenosine triphosphate (ATP) (Figure 10.36) functions as co-substrate, but can also serve as a cofactor in modulation of the activity of some enzymes. This compound is central in biochemistry and is synthesized in all mammalian cells. The biochemically functional end is the reactive triphosphate. The terminal phosphate–oxygen bond has a high free energy of hydrolysis, which means that the phosphate can be transferred from ATP to other acceptor groups. For example, as a co-substrate ATP is utilized by the kinases for the transfer of the terminal phosphate to various acceptors. A typical example is the reaction catalyzed by hexokinase (see Figure 15.4; p. 594).

ATP also serves as a modulator of the activity of some enzymes. These enzymes have binding sites for ATP, occupancy of which changes the affinity or reactivity of the enzyme toward its substrates. In these cases, ATP in these cases is an **allosteric effector** (p. 413).

Metal Ion Cofactors

Many enzymes require the presence of a metal ion for activity. Metal ions serve a structural role or function as a Lewis acid (a positive ion that can bind to unpaired electrons) or as an electron acceptor/donor in oxidation–reduction reactions. They can bind directly to an enzyme or to the substrate. The metal-ion-bound substrate is the actual substrate for the reaction. A very common reaction involves a Mg^{2+} ion bound to a nucleotide triphosphate; the metal ion binds to the phosphates making the phosphate ion more positive and susceptible to nucleophilic attack (Figure 10.37).

Metalloenzymes contain a tightly bound transition metal, such as Zn^{2+} or Fe^{2+}, which facilitates binding of substrate by forming a metal-bridged complex. Metals function either by binding substrate and promoting electrophilic (nucleophilic) catalysis at the site of bond cleavage or by stabilizing intermediates in the reaction pathway. In alcohol dehydrogenase, an enzyme-bound Zn^{2+} interacts with the oxygen in the substrate, changing the properties of the carbon to which the oxygen is attached (Figure 10.38). Zn^{2+} functions in carboxypeptidase and thermolysin, proteases with identical active sites, to

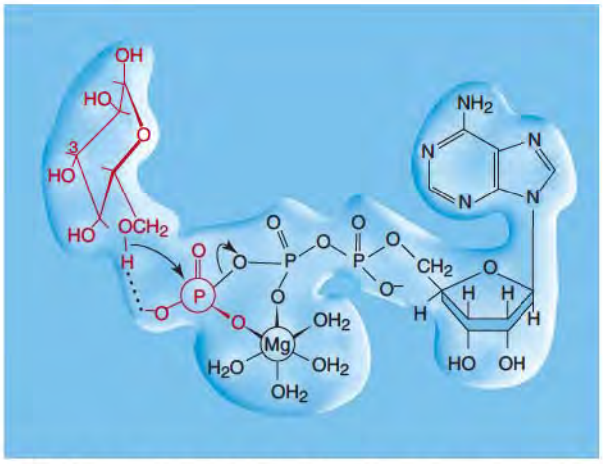

Figure 10.37 Role of Mg^{2+} as a substrate-bridged complex in the active site of the kinases. In hexokinase the terminal phosphate of ATP is transferred to glucose, yielding glucose 6-phosphate. Mg^{2+} coordinates with the ATP to form the true substrate and may labilize the terminal P—O bond of ATP to facilitate transfer of the phosphate to glucose. There are specific binding sites (light blue) on the enzyme (darker blue) for glucose (upper left in red) as well as the adenine and ribose moieties of ATP (black).

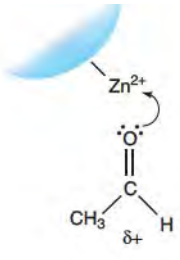

Figure 10.38 Binding of a carbonyl to Zn^{2+}. Zn^{2+} binding of the carbonyl of an aldehyde results in making the carbon atom partially positive and more receptive to accepting a hydride ion from NADH.

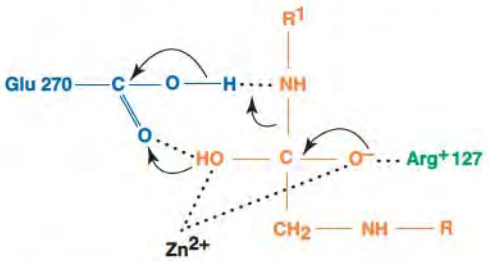

Figure 10.39 Stabilization of the transition state of the tetrahedral intermediate by Zn^{2+}. Positive charge on the Zn^{2+} stabilizes the negative charge that develops on the oxygens of the tetrahedral carbon in the transition state. The tetrahedral intermediate then collapses as indicated by the arrows, resulting in breakage of the peptide bond.

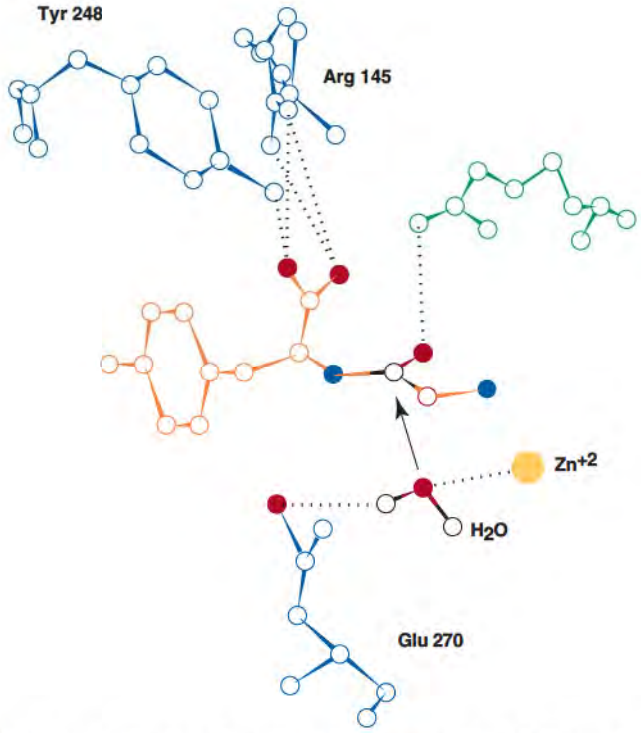

Figure 10.40 Zn^{2+} in the mechanism of reaction of carboxypeptidase A. Enzyme-bound Zn^{2+} generates a hydroxyl nucleophile from bound water, which attacks the carbonyl of the peptide bond as indicated by the arrow. Glu 270 assists by pulling the proton from the zinc-bound water. Redrawn from Lipscomb, W. N., and Robert, A. *Welch Found. Conf. Chem. Res.* 15:140, 1971.

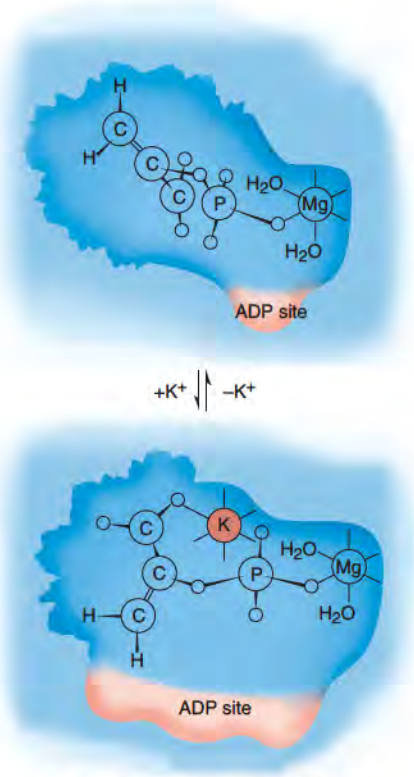

Figure 10.41 Model of the role of K^+ in the active site of pyruvate kinase. Pyruvate kinase catalyzes the reaction: phosphoenolpyruvate + ADP → ATP + pyruvate. Initial binding of K^+ induces conformational changes in the kinase, which result in increased affinity for phosphoenolpyruvate. In addition, K^+ orients the phosphoenolpyruvate in the correct position for transfer of its phosphate to ADP (not shown), the second substrate. Mg^{2+} coordinates the substrate to the enzyme active site. More recent results show the precise role of K^+ ions is not really known, but it appears that the ion allows for the proper orientation of the active site to permit catalysis to occur.

generate a hydroxyl group from water and to stabilize the transition state resulting from attack of the hydroxyl on the peptide bond. Figure 10.39 depicts the generation of the active-site hydroxyl by Zn^{2+}. Glu 270 functions as a base necessary to remove the proton from water. Stabilization of the tetrahedral transition state by Zn^{2+} is shown in Figure 10.40. The Zn^{2+} provides a counterion to stabilize the negative oxygen on the tetrahedral carbon.

In addition to the role of binding enzyme and substrate, metals also bind directly to the enzyme to stabilize it in the active conformation or perhaps to induce the formation of an active site. Mn^{2+} has such a role as do weakly bound alkali metals (Na^+ or K^+). In pyruvate kinase, K^+ induces an initial conformational change, which is necessary, but not sufficient, for ternary complex formation. On substrate binding, K^+ induces a second conformational change to the catalytically active ternary complex as indicated in Figure 10.41. Mammalian alcohol dehydrogenase is unique in that it possesses two molecules of Zn^{2+} per subunit; one is involved in catalysis whereas the other has a structural role. Each metal ion is bound to ligands; in this case they are amino acid side chains of the protein. For example, Zn^{2+} binds four ligands. In alcohol dehydrogenase the structural Zn^{2+} has four amino acids bound to it whereas the active site Zn^{2+} has just three with water or substrate serving as the fourth. Some compounds such as azide ion (N_3^-) or carbon monoxide (CO) bind to the substrate-binding site on metals, thus preventing the enzyme or protein from binding its proper substrate.

Role of Metals in Oxidation and Reduction

Metal ions such as copper and iron, with less than a full complement of electrons in their outer shell, can accept or donate electrons in oxidation–reduction reactions, but monovalent ions (Na^+ and K^+) or divalent ions (Zn^{2+}, Mg^{2+}, or Ca^{2+}) with their outer shell of electrons complete do not.

Iron–sulfur proteins, often referred to as nonheme iron proteins, are a unique class of metalloenzymes in which the active center consists of one or more clusters of sulfur-bridged iron chelates. In some cases the sulfur atoms come only from cysteine, and in

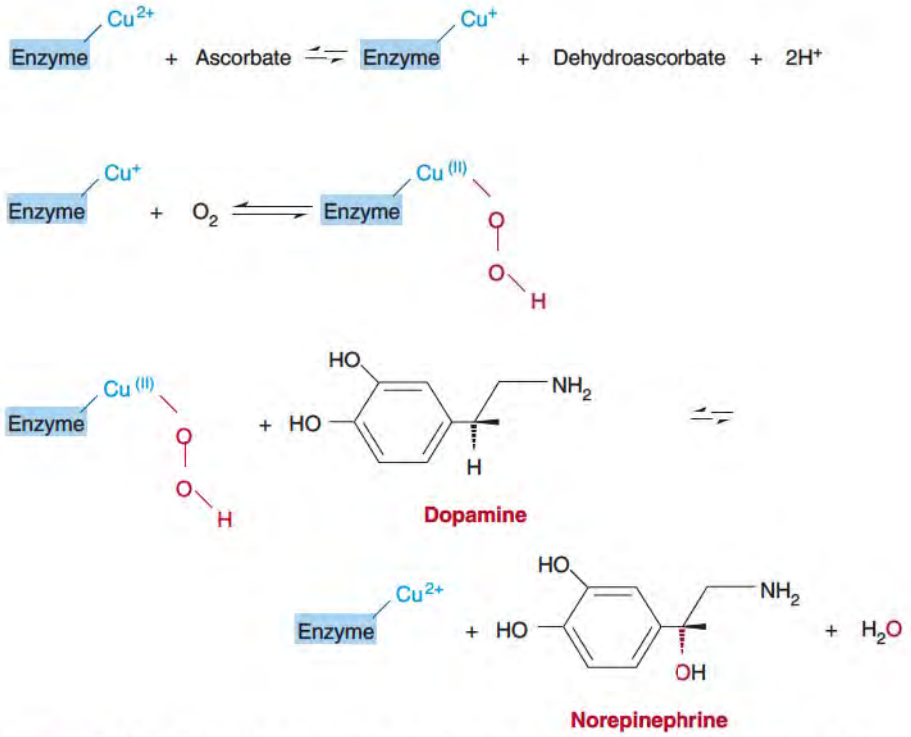

Figure 10.42 Role of copper in activation of molecular oxygen by dopamine hydroxylase. The normal cupric form of the enzyme is not reactive with oxygen but on reduction by the cosubstrate, ascorbate, generates a reactive enzyme-copper-bound oxygen radical that then reacts with dopamine to form norepinephrine and an inactive cupric enzyme.

others they come from both cysteine and free ionic sulfur. These nonheme iron enzymes have reasonably low reducing potentials (E_0') and function in electron-transfer reactions (p. 562). **Cytochromes** are heme iron proteins where the iron undergoes reversible one electron transfers. In some cases heme is bound to the apoprotein by coordination of amino acid side chains to the iron of heme. Thus, the metal serves not only a structural role but also participates in the chemical event. Copper and iron also have a role in activation of molecular oxygen. Copper is an active participant in several oxidases and hydroxylases. For example, dopamine β-hydroxylase catalyzes the introduction of one oxygen atom from O_2 into dopamine to form norepinephrine (Figure 10.42). The active enzyme contains one atom of cuprous ion that reacts with oxygen to form an activated oxygen–copper complex. The copper–hydroperoxide complex is thought to be converted to a copper (Il) $-O^-$ species that serves as the *active oxygen* in the hydroxylation of DOPA. Other species of active oxygen are generated in metalloenzymes and used for hydroxylation.

10.6 • KINETICS OF CHEMICAL REACTIONS

Rate of Product Formation

The rates of all chemical reactions can be expressed in mathematical terms. In developing the rate equations, either the formation of product or the disappearance of initial reactants can be determined; in most cases product formation is measured. From the mathematical relationships between the rate(s) of product(s) formation (termed **velocity**) as a function of substrate(s) concentration(s), some aspects of the mechanism of enzyme catalysis can be determined. An equation to describe the rate of product formation in any reaction contains a rate constant (k) and the concentration of all the substrates that change during the course of the reaction. In the reaction A + B $\rightarrow$ P, the change in concentration of product as a

function of time is d[P]/*dt* where [P] is concentration of product at any time *t*. The basic equation relating velocity to reactants is

$$d[P]/dt = k[A][B] \tag{10.2}$$

k is the rate constant and is a constant for a particular reaction. [A] and [B] are the concentrations of the substrates at any time. The rate constant is related to the energy of activation to reach the transition state and is changed by the addition of a catalyst. Rate constants can be altered only by changing the reaction conditions, that is, addition of catalyst or change of pH or ion composition.

First- and Second-Order Reactions

A reaction with only one substrate (A → P) is a first-order reaction with

$$d[P]/dt = k[A] \tag{10.3}$$

If there are two substrates, the reaction is a second-order reaction (Eq. 10.2). The units of *k* are different in the equations for a first- and second-order reaction. Since *d*[P]/*dt* has the units moles/minute (or any other unit of concentration or time), *k* in Eq. 10.2 would have the unit of 1/moles × min while in Eq. 10.3, the unit would be 1/min. If it takes two molecules of compound A to form product P, then the equation would be second order because the velocity of making P is related to a reaction of [A] + [A]. The equation would be $d[P]/dt = k[A][A]$ or $k[A]^2$, which is identical to a second-order reaction even though only one compound is involved. For $d[P]/dt = k[A][B]$, the reaction is first order with respect to both A and B, but the overall reaction is second order.

The concentration terms in the equation are only for those substrates whose concentrations change during the course of the reaction. In reactions involving water, the concentration of water is not altered (or not measurably). Thus if B is water in the reaction A + B → C, the value of B is a constant and the reaction is first order (Eq. 10.3).

Rate of Substrate Disappearance

For the simple reaction A → P, the velocity of the reaction can also be given by disappearance of substrate as a function of time, $-d[A]/dt$. The minus sign is necessary since the concentration of A is decreasing with time. The change in the concentration of product P with time is *d*[P]/*dt*, which is equal to the loss of substrate or $-d[A]/dt$.

$$d[P]/dt = -d[A]/dt = k[A] \tag{10.4}$$

The equation for the loss of substrate as a function of time is

$$d[A]/dt = -k[A] \tag{10.5}$$

and the integral of *d*A/A is ln A leading to

$$\ln[A] = 2.3 \log[A] = -kt + \text{constant} \tag{10.6}$$

Eq. 10.6 is the mathematical relationship for the loss of substrate as a function of time. At time of zero, [A] is the initial concentration $[A_0]$, so the equation can be rewritten as

$$\ln[A] = -kt + [A]_0$$

Thus

$$\ln[A/A_0] = -kt \tag{10.7}$$

or

$$2.3 \log[A/A_0] = kt$$

A plot of the ln[A] versus time is a straight line with a slope of $-k$ (Figure 10.43).

For comparison purposes, the term *half-life* is often used. The half-life ($t_{1/2}$ or $t_{50\%}$) is the time it would take for 50% of the substrate to be converted to product. Since the value $[A/A_0]$ would be 0.5 and the ln(0.5) = −0.69; this leads to

$$-0.69 = -kt_{50\%} \tag{10.8}$$

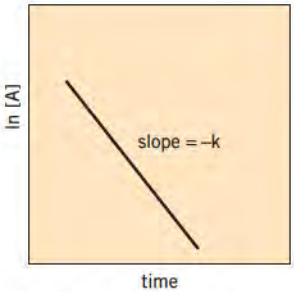

Figure 10.43 A plot of the ln[A] versus time for a first-order reaction.

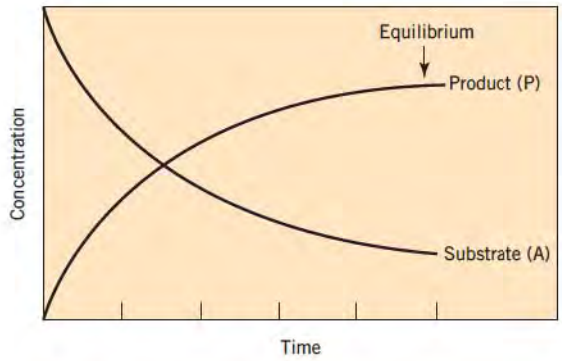

Figure 10.44 Plot of substrate disappearance and product formation. For a reversible reaction, no net change in substrate or product concentration occurs at equilibrium.

or half-life is equal to $0.69/k$. Thus, the larger the rate constant, the faster the reaction will deplete half the substrate. Radioactive decay is an example of a first-order reaction as are enzyme-catalyzed reactions under certain conditions.

Reversible Reactions

Many reactions are reversible. That is,

$$\mathrm{A} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{P}$$

One can write a velocity equation for the formation of product P or of starting material A.

$$d[\mathrm{P}]/dt = k_1[\mathrm{A}] - k_2[\mathrm{P}] \tag{10.9}$$

$$d[\mathrm{A}]/dt = k_2[\mathrm{P}] - k_1[\mathrm{A}] \tag{10.10}$$

At equilibrium, where there is no net change in concentrations of components, the rate of formation of one component is equal to the rate of formation of the other. Figure 10.44 is a plot of substrate disappearance and product formation. The velocity equation for product formation reflects that the material is being produced ($k_1[\mathrm{A}]$) but is also being lost as it goes back to starting material ($-k_2[\mathrm{P}]$). The negative sign shows that the material is being removed. A similar equation is written for the change is starting material. Since at equilibrium

$$d[\mathrm{P}]/dt = d[\mathrm{A}]/dt \tag{10.11}$$

then

$$k_1[\mathrm{A}] = k_2[\mathrm{P}] \qquad \text{so} \qquad k_1/k_2 = [\mathrm{P}]/[\mathrm{A}] \tag{10.12}$$

The ratio k_1/k_2 is the equilibrium constant, K_{eq}, and is equal to [P]/[A]. Even though the individual rate constants for a reversible reaction are independent of the equilibrium constant, the ratio of the constants is constrained by the equilibrium constant. The latter is related to the difference in free energy needed to make A and P (called heats of formation). Kinetics of complex reactions is presented in A Closer Look 10.4.

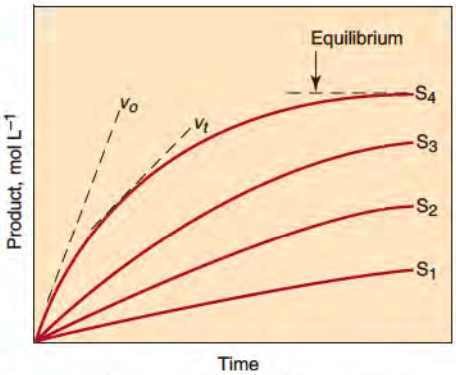

Figure 10.45 Progress curves for an enzyme-catalyzed reaction at different substrate concentrations and a constant concentration of enzyme. The initial velocity (v_0) of the reaction is determined from the slope of the progress curve at the beginning of the reaction. The initial velocity increases with increasing substrate concentration (S1–S4) but reaches a limiting value characteristic of each enzyme. The velocity at any time t is denoted as v.

10.7 • ENZYME KINETICS OF ONE-SUBSTRATE REACTIONS

An enzyme-catalyzed reaction is like a second-order reaction. Hence, with constant enzyme concentration, as substrate concentration is increased, the rate of reaction increases as shown in Figure 10.45. The velocity slows down during the course of the

A CLOSER LOOK 10.4

Complex Reactions

Nucleophilic displacement is a common organic reaction occurring in biochemical reactions. A general form of the reaction is R−X + Y → Y−R + X (where R represents part of an organic compound and X or Y represents a component such as an alcohol or amine group). The reaction can occur in two different ways, each leading to a different rate equation.

The first possibility is that the compound R–X dissociates, forming $R^+ + X^-$. Next Y can attack R^+ to form the final product, R–Y. The second possibility is Y will attack R–X directly, displacing X to form the same final product. The kinetic equations for the two reactions are different.

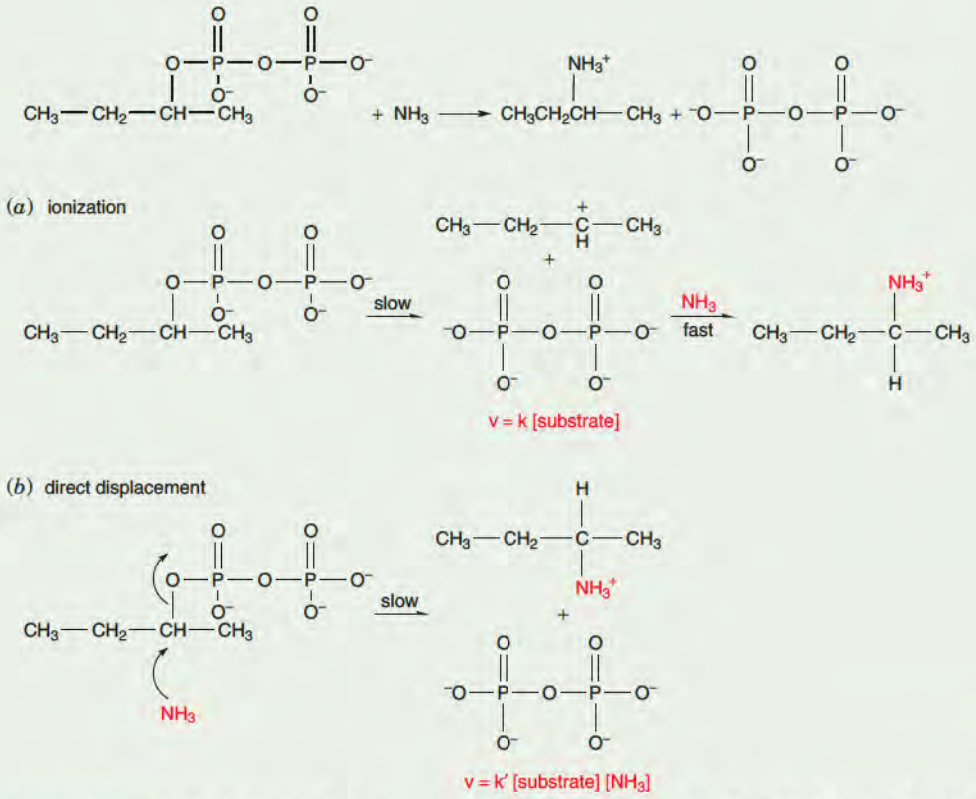
The velocity for the first step in the reaction of R–X going to $R^+ + X^-$ is

$$d[\text{R–X}]/dt = -k[\text{RX}]$$

For the second half of the reaction, $R^+ + Y$, the velocity is given by $k'[R^+][Y]$. If the first step is very slow compared to the second step, then the overall velocity will be governed by only the first step. In kinetics, only the slow steps are measured. To illustrate, assume that R–X goes to $R^+ + X^-$ at a rate of 10 μM/min and the attack of Y on R^+ proceeds at 1000 μM/min. Thus, as a molecule of R^+ is formed, it very rapidly becomes the final product. Increasing the fast step will not alter the rate of product formation for it cannot be formed faster than the velocity of the slowest step. This means that the rate of formation of product will be described by the rate equation $d[\text{R} - (-\text{X})]/dt = -k_1[\text{RX}]$. This reaction is independent of the concentration of component Y. That is, the reaction is a first-order reaction. It can be said that the reaction is **zero order** with respect to [Y], meaning that the reaction is independent of the concentration of Y. (Recall that $[Y]^0 = 1$.) Increasing the concentration of Y will have no affect on the velocity of the reaction.

In the reaction of Y attacking R–X, the velocity term contains concentrations of both substrates. That is, $d[\text{R–X}]/dt = -k_2[\text{R–X}][Y]$, a traditional second-order reaction. The major difference between the two reactions pathways is that the slowest step in one involves the transition state for R–X going to $R^+ + X^-$. In the other, the transition step involves Y attacking R–X (Figure 10.45, p. 397). To reiterate, kinetics tells something about the slower steps that occur during a reaction. The slowest step that occurs during an enzyme-catalyzed reaction is called the rate-limiting step.

Complex reaction kinetics occurs when monitoring the flow of compounds through a metabolic pathway. The velocity of the slowest step is what will govern the rate of product formation.



Nucleophilic displacement reactions. (*a*) Ionization mechanism. (*b*) Direct displacement mechanism. Note that in the ionization mechanism, the velocity of the reaction is a function of the concentration of only one substrate, whereas in the direct displacement the velocity depends on both substrate concentrations.

reaction because the concentration of substrate is becoming depleted or product is starting to accumulate. Assuming the reaction is reversible, it will reach equilibrium. By calculating the initial velocity (v_0) (i.e., velocity before product starts to accumulate) of the reaction at different substrate concentrations, one can obtain the curve presented in Figure 10.46. The velocity becomes zero order with respect to substrate at high concentrations of substrate. That is, the velocity no longer increases with an increase in [S]. The reason is that the enzyme and substrate form a complex, and the rate of product formation is proportional to the concentration of the complex. All of the enzyme will be in the complex at high substrate concentrations. The enzyme will be released from the complex by reversibly dissociating the substrate or proceed to form products. The overall reaction is written as

$$E + S \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_3} E + P \tag{10.13}$$

Rate constants k will be numbered such that the ones leading to products will be odd numbers (k_1, k_3, and k_5), while the reversible steps will be even ones (k_2, k_4, and k_6); some are first-order and others second-order constants. *The units of first- and second-order constants are different, meaning that they cannot be added to each other but can be multiplied or divided.*

The rate of formation of product is the term leading to product times the rate constant.

$$d[P]/dt = k_3[ES] \tag{10.14}$$

To determine the rate of product formation, it is necessary to find the value of ES as a function of the concentration of enzyme and substrate. Eq. 10.14 can be solved for the rate of the reaction (see A Closer Look 10.5 for derivation of the equation). The final form is

$$v = \frac{k[E][S]}{K + [S]} \tag{10.15}$$

where k is a rate constant and K is a constant which includes the individual rate constants relating to the substrate's interaction with the enzyme.

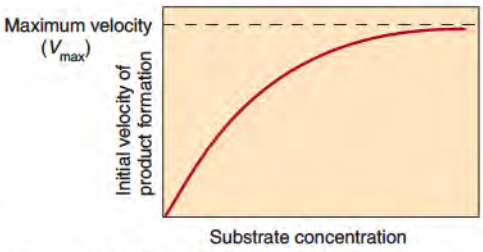


Figure 10.46 Plot of velocity versus substrate concentration for an enzyme-catalyzed reaction. Initial velocities are plotted against the substrate concentration at which they were determined. The curve is a rectangular hyperbola, which asymptotically approaches the maximum velocity possible with a given amount of enzyme.

A CLOSER LOOK 10.5

Derivation of the Michaelis–Menten Equation

In order to derive the Michaelis–Menten equation, it is necessary to determine the concentration of ES. The rate of formation of ES is given by $k_1[E_f][S]$, where $[E_f]$ is the concentration of free enzyme. The utilization of ES is governed by two reactions: ES returning to starting material, given by $k_2[ES]$, and ES going to products, $k_3[ES]$. Combining these terms leads to an equation describing the change in concentration of ES.

$$d[ES]/dt = k_1[E_f][S] - k_2[ES] - k_3[ES]$$

Assuming that the concentration of ES is constant except for the first few milliseconds after contact of substrate and enzyme, $d[ES]/dt = 0$. This is referred to as the *steady-state assumption*, meaning the concentration of ES during the initial time period of the enzyme-catalyzed reaction (period for measuring the initial rate). The validity of the steady-state condition can be proven mathematically. Substituting $[E_f]$ with $[E_t] - [ES]$, where E_t is the total enzyme concentration and rearranging, leads to

$$k_1([E_t] - [ES])[S] = (k_2 + k_3)[ES]$$

Solving for [ES], one obtains

$$[ES] = \frac{k_1[E_t][S]}{(k_2 + k_3) + k_1[S]}$$

Since the rate of product formation (v) of the reaction is $k_3[ES]$, multiplying the above equation by k_3 gives

$$v = \frac{k_3 k_1[E_t][S]}{(k_2 + k_3) + k_1[S]}$$

To convert this equation into the Michaelis–Menten equation, the numerator and denominator are divided by k_1.

$$v = \frac{k_3[E_t][S]}{(k_2 + k_3)/k_1 + [S]} \text{ or } v = \frac{V_m[S]}{K_m + [S]}$$

k_3E_t is the maximum velocity of the reaction (V_m), with all the enzyme in the ES form, and therefore k_3 is k_{cat}. The constants in the denominator are defined as K_m. It is apparent that K_m is not a simple dissociation constant. If k_3 were very small compared to k_2, then the resulting ratio would be k_2/k_1, which is K_d, the dissociation constant.

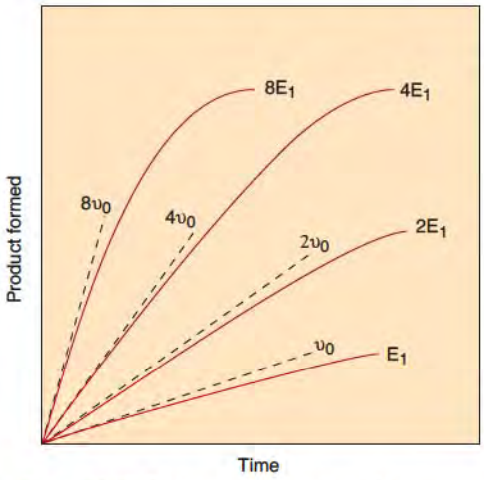

Figure 10.47 Progress curves at variable concentrations of enzyme and saturating concentrations of substrate. The initial velocity (v_0) doubles as the enzyme concentration doubles. Since the substrate concentrations are the same, the final equilibrium concentrations of product will be identical in each case; however, equilibrium will be reached at a slower rate in those assays containing small amounts of enzyme.

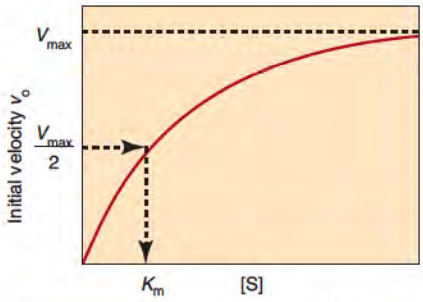

Figure 10.48 Graphic estimation of K_m from the v_0 versus [S] plot. K_m is the substrate concentration at which the enzyme has half-maximal activity.

Michaelis–Menten Equation

The simplest enzyme reaction where one substrate goes to one product is

$$E + S \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \underset{k_4}{\overset{k_3}{\rightleftharpoons}} E + P \tag{10.16}$$

If the reaction in Eq. 10.16 is essentially irreversible ($k_4 = 0$ or [P] is not present as would be found when enzyme and S are first mixed), the equation for the rate product formation is

$$v = \frac{k_3[E][S]}{(k_3 + k_2)/k_1) + [S]} \tag{10.17}$$

Combining constants in the denominator into a term called K_m and if the reaction ES → E + P in Eq. 10.16 is the rate-limiting step, then k_3 defines the catalytic activity of the enzyme (k_{cat}), and the equation becomes

$$v = \frac{k_{cat}[E_t][S]}{(K_m + [S])} \tag{10.18}$$

Note the similarity of Eqs. 10.15 and 10.18. Since k_{cat} (the rate constant) and $[E_t]$ (the total enzyme concentration) are constants, $k_{cat}[E_t] = V_{max}$. The equation can be written as

$$v = \frac{V_m[S]}{(K_m + [S])} \tag{10.19}$$

and is referred to as the **Michaelis–Menten equation**. For reactions that are more complicated, k_{cat} is composed of a collection of rate constants. V_m in Eq. 10.19 is the **maximum velocity** of the reaction at a defined enzyme concentration and has the unit of moles of product per unit time. Thus V_m (that is, $k_3[E_t]$ or $k_{cat}[E_t]$) is a constant for a fixed concentration of enzyme. If the enzyme concentration is increased or decreased, V_{max} will increase or decrease respectively (Figure 10.47). K_m is composed of individual rate constants; however, from Eq. 10.18, it can be stated that *K_m is the concentration of substrate where the velocity of the reaction (v) is one-half of the maximum velocity (V_m)*, that is, $v/V_m = 0.5$ (Figure 10.48) when $K_m = [S]$. When v is equal to $\frac{1}{2}V_m$, one-half the concentration of total enzyme is in a complex with substrate and one-half is free. In contrast, when $[S] \gg K_m$ essentially 100 percent of the enzyme is in the ES complex. Under this condition the reaction reaches V_m since the velocity would be $v = V_m$. It is usually considered that V_m is approached when [S] is close to $20[K_m]$, since under these conditions $v = V_m \times 20/21$, or $0.95V_m$. The biphasic nature of enzyme mechanisms, that is binding followed by modification of substrate, is reinforced in Clin. Corr. 10.3.

CLINICAL CORRELATION 10.3

A Case of Gout Demonstrates Two Phases in the Mechanism of Enzyme Action

The two phases of the Michaelis–Menten model of enzyme action, binding followed by modification of substrate, are illustrated by studies on a family with gout. The patient excreted three times the normal amount of uric acid per day and had markedly increased levels of 5′-phosphoribosyl-α-pyrophosphate (PRPP) in his red blood cells. PRPP is an intermediate in the biosynthesis of AMP and GMP, which are converted to ATP and GTP. Uric acid is a product of the degradation of AMP and GMP. Assays *in vitro* revealed that the patient's red cell PRPP synthetase activity was increased threefold. The pH optimum and the K_m of the enzyme for ATP and ribose 5-phosphate were normal, but V_{max} was increased threefold! This increase was not due to an increase in the amount of enzyme; immunologic testing with an antibody specific to the enzyme revealed similar quantities of the enzyme protein as in normal red cells. This finding demonstrates that the binding of substrate as reflected by K_m and the subsequent chemical event in catalysis, which is reflected in V_{max}, are separate phases of the overall catalytic process. This situation holds only for those enzyme mechanisms in which $k_3 \gg k_2$.

Becker, M. A., Kostel, P. J., Meyer, L. J., and Seegmiller, J. E. Human phosphoribosyl pyrophosphate synthetase: Increased enzyme specific activity in a family with gout and excessive purine synthesis. *Proc. Natl. Acad. Sci. USA* 70:2749, 1973.

If the reaction is more complex such that

$$E + S \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_3} ES' \xrightarrow{k_5} E + P \tag{10.20}$$

where ES′ represents a modified but independent form of the complex, then the velocity equation becomes

$$v = \frac{k_3k_5/(k_3 + k_5)[E_t][S]}{k_5(k_2 + k_3)/k_1(k_3 + k_5) + [S]} \tag{10.21}$$

Inspection of Eqs. 10.17 and 10.21 reveals that the generalized form of the equation is

$$v = \frac{\text{Constant}[E_t][S]}{\text{Constant} + [S]} \tag{10.22}$$

This is the same general equation as Eq. 10.18. The numerator rate constants are grouped to become the k_{cat} term while the constants in the denominator are defined as K_m. Thus, both k_{cat} and K_m are typically composed of a complex set of individual rate constants. The specific constants that make up the terms are related to the actual kinetic mechanism and magnitude of the individual rate constants. As an example, if the value of k_3 is much larger than k_5 in Eq. 10.21, k_{cat} would reduce to k_5 because the sum of k_3 and k_5 would be essentially the value of k_3. If, though, the two rate constants had similar values, then k_{cat} would be composed of many terms, as would K_m whose units are concentration.

Concentration of Free Enzyme

The derivation of the Michaelis–Menten equation requires a careful account of all forms of the enzyme. It is assumed that the concentration of substrate is greater than that of the enzyme, so during the initial course of the reaction being measured the value of [S] does not change. Obviously, various values of [S] can be used, but for each it will remain constant during the reaction. For the simple reaction $E + S \rightleftarrows ES \rightarrow E + P$, the concentration of enzyme is always the sum of the free enzyme and the substrate-bound enzyme; that is

$$[E_t] = [E_f] + [ES] \tag{10.23}$$

$[E_t]$ is the total concentration of enzyme and $[E_f]$ is the concentration of free enzyme. It is E_f that is necessary in a reaction to interact with substrate. The concentration of free enzyme is not directly measured but rather the total enzyme concentration. This means

$$[E_t] - [ES] = [E_f] \tag{10.24}$$

If there were other forms of the enzyme such as a form with an inhibitor bound (p. 407), then Eq. 10.24 would have to be expanded to include each form of enzyme.

Meaning of K_m

K_m consists of a number of rate constants and is not a derived dissociation constant (K_d). Its value, however, is used often to indicate how well a substrate interacts with an enzyme. A K_m of 10^{-7} M indicates that the substrate has a greater affinity for the enzyme than if the K_m is 10^{-5} M. The smaller the value of K_m, the tighter is the interaction between substrate and enzyme. Even though K_m is not a dissociation constant, the smaller value means it takes less substrate to bind 50% of the enzyme (Clin. Corr. 10.4).

An example of the importance of K_m is the physiological utilization of glucose. Glucose can be phosphorylated by two different kinases to form glucose 6-phosphate. Liver contains both hexokinase and glucokinase that catalyze the identical reaction of glucose + ATP → glucose 6-phosphate + ADP. For hexokinase, the K_m for glucose is 0.1 mM whereas for glucokinase it is 5 mM. When the concentration of blood sugar is low, as occurs in the fasted state, hexokinase is used to phosphorylate glucose, but when blood glucose increases after feeding, the high K_m enzyme also functions.

CLINICAL CORRELATION 10.4

Physiological Effect of Changes in Enzyme K_m Values

The unusual sensitivity of some Asians to alcoholic beverages has a biochemical basis. In some Japanese and Chinese, much less ethanol is required to produce vasodilation, resulting in facial flushing and rapid heart rate, than is required to achieve the same effect in Europeans. The physiological effects are due to acetaldehyde generated by liver alcohol dehydrogenase. Acetaldehyde is converted to acetate by aldehyde dehydrogenase (ALDH). One amino acid at position 487 in the 500–amino acid subunit of the tetrameric enzyme is changed in some of the affected individuals. The active enzyme has a glutamate while the inactive variant has a lysine. The Asian variant was found to have a very low activity, and the K_m for NAD^+ increased from 30 μM to 7000 μM. Even though the enzyme was active, it would have very little activity in the liver as the K_m was so high and k_{cat} was low.

In addition affected individuals were heterozygotic, having genes for both the active glutamate enzyme and the essentially inactive lysine enzyme. It was expected that their enzyme would be 50% active, yet it had very low activity. ALDH forms tetramers with the two monomers (E_4, E_3K, E_2K_2, EK_3, and K_4) where E_4 and K_4 are homotetrameric forms of the glutamate- and lysine-containing subunits, respectively and the others are the heterotetramers. E_3K had 50% of the total activity, not 75%, while EK_3 had essentially no activity, not the 25% one could expect from the one active subunit. The K subunit was dominant in that it could inactivate the subunit to which it was paired as the residue at position 487 interacted with an arginine at position 475. When a glutamate was at position 487 a stable salt bond formed, but when a lysine was at position 487, it caused the arginine to move. The movement disrupted the NAD binding pocket even though residue 487 was not in contact with the Rossmann fold. This example illustrates the fact that a point mutation on the enzyme can affect the active site even though the residue is not in contact with the region. It further demonstrates that one subunit can be dominant over another.

Invest.* 83:314, 1989; and Zhou, J., and Weiner, H. Basis for half-of-the-site reactivity and the dominance of the K487 oriental subunit over the E487 subunit in heterotetrameric human liver mitochondrial aldehyde dehydrogenase. *Biochemistry* 39:12019, 2000.

Turnover Number (k_{cat})

In Eq. 10.18, k_{cat} in the numerator has units of 1/time. This constant is also referred to as the **turnover number** of the enzyme, that is, the number of molecules of substrate converted to product per unit time per molecule of enzyme. The larger the value of k_{cat} for an enzyme, the faster the reaction will be. In general, this term represents the slowest step(s) in the overall reaction.

Significance of k_{cat} in the Michaelis–Menten Equation

When Substrate Concentration Is Much Larger than K_m

Eq. 10.18 is in the form of a general hyperbolic equation. When the value of [S] is much larger than the value of K_m, the value of the denominator is essentially the value of [S], and the equation can be approximated by

$$v = \frac{k_{cat}[E][S]}{[S]} = k_{cat}[E] \qquad (10.25)$$

That is, the velocity becomes independent of the concentration of S; the reaction becomes zero order with respect to S. This is found in the portion of curve where the velocity essentially levels off and is not increased as the concentration of [S] increases (slope = 0) (see Figure 10.46, p. 399). The reaction is proceeding at its maximum velocity under these conditions because essentially 100 percent of the enzyme is in the ES complex. The instant a molecule of product is made it leaves the enzyme and another molecule of S binds enzyme, always keeping the enzyme saturated with S. Under these conditions the rate is governed strictly by the terms that govern the reaction of ES going to product (ES $\rightarrow$ E + P).

When Substrate Concentration Is Much Smaller than K_m

When [S] is very small compared to K_m, Eq. 10.17 can be approximated as

$$v = \frac{k_{cat}[E_t][S]}{K_m} \quad \text{or} \quad v = \frac{V_{max}[S]}{K_m} \qquad (10.26)$$

A plot of v versus [S] is linear only when [S] $\ll K_m$ value. Since for any chemical reaction the velocity of product formation is a rate constant times the concentration of the reactants, the term k_{cat}/K_m can be considered as a second-order rate constant since there are two concentration terms in the rate equation ([E_t] and [S]). The fact that this ratio is equivalent to a second-order rate constant puts certain constraints on the ratio. For example, a rate constant cannot be faster than the rate two molecules diffuse in solution. Even if no energy of activation is required, the two molecules have to collide with each other in order for a reaction to occur. The rate constant for a second-order diffusion reaction is around 10^9/mole/sec. Thus, if k_{cat} is very large, K_m cannot be very small or the ratio would exceed the diffusion rate. As an example, catalase, an enzyme that converts hydrogen peroxide to oxygen and water, has a k_{cat} of 4×10^7/sec. The K_m for hydrogen peroxide, however, is 1 M, a very high value. The k_{cat}/K_m ratio is less by a factor of 25 (10^9 versus 4×10^7) of the theoretical maximum velocity that second-order reactions can attain. Catalase is one of the fastest known enzymes when the term for k_{cat}/K_m is measured.

k_{cat} can be a very low number only (such as 1 to 10/sec) if the K_m for substrate is very low (as an example, 1×10^{-9} M). This slow rate means that one molecule of enzyme would produce just 1 to 10 molecules of product per second. The reaction is so slow because the substrate binds very tightly to the enzyme. A great deal of energy is required to convert the bound substrate to the transition state. An extremely small K_m (high affinity) for substrate requires the chemical reaction to be slow, whereas a large K_m (low affinity) means that k_{cat} can be high. The values of k_{cat}/K_m for enzymes range from 10 to 10^7/sec.

Reversible Reactions

Another limitation to the ratio of k_{cat}/K_m occurs when the reaction is reversible.

$$E + S \underset{k_r}{\overset{k_f}{\rightleftharpoons}} E + P \tag{10.27}$$

k_f and k_r are the forward and reverse rate constants (the terms ES and EP are ignored because they are the same for both directions). It can be derived that k_f is $(k_{cat}/K_m)_f$ and k_r is $(k_{cat}/K_m)_r$. For a reversible reaction, the equilibrium constant K_{eq} = ([P]/[S]) is k_f/k_r or

$$K_{eq} = \frac{(k_{cat}/K_m)_f}{(k_{cat}/K_m)_r} \tag{10.28}$$

The values for k_{cat} and K_m cannot change randomly since their ratio has to be equal to K_{eq}. This implies that if a mutant of an enzyme has a greater value of k_{cat} than the original enzyme, some other constant must change to satisfy the equilibrium situation. These equilibrium-type relationships are called **Haldane** relationships.

Low K_m versus High k_{cat}

Since the ratio of k_{cat}/K_m has an upper limit, the question can be raised as to whether it would be preferable for an enzyme to have a very low K_m or a very high k_{cat}. Frequently it is considered that a low K_m is most desirable, and compounds with the lowest K_m are reported as the best substrates. Actually, the compound with the highest k_{cat}/K_m ratio is the best substrate. At a constant k_{cat}/K_m, it is better to have a high k_{cat} rather than a low K_m. An example is presented in Table 10.4. At a fixed concentration of substrate, 1 mM in the example, the overall velocity is always faster when K_m is high as that forces k_{cat} to be larger to satisfy the k_{cat}/K_m ratio. Thus, *when evaluating different substrates for an enzyme, the substrates with the highest k_{cat}/K_m value should be considered the better substrate for the enzyme not the one with the lowest K_m.*

In a cell it is not just the k_{cat} and K_m terms that are important, but one must take into account the total concentration of enzyme. The velocity term is first order with respect to enzyme, so a few picomoles of an enzyme with a k_{cat}/K_m of 10^7/sec/M in the cell would be less efficient at converting a substrate to product than would a nanomole of an enzyme with a k_{cat}/K_m of 10^5/sec/M.

TABLE 10.4 • K_m and k_{cat} Relationships[a]

K_m (M)	k_{cat} (s^{-1})	Rate (s^{-1})
10^{-6}	1	1
10^{-5}	10	9
10^{-4}	10^2	90
10^{-3}	10^3	500
10^{-2}	10^4	909
10^{-1}	10^5	990
1	10^6	999

[a]Reaction conditions: $k_{cat}/K_m = 10^6 M^{-1}s^{-1}$ and [S] = 10^3M.

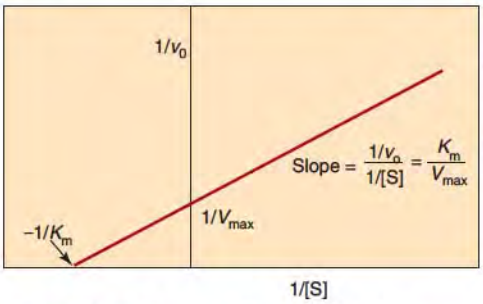

Figure 10.49 Determination of K_m and V_{max} from the Lineweaver–Burk double-reciprocal plot. Plots of the reciprocal of the initial velocity versus the reciprocal of the substrate concentration used to determine the initial velocity yield a line whose *x*-intercept is $-1/K_m$, because at $1/v_0 = 0$, $1/[S] = 1/Km$ in Eq. 10.29.

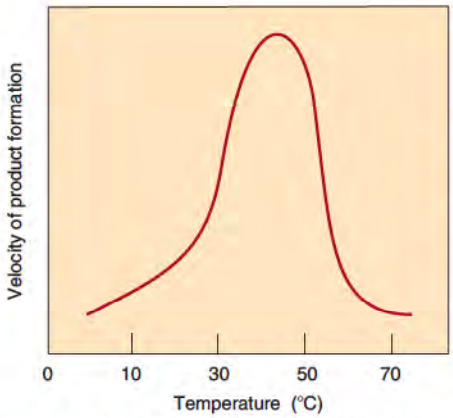

Figure 10.50 Temperature dependence of a typical mammalian enzyme. To the left of the optimum, the rate is low because the environmental temperature is too low to provide enough kinetic energy to overcome the energy of activation. To the right of the optimum, the enzyme is inactivated by heat denaturation.

Calculating the Constants

The K_m can be approximated from plots of v versus [S]. Graphical presentations allow for the calculation of the kinetic constants. The most common graphical presentation is based on the **Lineweaver–Burk equation**, which is the reciprocal of the Michaelis–Menten equation. The reciprocal of Eq. 10.19 is

$$\frac{1}{v} = \frac{1}{V_m} + \frac{K_m}{V_m} \times \frac{1}{[S]} \tag{10.29}$$

A plot of $1/v_0$ versus $1/[S]$ is a straight line (Figure 10.49); the intercept on the *y*-axis is $1/V_m$, the intercept on the *x*-axis is $-1/[S]$, which is equivalent to $-1/K_m$; the slope of the line is K_m/V_m. Thus from the graph of $1/v_0$ at different concentrations of $1/[S]$, two key parameters of the enzyme-catalyzed reaction can be determined. Alternatively, computer programs can calculate the k_{cat} and K_m from the velocity and substrate data.

Substrate and Product Bind to the Same Site

The presence of product will act as an inhibitor of the reaction since its presence can prevent substrate from binding. It will be a competitive inhibitor since both S and P bind to E_f. The equation relating the initial velocity of the reaction in the presence of product is

$$v = \frac{V_m[S]}{K_m(1 + [P]/K_{mp}) + [S]} \tag{10.30}$$

where K_{mp} is the K_m for product, assuming the reaction could be reversible. Product is initially not present when running an assay *in vitro* but starts to accumulate with time. A graph of product formation as a function of time will initially be linear, but the slope will decrease with time as product accumulates and acts as an inhibitor (see Figure 10.44, p. 397).

Effect of Assay Conditions

When running a reaction under V_m conditions, essentially 100% of the enzyme is in the ES complex. In contrast, when a reaction is studied where $[S] \ll K_m$, the effect being measured would reflect what is occurring with both free and substrate-bound enzyme. Thus to study the effect of an environmental change such as pH, the assay is usually conducted under V_{max} conditions. The effect of experimental conditions under V_{max} conditions gives information about the k_{cat} term for all the enzyme is bound to substrate. To evaluate the effect of pH on the free enzyme, then k_{cat}/K_m as a function of pH would be determined.

External conditions, such as pH, temperature, and salt concentration, affect enzyme activity. These effects are very important when running enzyme assays *in vitro*.

Temperature

A plot of velocity versus temperature for most mammalian enzymes is a bell-shaped curve with an optimum between 40°C and 45°C (Figure 10.50). Above this temperature, heat denaturation of the enzyme occurs; some enzymes will denature at lower temperatures. Typically between 0°C and 40°C, enzymes show a two-fold increase in activity for every 10°C increase. Mutation of an enzyme to a thermolabile form can have serious consequences (Clin. Corr. 10.5).

CLINICAL CORRELATION 10.5

Thermal Lability of Glucose-6-Phosphate Dehydrogenase Results in Hemolytic Anemia

In red cells, glucose-6-phosphate dehydrogenase (G6PD) is an important enzyme for the maintenance of the membrane integrity. A deficiency or inactivity of this enzyme leads to a hemolytic anemia. In other cases, a variant enzyme is present that normally has sufficient activity to maintain the membrane but fails under conditions of oxidative stress. A mutation of this enzyme leads to a protein with normal kinetic constants but a decreased thermal stability. This condition is especially critical to the red cell, since it is devoid of protein-synthesizing capacity and cannot renew enzymes as they denature. The end result is a greatly decreased lifetime for those red cells that have an unstable G6PD. Those red cells are also susceptible to drug induced hemolysis.

Luzzato, L., and Mehta, A., Glucose-6-phosphate dehydrogenase deficiency. In Scriver, C. R., Beaudet, A. L., Sly, W. S., and Valle, D. (Eds.), *The Metabolic and Molecular Bases of Inherited Disease*, 7th ed. New York: McGraw Hill, 1995, 3369.

pH

Nearly all enzymes show a bell-shaped pH-velocity profile, but the maximum (**pH optimum**) varies greatly with different enzymes. Alkaline and acid phosphatases with very different pH optima are both found in humans (Figure 10.51). The bell-shaped curve and its position on the *x*-axis are dependent on the particular ionized state of the substrate that will be optimally bound to the enzyme. This in turn is related to the ionization of specific amino acid residues that constitute the substrate-binding site. In addition, amino acid residues involved in catalyzing the reaction must be in the correct charge state to be functional. Clin. Corr. 10.6 describes the effect of a mutation leading to a change in the pH optimum of a physiologically important enzyme.

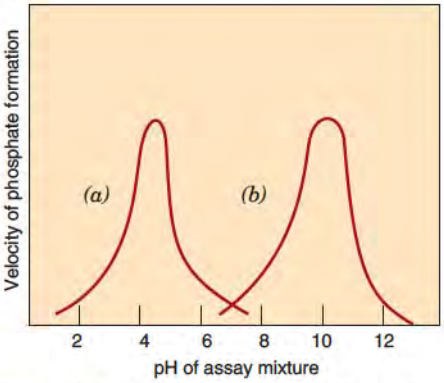

Figure 10.51 The pH dependence of (*a*) acid and (*b*) alkaline phosphatase reactions. In each case the optimum represents the ideal ionic state for binding of enzyme and substrate and the correct ionic state for the amino acids side chains involved in the catalytic event.

10.8 • KINETICS OF TWO-SUBSTRATE REACTIONS

Sequential Mechanism

There are two mechanisms of interactions for a two-substrate reaction as illustrated in Figure 10.52. In the **sequential mechanism**, both substrates bind to the enzyme in a sequential manner to form a ternary complex. With substrates A and B, the ternary complex would be E-A-B (A, B, C, . . . are substrates and P, Q, R, . . . are products). If substrate A binds prior to B, this is called an **ordered-sequential reaction** whereas if either A or B bind first, the reaction is called a **random-sequential reaction**. The equation for the sequential reaction contains K_m terms for both substrates A and B (K_a and K_b) and a term K_{ia}, the dissociation constant for substrate A. To find the various constants, a double reciprocal plot of $1/v$ versus 1/[A] is plotted for the reaction with different fixed concentrations of substrate B (Figure 10.53). The resulting plot shows a series of lines that intersect with each other. The individual constants can be found by plotting the slopes and intercepts as a function of [B].

Ping-Pong Mechanism

The second mechanism for a two-substrate reaction is called a **ping-pong mechanism**. Substrate A binds to the enzyme, and it is converted to product P, leaving a modified enzyme. The modified enzyme binds substrate B, which is then converted to product Q. Enzymes that exhibit ping-pong kinetics are modified by the substrate. Kinases that follow a ping-pong mechanism do so by having ATP or another nucleotide triphosphate first bind to and then phosphorylate the enzyme. ADP dissociates, and the second substrate

CLINICAL CORRELATION 10.6

Alcohol Dehydrogenase Isoenzymes with Different pH Optima

In addition to the change in aldehyde dehydrogenase isoenzyme composition in some Asians, different alcohol dehydrogenase (ADH) isoenzymes are also observed. ADH is encoded by three genes, which produce three different polypeptides, α, β, and γ. Three alleles are found for the β-gene that differ in a single nucleotide base; this causes substitutions for arginine. The substitutions are shown here.

	Residue 47	*Residue 369*
β_1	Arg	Arg
β_2	His	Arg
β_3	Arg	Cys

The liver β_3 form has ADH activity with a pH optimum near 7, compared with 10 for β_1, and 8.5 for β_2. The rate-determining step in alcohol dehydrogenase is the release of NADH. NADH is held on the enzyme by ionic bonds between the phosphates of the coenzyme and the arginines at positions 47 and 369. In the β_1 isozyme this ionic interaction is not broken until the pH is quite alkaline and the guanidinium group of arginine starts to dissociate H^+. Substitution of amino acids with lower pK values, as in β_2 and β_3, weakens the interaction and lowers the pH optimum. Since the release of NADH is facilitated, the V_{max} values for β_2 and β_3 are also higher than for β_1.

Burnell, J. C., Carr, L. G., Dwulet, F. E., Edenberg, H. J., Li, TK., and Bosron, W. F. The human β_3 alcohol dehydrogenase subunit differs from β_1 by a cys- for arg-369 substitution which decreases NAD(H) binding. *Biochem. Biophys. Res. Commun.* 146: 1227, 1987.

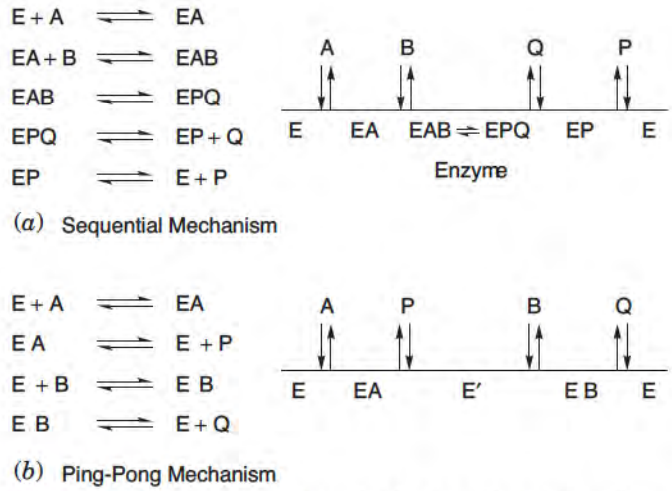

Figure 10.52 Mechanisms of interaction for two substrate reactions. (*a*) Sequential mechanism. (*b*) Ping-pong mechanism.

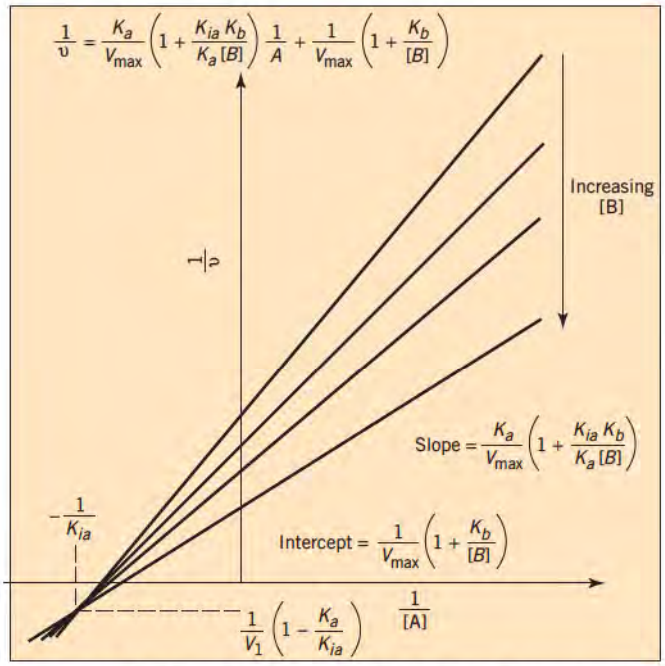

Figure 10.53 Double-reciprocal plot of initial velocity for a sequential reaction. Substrate B is fixed at specified concentrations, and substrate A varied. The rate equation is

$$\frac{1}{v} = \frac{K_a}{V_{max}}\left(1 + \frac{K_{ia}K_b}{K_aB}\right)\frac{1}{A} + \frac{1}{V_{max}}\left(1 + \frac{K_b}{B}\right)$$

binds to the phosphorylated enzyme followed by phosphate transfer to produce the phosphorylated acceptor. Many enzymes that use coenzymes that do not dissociate employ ping-pong reactions.

The equation relating the velocity to the concentrations of A and B in the ping-pong mechanism is similar to the equation for the sequential reaction, but most significantly it does not have the K_{ia} term as found in the sequential reaction. Double reciprocal plots for this reaction result in a series of parallel lines (Figure 10.54). Again, the individual K_m and V_m values can be obtained from the slopes and intercepts after plotting the values obtained at each concentration of B.

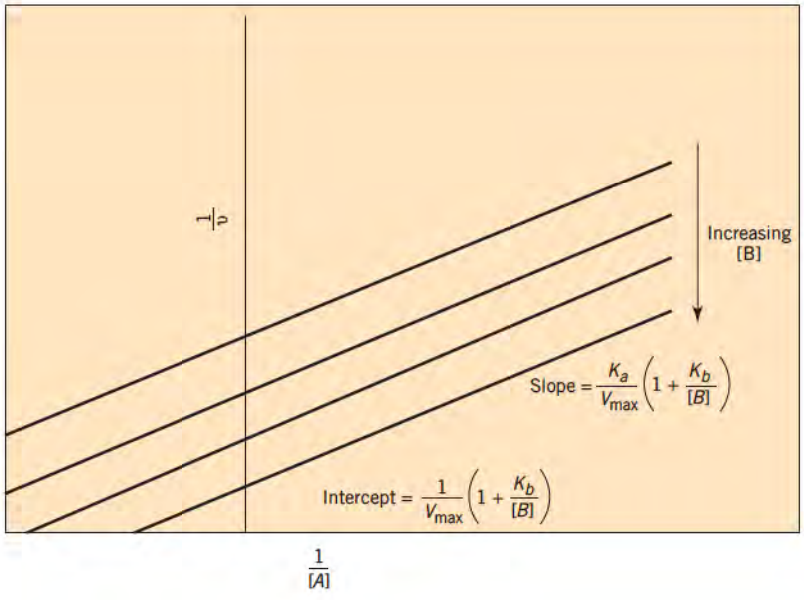

Figure 10.54 Double-reciprocal plot of initial velocity for a ping-pong reaction. Substrate B is fixed at specified concentrations, and substrate A varied. The rate equation is

$$\frac{1}{v} = \frac{K_a}{V_{max}}\left(1 + \frac{K_b}{B}\right) + \frac{1}{V_{max}}\left(1 + \frac{K_b}{B}\right)$$

K_{mapp}

Often the K_m for just one of the substrates is desired. Performing the reaction in the presence of very high concentrations of substrate A and varying the concentration of B permits determination of a K_{mapp} for substrate B. This is possible because when [A] $\gg K_a$, the velocity equation reduces to a simple Michaelis–Menten equation.

10.9 • INHIBITORS

Much of our basic knowledge of metabolic pathways was obtained by using inhibitors of specific enzymes. Pharmaceutical compounds are now designed as inhibitors of specific enzymes, and many naturally occurring compounds are inhibitors (Clin. Corr. 10.7). Inhibitory compounds can bind to the free enzyme or to the ES complex and affect the velocity of the reaction. With an inhibitor, EI and/or ESI (where I is an inhibitor) can exist. An equation relating the total concentration of enzyme to all its possible complexes results in a new Michaelis–Menten equation containing the term $1 + [I]/K_i$ where K_i is the dissociation constant of EI or ESI. k_{cat} in the presence of the inhibitor is an apparent k_{cat} (k_{catapp}), and K_m will be an apparent K_m (K_{mapp}); that is, a value will be measured, but it will be different from the value that would be found in the absence of inhibitor. The inhibitor concentration does not change during the course of the reaction, so [I] is a constant. Several classes of inhibitors are defined on the basis of these reaction kinetics.

Competitive Inhibition

Competitive inhibition occurs when an inhibitor competes with the substrate for binding to the free enzyme. Some **competitive inhibitors** are structurally similar to the substrate or product, whereas others are structurally quite different. For example, malonate is a competitive inhibitor of succinic dehydrogenase (Figure 10.55 and p. 555), binding presumably to the substrate-binding site. Pyrazole is a competitive inhibitor of alcohol dehydrogenase, but its structure is quite different from the substrate. If an inhibitor binds to the active site or to a different site and prevents S from binding, the reaction would be as in Figure 10.56. The inhibitor competes with substrate for binding to the enzyme, so when there is a very large concentration of substrate, the action of the inhibitor will be overcome. The amount of enzyme in the ES complex will be a function of [S], [I], K_m, and K_i (k_5/k_6). Since $E_t = E_f + ES + EI$, Eq. 10.31 is obtained.

$$v = \frac{k_3 k_1 [E_t][S]}{(k_2 + k_3)(1 + [I]/K_i) + k_1[S]} \tag{10.31}$$

Dividing all terms by k_1 yields Eq. 10.32 since $(k_2 + k_3)/k_1$ is K_m in the absence of I.

$$v = \frac{k_3[E][S]}{K_m(1 + [I]/[K_i]) + [S]} \tag{10.32}$$

Note the similarity of Eqs. 10.32 and 10.16. A number of constants are found in the denominator, and those can be group to be called K_{mapp} since the [I] is constant, the term $1 + [I]/K_i$ is a constant. The K_m measured in the presence of inhibitor will be a K_{mapp}, but it is the true K_m times $(1 + [I]/K_i)$. The presence of the inhibitor will cause the reaction to become slower at lower substrate concentrations because the constants in the denominator are larger than if no inhibitor is present. Only when [S] is much greater than K_{mapp} would V_{max} be obtained as the denominator would be approximately just [S]. Under this condition, virtually no inhibitor will bind to enzyme (Clin. Corr. 10.8). Both the substrate and the inhibitor compete for binding, thus increasing the concentration of the substrate will overcome the action of the inhibitor. Therapeutically, competitive inhibitors are useful only if the value of $[I]/K_i$ is high so the inhibitor can function in the presence of even high concentrations of substrate. Low values for K_i (tight binding) are desired so large amounts of inhibitor need not be required to inhibit the enzyme.

CLINICAL CORRELATION 10.7

Inhibitors of Xanthine Oxidase Isolated from Plants

Gout is an inflammatory disease caused by the overproduction or undersecretion of uric acid, the end product of purine catabolism (p. 820). The terminal step in purine metabolism is catalyzed by xanthine oxidase. A common treatment for gout is the use of allopurinol, a structural analog of xanthine and an inhibitor of the enzyme. Many older societies used medicinal plants and have maintained records of which are effective. Records of Vietnamese traditional medicine indicate that 96 plants, including *Chrysanthemum sinense,* have been used to treat gout. A few extracts from these plants were found to inhibit mammalian xanthine oxidase, some nearly as effective as allopurinol. Their structures are quite different from that of allopurinol and xanthine. The results indicate that study of compounds from traditional medicine may lead to new pharmaceuticals.

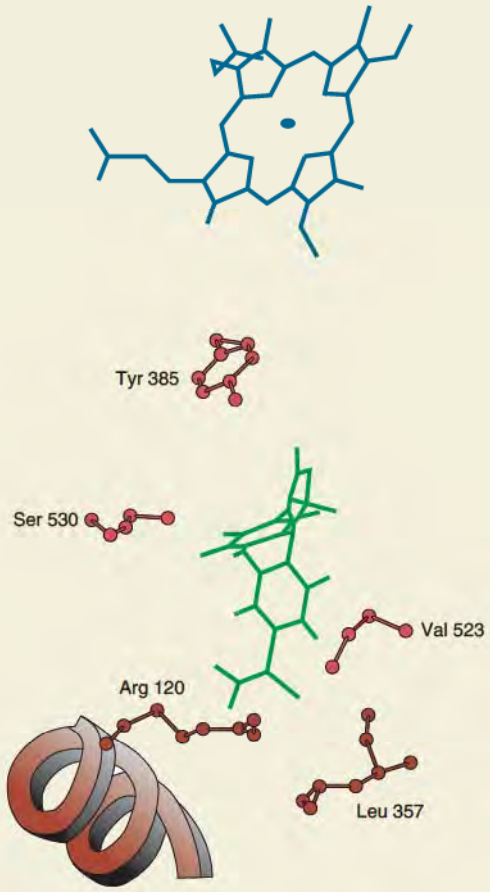
CLINICAL CORRELATION 10.8

Design of a Selective Inhibitor

Prostaglandins are a very important class of paracrine hormones derived from long-chain unsaturated fatty acids (p. 737). One of the early steps in their synthesis involves an enzyme, cyclooxygenase (COX). Among the many physiological effects of the prostaglandins are the pain and inflammation associated with arthritis. Traditionally, arthritis has been treated with aspirin and other nonsteroidal anti-inflammatory drugs that have been shown to work by inhibiting the cyclooxygenases, thus decreasing the levels of "bad" prostaglandins causing the symptoms. A serious problem with these drugs is the development of gastrointestinal bleeding and perforation caused by a concomitant decrease in the "good" prostaglandins which are protective of the gastrointestinal mucosa.

There are two different cyclooxygenases, COX-1 and COX-2, which have different tissue distributions. The COX-2 enzyme is inducible by mediators from the arthritic condition, whereas COX-1 constitutively synthesizes the mucosa-sparing prostaglandins. The only significant difference in the active sites of the two enzymes is that COX-2 has a valine rather than isoleucine at residue 523. The smaller valine allows for preferential binding of custom designed inhibitors resulting in selective inhibition of COX-2. Such a custom-designed drug, VIOXX® is shown modeled into the COX-1 active site.

Key amino acid side chains forming the substrate-binding pocket are shown in red, and the heme, which participates in prostaglandin synthesis, is shown in blue. It has been shown that aspirin acetylates serine 530 in both COX-1 and -2 whereas VIOXX® selectively binds to and inhibits COX-2, thus preserving the production of "good" prostaglandins by COX-1. The phenyl group of aspirin occupies the identical location in the active site as the phenyl group of VIOXX®. Initially VIOXX®-like drugs appeared to be competitive inhibitors. With COX-2, but not with COX-1, however, a time-dependent irreversible inhibition occurs that does not involve a covalent linkage. VIOXX® came on the market in 2000 and made a tremendous difference in the quality of life for arthritic patients. Unfortunately, significant side effects involving the heart have developed with some patients, and the drug was withdrawn from the market.



Gierse, J. K., McDonald, J. J., Hauser, S. D., Rangwala, S. H., Koboldt, C. M., and Seibert K. A single amino acid difference between cyclooxygenase-1 (COX-1) and -2 (COX-2) reverses the selectivity of COX-2 specific inhibitors. *J. Biol. Chem.* 271: 15810, 1996.

Uncompetitive Inhibition

An inhibitor can bind to the ES complex rather than the free enzyme, as indicated in Figure 10.57. It is not binding to the substrate-binding site but to an alternative binding site that does not prevent substrate from binding. The Michaelis–Menten equation will be

$$v = \frac{V_{max}\,[S]/(1 + [I]/K_i)}{(K_m + [S])/(1 + [I]/K_i)} \tag{10.33}$$

k_{cat} is now decreased, so the V_{max} will be decreased compared to the value in the absence of inhibitor and the K_{mapp} term is also changed. This situation is called **uncompetitive inhibition**. In contrast to competitive inhibition, increasing the concentration of substrate will not overcome the effect of the inhibitor because [I] is binding to ES complex and not free enzyme.

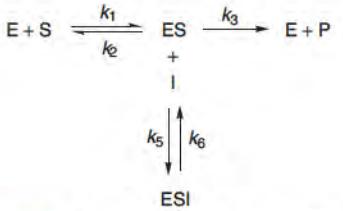


Figure 10.57 Reaction of an uncompetitive inhibitor reacting with the enzyme–substrate complex.

Noncompetitive Inhibition

A more complicated situation occurs if a reversible inhibitor binds to both the free enzyme and the ES complex. A variety of situations can occur depending on how the presence of I affects the binding of substrate and the ability of the enzyme to catalyze the reaction (Figure 10. 58).

The Michaelis–Menten equation is very complex as both ES and ES-I can yield products. If I binds with the same affinity to both E and ES and k'_3 is zero, then the following equation can be derived:

$$v = \frac{V_{max}[S]/(1 + [I]/K_i)}{K_m + [S]} \tag{10.34}$$

This mode of binding leads to an inhibition of activity in the presence of even high concentrations of [S]. If k'_3 is not zero, then a different situation arises since the ES-I complex will produce product.

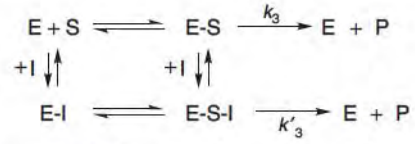

Figure 10.58 Reaction of a noncompetitive inhibitor reacting with an enzyme.

Lineweaver–Burk Plots in the Presence of Inhibitors

Competitive and Noncompetitive Inhibitors

The Michaelis–Menten equation for an enzyme reaction performed in the presence of the three different types of reversible inhibitors leads to different double-reciprocal plots (Figure 10.59). The reason being that the term $1 + [I]/K_i$ is found associated with the K_m or k_{cat} term depending on what type of inhibitor is being used. In the case of a competitive inhibitor (Figure 10.59*a*), V_{max} is not changed at high substrate concentrations, so the velocity lines in the absence and presences of different inhibitor concentrations intersect on the *y*-axis. With uncompetitive inhibition as the inhibitor concentration is changed, a series of parallel lines forms since the slope of the line is V/K and both V and K terms contain the $(1 + [I]/K_i)$ term (Figure 10.59*b*). With noncompetitive inhibition, the inhibitor binds to both E and ES and the Lineweaver–Burk plot is a family of lines that intersect on the *x*-axis.

The double-reciprocal plots can be used to determine the mode of inhibitor binding. From the intercepts on the *x*- and *y*-axis, V_{mapp} and K_{mapp} can be calculated. If the K_m for a substrate is known, then the K_i for the inhibitors can be calculated.

Noncompetitive inhibitors effectively reduce the concentration of free enzyme, and thus velocity is decreased (Figure 10.59*c*). Even if substrate were saturating ($[S] \gg K_m$), the observed maximum velocity would be lower than it would be in the absence of the inhibitor. Compounds that are these types of inhibitors are more useful as drugs since they inhibit the enzyme independent of the concentration of substrate.

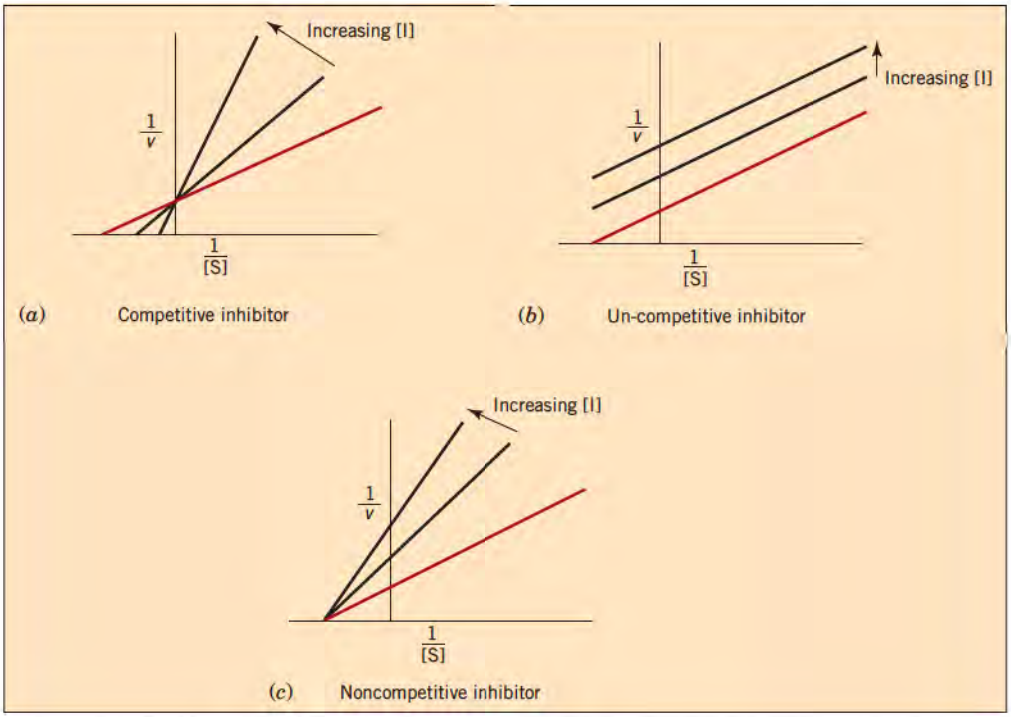

Figure 10.59 Double-reciprocal plots for competitive, uncompetitive, and reversible noncompetitive inhibition. A competitive inhibitor binds at the substrate- binding site and effectively increases the K_m for the substrate. An uncompetitive inhibitor causes an equivalent shift in both V_{max} and K_m resulting in a line parallel to that given by the uninhibited enzyme. A reversible noncompetitive inhibitor binds with both E and ES, presumably at a site other than the substrate- binding site; therefore the effective K_m does not change, but the apparent V_{max} decreases. Red lines are in the absence of inhibitor.

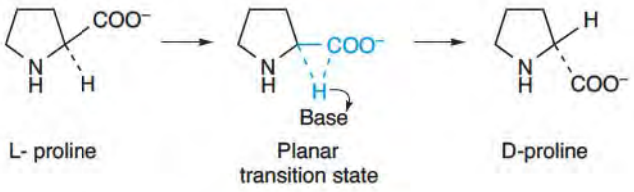
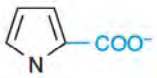


(*a*) Proline racemase reaction



(*b*) Pyrrole-2-carboxylate is planar as in transition state.

Figure 10.60 Pyrrole-2-carboxylate mimics the planar transition state and is an excellent inhibitor of proline racemase.

Inhibitors of Two-Substrate Reactions

A competitive inhibitor of a two-substrate reaction usually inhibits only one of the two substrates. If the compound binds to only free enzyme, it will be competitive against substrate A. If the inhibitor binds to the E-A complex, then it will be competitive against substrate B. The K_i value for inhibitors of two-substrate reactions can be determined by varying the concentration of one substrate in the presences of an excess of the other substrate. The reactions for noncompetitive inhibitors would be the same as with a single substrate.

Other Inhibitors

Transition-State Inhibitors

Enzymes lower the energy of activation by stabilizing the transition state not the binding of substrate. Thus, if a compound resembled the transition state, it might bind more tightly to the enzyme than a compound resembling the substrate. These inhibitors have a K_i value much lower than the K_m for substrate. No one has ever seen a transition state, so proposed structures are based on chemical intuition. An example of a transition-state analog is an inhibitor of proline racemase (Figure 10.60). During the enzyme reaction, the tetrahedral substrate will become planar during the conversion of L- to D-proline; pyrrole 2-carboxylate structurally resembles the proposed transition state.

Mechanism Based or Suicide Inhibitors

Enzymes perform complex reactions where many transient intermediates occur as substrate is transformed to product. Compounds have been synthesized where the enzyme performs an initial step in the reaction but then converts the substrate into a form that remains covalently attached to the enzyme. The activity of the enzyme will be destroyed and hence the name **suicide** inhibitor.

Irreversible Inhibitors

Compounds that chemically modify and inactivate an enzyme are classified as **irreversible inhibitors**. These react with amino acids residues (Figures 10.61 and 10.62). Aspirin and Antabuse, a drug given to deter people from abusive alcohol consumption, are examples of irreversible enzyme inhibitors used clinically (Clin. Corrs. 10.9 and 10.10).

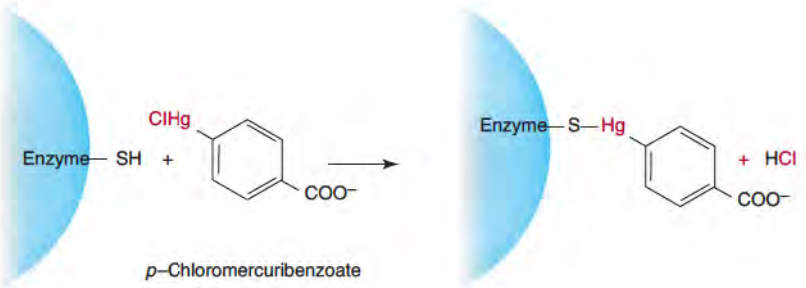


Figure 10.61 Enzyme inhibition by covalent modification of an active site cysteine.

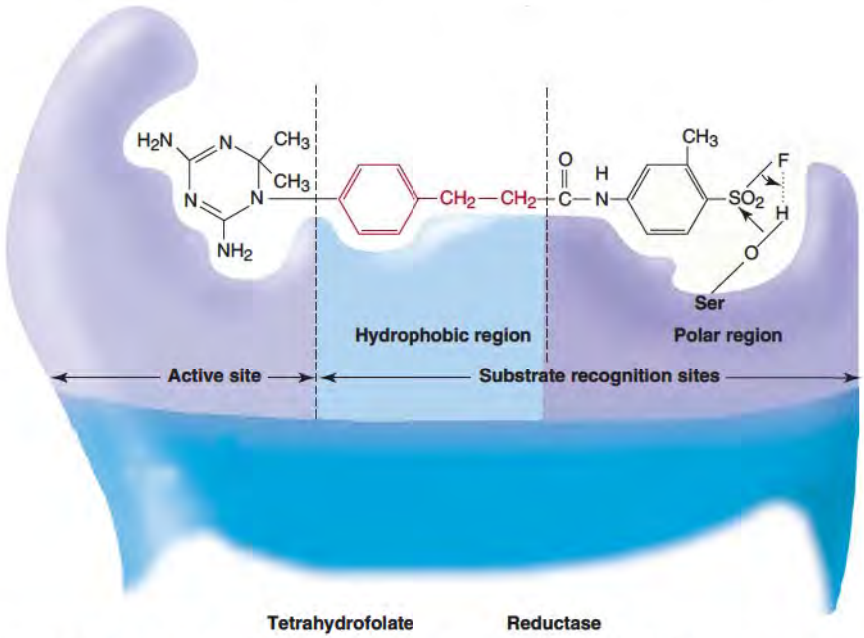

Figure 10.62 Site-directed inactivation of tetrahydrofolate reductase. The irreversible inhibitor, a substituted dihydrotriazine, structurally resembles dihydrofolate and binds specifically to the dihydrofolate site on dihydrofolate reductase. The triazine portion of the inhibitor resembles the pterin moiety and therefore binds to the active site. The ethylbenzene group (in red) binds to the hydrophobic site normally occupied by the *p*-aminobenzoyl group. The reactive end of the inhibitor contains a reactive sulfonyl fluoride that forms a covalent linkage with a serine hydroxyl on the enzyme surface. Thus, this inhibitor irreversibly inhibits the enzyme by blocking access of dihydrofolate to the active site. This is not a suicide inhibitor but an example of an inhibitor that binds to the active site and has a reactive group.

Enzyme Inhibitors as Drugs

New pharmacologically active compounds are screened for their affect on a variety of enzymes. Drugs designed to inhibit enzymes unique to a microorganism will produce fewer side effects in patients. A classic example is sulfa drugs because bacteria convert *p*-aminobenzoic acid to folic acid whereas humans do not have the enzyme for this reaction (Figure 10.63). Subtle differences that exist between isozymes of mammalian enzymes are being exploited in order to produce specific inhibitors. An example is **sildenafil** (trade name **Viagra**), a drug for erectile dysfunction, which inhibits a specific

CLINICAL CORRELATION 10.9

A Case of Poisoning

Emergency room personnel encounter many instances of pesticide poisoning and must be equipped to recognize and treat these cases. Many of the common insecticides are organophosphate compounds that irreversibly inhibit the action of acetylcholine esterase (AChE) in the postsynaptic fibers of the cholinergic neurons (p. 948) by forming stable phosphate esters with a specific serine in the active site of the esterase. Inhibition of AChE prevents the hydrolysis of acetylcholine in the synapse resulting in constant stimulation of the end organs of these neurons. The most prominent effects of pesticide poisoning in humans are paralysis of the respiratory muscles and pulmonary edema. If given early enough, a drug like pralidoxime can displace the alkyl phosphate from the pesticide bound to the active site serine and regenerate an active AchE.

CLINICAL CORRELATION 10.10

Mushrooms and Alcohol Metabolism

Coprine, a toxin produced by the Inky Cap mushroom, forms a covalent bond with aldehyde dehydrogenase, an enzyme involved in the metabolism of alcohol. Coprine is not usually very toxic except in individuals who consume an alcoholic beverage while eating the mushrooms. That person gets a toxic reaction to the accumulated acetaldehyde formed in the oxidation of ethanol.

Disulfuram, a drug used to deter abusive consumption of alcohol is sold under the name Antabuse®, which is also a covalent inhibitor of aldehyde dehydrogenase. The drug makes the patient ill if he or she consumes alcohol. Disulfuram was originally used as an antioxidant in the rubber industry where it was observed that workers became ill when having a drink after work.

The inhibitor does not dissociate from the enzyme and the only way to restore the activity is by biosynthesis of new enzyme in the tissue.

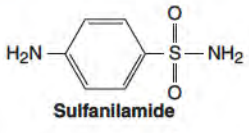

Figure 10.63 Structure of *p*-aminobenzoate and sulfanilamide, a competitive inhibitor of a bacterial enzyme involved in the synthesis of folic acid.

TABLE 10.5 • Representative Drugs That Inhibit Specific Enzymes

Drug	*Enzyme Target*	*Disease*
Amrubicin®	Topoisomerase 2	Cancer chemotherapy
Antabuse®	Aldehyde Dehydrogenase	Alcoholism
Captopril®	Angiotensin-converting enzyme	Hypertension
Celebrex®	Cyclooxygenase-2	Arthritis
Digoxin®	Na^+-K^+-Exchanging ATPase	Heart problems
Hycamtin®	Topoisomerase 1	Cancer chemotherapy
Lipitor®	3-hydroxy-3-methylglutaryl CoA	High cholesterol
Viagra®	Phosphodiesterase 5	Erectile dysfunction

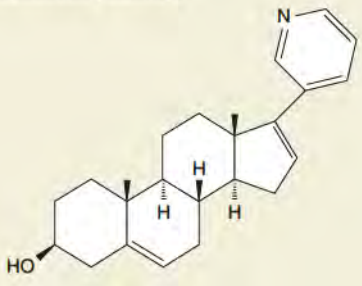
isozyme of phosphodiesterase (p. 447). A compound may be found to be a specific for an enzyme *in vitro,* but it may also inhibit enzymes not tested in the screening process. Representative drugs that are inhibitors of enzymes are presented in Table 10.5. Clin. Corrs. 10.11 and 10.12 describe two very specific examples. A Closer Look 10.6 describes a method to rapidly identify new enzyme inhibitors and activators.

CLINICAL CORRELATION 10.11

Testosterone and Prostate Cancer

Prostate cancer is one of the most common forms of cancers and affects only men. During an early stage of the disease the tumor requires testosterone. With time, the tumor cells mutate so they no longer need testosterone. The tumor cells are referred to as hormone refractive cells. Some investigators feel that even in the early stages of disease, there are a few cells that are already hormone refractive.

Investigators consider that the cells they thought were hormone refractive actually respond to a very low level of testosterone which might be found even after castration (surgically or chemically). A new approach to combat hormone refractive disease is to use an inhibitor of a cytochrome P450 (Cyp17A1), an enzyme involved in the biosynthesis of the hormone. Abiraterone has been tested as an *in vivo* inhibitor of the nontestis testosterone pathway.



Structure of Abiraterone.

CLINICAL CORRELATION 10.12

Natural Products as Inhibitors of Enzymes

Some fruits contain compounds that affect the metabolism of specific drugs. Individuals consuming the food and the drug can have an adverse effect. Perhaps the best-studied interaction is with grapefruit. This fruit contains a class of organic compounds called furanocoumarins, and it was found that some members inhibit a cytochrome P450 (CYP3A4) in the intestine but not in the liver. A number of statin drugs used to treat high cholesterol and some blood pressure medications are partially metabolized in the intestines and require the involvement of the CYP3A4. Consuming grapefruit while taking the drug alters the pharmokinetics of a variety of drugs and may present dire consequences. Once the drug is in the circulating system, its metabolism is no longer inhibited.

In spite of the effect of grapefruit juice on CYP3A4, studies have shown that it has many known good effects on the body because of the antioxidants it possesses. The grapefruit effect was discovered during a study on the interaction of ethanol with a blood pressure medication called felodipine (brand name Plendil®). Grapefruit juice was used as the vehicle for the ethanol, and ultimately the investigators realized that the inhibition of drug metabolism was due to the juice and not ethanol.

Kiani, J., and Imam, S. Z. Medicinal importance of grapefruit juice and its interaction with various drugs. *Nutr. J.* 6: 33, 2007.

A CLOSER LOOK 10.6

High-Throughput Screening to Find Inhibitors and Activators of Enzymes

Inhibitors of enzymes have been found from natural compounds occurring in plants, bacteria, and mold. A chemical-library screening procedure is used for the search of new enzyme inhibitors, especially by the pharmaceutical industry. Tens of thousands of compounds and extracts of natural product are rapidly tested for their ability to inhibit an enzyme or affect cell function. Different combinations of test materials are robotically added to the test system. Those which affect the enzyme are then analyzed so that new biologically active chemicals can be identified. The advantage of this approach is that compounds with a variety of different structures can be tested, without a preconceived idea of what should be the structure of the effector. Depending on the assay, it is possible to screen for any type of effector.

Assay Guidance Manual 5.0. Eli Lilly and Company and NIH Chemical Genomics Center, 2008. Available online at http://www.ncgc.nih.gov/guidance/manual_toc.html.

10.10 • REGULATION OF ENZYME ACTIVITY

Covalent Modification

Cells have the ability to regulate the activity of key enzymes by covalent modification of the protein. There are many protein kinases that catalyze phosphorylation of serine, threonine, or tyrosine residues on specific enzymes and protein phosphorylases that remove the phosphate by hydrolysis. Depending on the enzyme, phosphorylation can activate an inactive enzyme or inactivate an active enzyme. Groups such as sulfate and acetate can also be added to alter enzymatic activity. Since both phosphorylation and dephosphorylation are performed by enzymes, this reversible covalent modification is a rapid and effective way of controlling enzyme activity.

Allosteric Control of Enzyme Activity

The activity of many enzymes can be modulated by ligands binding to the enzyme at sites other than the substrate-binding site. These sites are referred to as allosteric sites (Figure 10.64). **Allosteric** is derived from the Greek root *allo,* meaning "the other." An allosteric site is a unique region of the enzyme quite different from the substrate-binding site. The ligands that bind at the allosteric site are called allosteric effectors or modulators and are not modified during the course of the enzyme reaction. Binding of an allosteric effector causes a conformational change of the enzyme so that the affinity for the substrate or other ligands also changes. Positive (+) allosteric effectors increase the enzyme affinity for

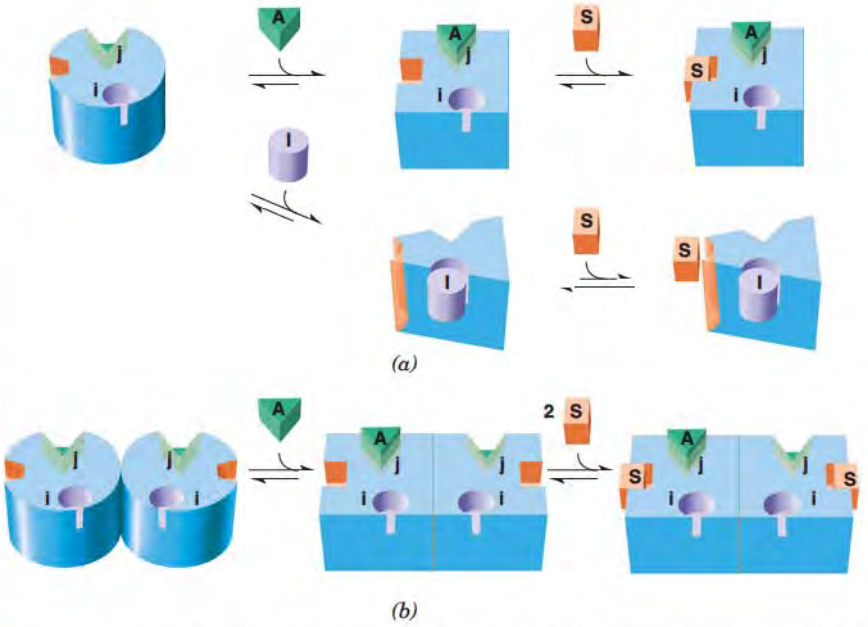


Figure 10.64 **Models of allosteric enzyme systems.** (*a*) Model of a monomeric enzyme. Binding of a positive allosteric effector, A (green), to the activator site, j, induces a new conformation to the enzyme, one that has a greater affinity for the substrate. Binding of a negative allosteric effector (purple) to the inhibitor site, i, results in an enzyme conformation having a decreased affinity for substrate (orange). (*b*) A model of a polymeric allosteric enzyme. Binding of the positive allosteric effector, A, at the j site causes an allosteric change in the conformation of the protomer to which the effector binds. This change in the conformation is transmitted to the second protomer through cooperative protomer–protomer interactions. The affinity for the substrate is increased in both protomers. A negative effector decreases the affinity for substrate of both protomers.

substrate. The reverse is true for negative (–) allosteric effectors. The allosteric site at which the positive effector binds is referred to as an activator site; the negative effector binds at an inhibitory site. The existence of allosteric sites is illustrated in Clin. Corr. 10.13.

Allosteric enzymes are divided into two classes on the basis of the effect of the allosteric effector on the K_m or V_{max}. In the **K class** the effector alters the K_m but not V_{max}, whereas in the **V class** the effector alters V_{max} but not K_m. In the K class, a negative effector binding at an allosteric site increases the K_m for the substrate. Similarly in V class enzymes, positive and negative allosteric modifiers increase or decrease the rate of breakdown of the ES complex to products. There are a few enzymes in which both K_m and V_{max} are affected by the modifier.

In theory, a monomeric enzyme can undergo an allosteric transition in response to a modulating ligand (Figure 10.64*a*). However, only a few monomeric allosteric enzymes are known including ribonucleoside diphosphate reductase and pyruvate-UDP-N-acetylglucosamine transferase. Most allosteric enzymes are oligomeric consisting of several subunits (Figure 10.64*b*). Binding of ligand to one protomer can affect the binding of ligands on the other protomers in the oligomer. If the same ligand binds at the allosteric site and is also the substrate for the enzyme, the effect is referred to as a **homotropic interaction**. Homotropic interactions are almost always positive. A **heterotropic interaction** is the effect of one ligand binding at the allosteric site on the binding of a different ligand at the active site. Heterotropic interactions can be positive or negative. Examples are the effect of a negative effector on the binding of substrate or the positive effect of an allosteric activator on substrate binding. Heterotropic and homotropic effects in oligomeric enzymes are mediated by cooperativity between subunits.

Most of the enzymes subject to allosteric modulation are rate-determining enzymes in metabolic pathways or are located at a junction where the substrate can be used for more than one pathway.

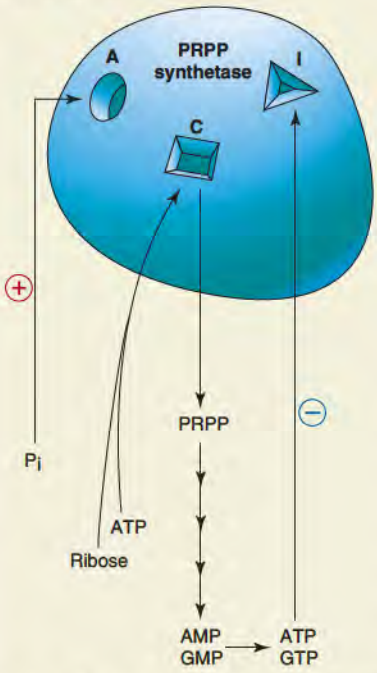
Multi-subunit Enzymes: Cooperativity

Many enzymes are multimers consisting of either the same or different monomeric subunits. Subunits of some multimeric enzymes act independently of each other, with

CLINICAL CORRELATION 10.13

A Case of Gout Demonstrates the Difference between an Allosteric- and Substrate-Binding Site

The realization that allosteric inhibitory sites are separate from allosteric activator sites as well as from the substrate binding and catalytic sites is illustrated by a study of a patient with gout whose red blood cell PRPP level was increased. It was found that the patient's PRPP synthetase had normal K_m and V_{max} values and sensitivity to activation by phosphate. The increased PRPP levels and hyperuricemia arose because the end products of the pathway (ATP, GTP) were not able to inhibit the synthetase through the allosteric inhibitory site. It was suggested that a mutation in the inhibitory site or in the coupling mechanism between the inhibitory and catalytic site led to failure of the feedback control mechanism.



Sperling, O., Persky-Brosh, S., Boen, P., and DeVries, A. Human erythrocyte phosphoribosyl pyrophosphate synthetase mutationally altered in regulatory proprties. *Biochem. Med.* 7: 389, 1973.

CLINICAL CORRELATION 10.14

Ambiguity in the Assay of Mutated Enzymes

Structural gene mutations leading to production of enzymes with increases or decreases in K_m are frequently observed. A case in point is a patient with hyperuricemia and gout, whose red blood cell hypoxanthine-guanine-phosphoribosyltransferase (HGPRT) showed little activity in assays *in vitro*. This enzyme is involved in the salvage of purine bases and catalyzes the reaction.

$$\text{Hypoxanthine} + \text{PRPP} \rightarrow \text{inosine monophosphate} + \text{PPi}$$

where PRPP is phosphoribosyl pyrophosphate.

The absence of HGPRT activity results in a severe neurological disorder known as Lesch–Nyhan syndrome (p. 816), yet this patient did not have the usual clinical signs of this disorder. Immunological testing with a specific antibody to the enzyme revealed as much cross-reacting material in the patient's red blood cells as in normal controls, indicating that the enzyme was being synthesized but was inactive in the assay *in vitro*. Increasing substrate concentration in the assay of the patient's red cell hemolysate restored full activity. This anomaly is apparently due to a mutation in the substrate-binding site of HGPRT, leading to an increased K_m. The substrate concentration in the standard assay and in the red blood cells was not high enough to bind to the enzyme. This case reinforces the point that an accurate enzyme determination is dependent on zero-order kinetics, that is, the enzyme being saturated with substrate.

Sorenson, L., and Benke, P. J. Biochemical evidence for a distinct type of primary gout. *Nature* 213: 1122, 1967.

events taking place in one subunit not influencing the activity of the other subunits. For these enzymes k_{cat} or V_{max} values can be divided by the number of subunits to obtain the actual turnover number per subunit. In other multi-subunit enzymes, an event in one subunit affects the ability of the adjacent subunits to function. In these situations, the K_m for substrate is usually changed but in some cases k_{cat} is altered (Clin. Corr. 10.14).

One subunit in a multimer can affect the properties of an adjacent subunit by changing the conformation of the subunits after substrate binds to it (Figure 10.64*a*). The altered monomer could bind substrate more easily and hence is more saturated without the substrate concentration increasing. If the binding becomes easier (decrease in K_m), then the enzyme is said to exhibit **positive cooperativity**; this is analogous to hemoglobin binding oxygen (p. 358). When the structural change makes binding of substrate to the second subunit more difficult (increase in K_m), then the enzyme is said to exhibit **negative cooperativity**.

The test for an enzyme exhibiting cooperativity is a plot of velocity versus [S]. The curve will be sigmoidal rather than hyperbolic (Figure 10.65*a*) and a double-reciprocal plot will not be linear (Figure 10.65*b*). This occurs because the K_m will change as the concentration of substrate changes.

It is very difficult to calculate precise K_m values for an enzyme exhibiting either positive or negative cooperativity. The value, however, is estimated from the concentration of substrate that allows v to be 50% of V_{max}; it is referred to as $K_{0.5}$. The Hill equation, employed to explain the cooperative binding of oxygen to hemoglobin (p. 358), is used to calculate the Hill coefficient that estimates the degree of cooperativity between interacting subunits of an enzyme. Values of less than 1 demonstrate negative cooperativity, and values greater than 1 positive cooperativity. Representative examples of positive and negative cooperativity are illustrated in Figure 10.66.

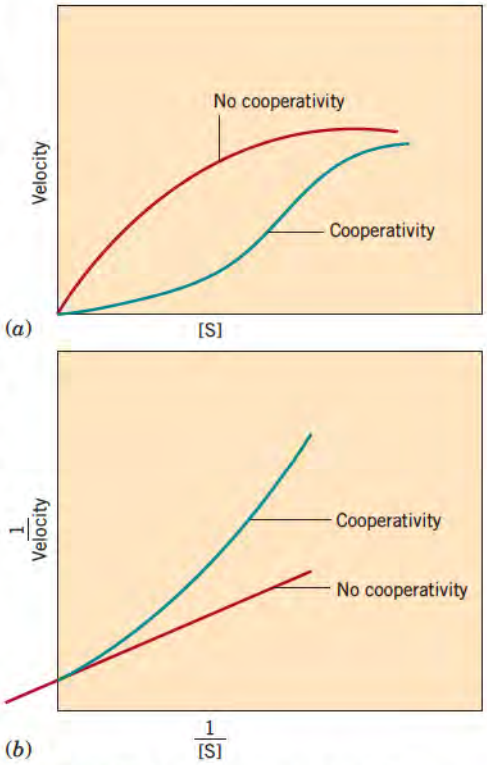


Figure 10.65 Plots for enzymes that exhibit cooperativity are atypical. (*a*) Velocity versus substrate plot and (*b*) double-reciprocal plot. Cooperative curves are for positive cooperativity.

Models to Explain Cooperativity

There are two models to explain cooperativity. Both use the premise that there are interactions between the subunits, and the conformation of the subunit binding a ligand is different from that of the subunit in the absence of ligand. The major difference between the models relates to whether the two conformations are preexisting or they occur only after ligand binds.

The **sequential model** proposes that when ligand binds to one subunit (A), there is a change in the conformation of the subunit, which then induces a conformational change in a contiguous subunit (B). The effect of ligand binding is sequentially transmitted through the interface between subunits producing increased or decreased affinity for the ligand by B (Figure 10.67*a*). In this model numerous hybrid states occur, giving rise to cooperativity and

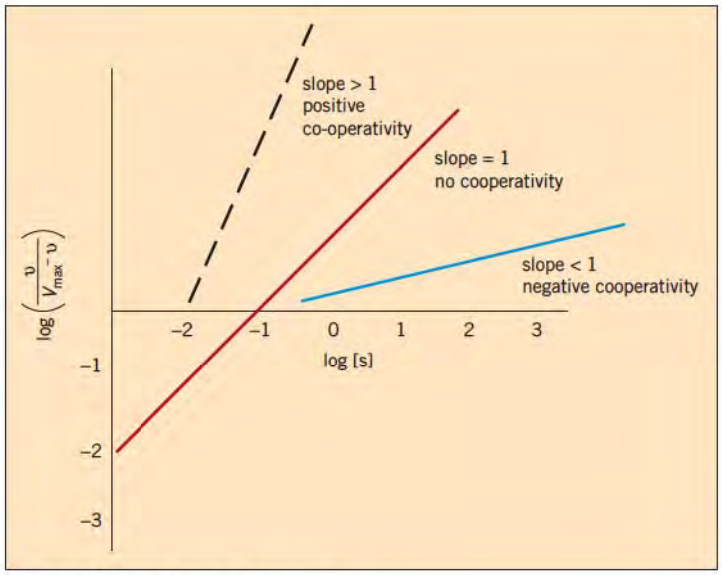

Figure 10.66 Hill plot for an allosteric enzyme.

sigmoid plots of velocity versus [S]. Both positive and negative cooperativity can be accommodated by the model. Positive allosteric modulators can induce a conformation in the subunit that has an increased affinity for the substrate, and a negative modulator induces a different conformation in the subunit resulting in decreased affinity for substrate. A similar argument can be made for enzymes where k_{cat} is changed.

The **concerted model** proposes that the two conformations are in equilibrium in the absence of ligand and the equilibrium is driven toward the ligand-bound conformation as ligand binds. The two states in the concerted model are called the T (tense or taut) and the R (relaxed) (Figure 10.67*b*). Though both states can bind ligand, one state binds it more tightly. Activators and substrates bind to the R state and shift the preexisting equilibrium toward the R state. With more of the protein in the R state, it is easier for the next molecule of substrate or activator to bind. Conversely, inhibitors favor the T state. In the presence of

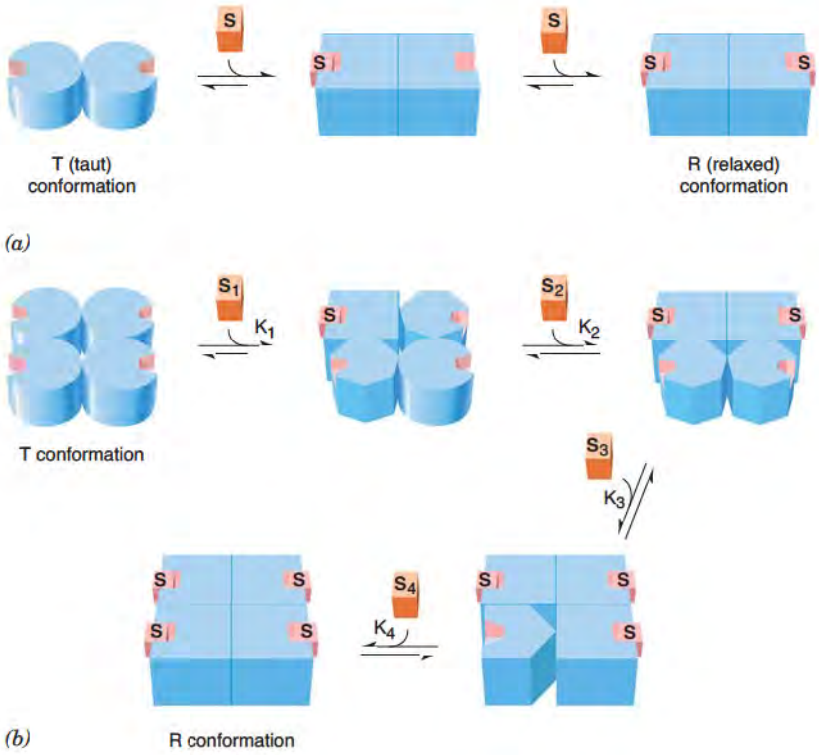

Figure 10.67 Models of cooperativity. (*a*) The concerted model. The enzyme exists in only two states, the T (tense or taut) and R (relaxed) conformations. Substrates and activators have a greater affinity for the R state and inhibitors for the T state. Ligands shift the equilibrium between the T and R states. (*b*) The sequential induced-fit model. Binding of a ligand to any one subunit induces a conformational change in that subunit. This conformational change is transmitted partially to adjoining subunits through subunit–subunit interaction. Thus the effect of the first ligand bound is transmitted cooperatively and sequentially to the other subunits (protomers) in the oligomer, resulting in a sequential increase or decrease in ligand affinity of the other protomers. The cooperativity may be either positive or negative, depending on the ligand.

an inhibitor, it is more difficult for the substrate to bind to the T conformation. Although this model accounts for the kinetic behavior of many enzymes, it cannot easily account for negative cooperativity.

Regulatory Subunits Modulate the Activity of Catalytic Subunits

The allosteric-binding site, as discussed, is considered to reside on the same subunit as the catalytic site, and all subunits of the enzyme are identical. In several enzymes a distinct regulatory protein subunit exists. These regulatory subunits (R) have no catalytic function, but their binding with the catalytic subunit (C) modulates the activity of the catalytic subunit through an induced conformational change. Protein kinase A is regulated by this mechanism (Figure 10.68). In the absence of cAMP, the R subunit binds to the C subunit causing inhibition of the activity. When cAMP binds to the R subunit, there is a conformational change of R leading to a dissociation of R from C. The C subunit is now catalytically active.

Calmodulin (p. 493), a Ca^{2+}-binding protein, is a regulatory subunit for some enzymes that use Ca^{2+} as a modulator of their activity. Binding of Ca^{2+} to calmodulin causes a conformational change, allowing it to bind to the Ca^{2+}-dependent enzyme.

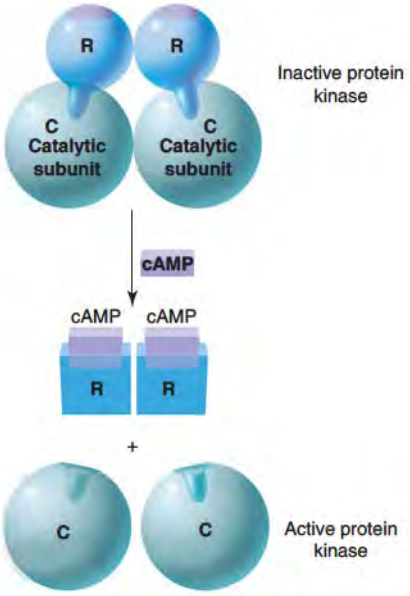

Figure 10.68 Model of allosteric enzyme with separate catalytic (C) and regulatory (R) subunits. The regulatory subunit of protein kinase A contains a pseudo substrate region in its primary sequence that binds to the substrate site of the catalytic subunit. In the presence of cAMP the conformation of the R subunit changes so that the pseudo substrate region can no longer bind, resulting in release of active C subunits.

10.11 • REGULATION OF METABOLIC PATHWAYS

The physiological integration of many enzymes into a metabolic pathway as well as the interrelationship of the products of one pathway with the activity of other pathways is controlled. It is not necessary to regulate the activity of every enzyme in a pathway. Rather modulation of the activity of one or more key enzymes of the pathway is sufficient. One enzyme-catalyzed reaction is usually slower than the others. This is the **rate-limiting step** for the pathway. Thus, the rate of flux of substrates in the sequence is dependent on one enzyme in the entire pathway. Altering the kinetic properties of this one enzyme has a large effect of the rate of formation of the final product.

Another site to regulate a metabolic pathway is at the first irreversible reaction unique to the pathway; this step is referred to as the **commitment step**. The rate-limiting enzyme is not necessarily the one catalyzing the committed step. In addition, in some pathways one intermediate substrate serves as an intermediate for two or more metabolic transformations each leading to different products. Regulating the enzymes at these branch points would control the flux of metabolites through the two pathways. The activity of the enzyme associated with the committed step or with the rate-limiting step can be regulated in a number of ways.

Cellular Enzyme Concentration

Many inducible enzymes have half-lives of less than 1 h, whereas many constitutive enzymes have half-lives of days. Cells regulate enzyme concentration by changing the rate of de novo synthesis at either the transcriptional or translational level. For example, glucose represses the de novo synthesis of pyruvate carboxykinase, the rate-limiting enzyme in the conversion of pyruvate to glucose. If sufficient glucose is available in the blood, there is a low level of pyruvate carboxykinase in the liver. Low blood levels of glucose lead to an increase in the enzyme and increase in glucose synthesis.

Activators, Inhibitors, and Covalent Modification

Short-term regulation of an enzyme occurs through modulation of the activity by activators, inhibitors, and covalent modification. When the cellular concentration of deoxyribonucleotides increases such that the cell has sufficient amounts for synthesis of DNA, the key enzyme of the synthetic pathway is inhibited by the end products of the pathway, resulting in a slowdown of the synthetic pathway. This is referred to as **feedback inhibition** (Figure 10.69*a*). In addition to feedback within a pathway, feedback inhibition of other pathways can also occur. This is referred to as **cross-regulation**. Here a product of one pathway serves as an inhibitor or activator of an enzyme occurring early in another pathway (Figure 10.69*b*). A good example is the cross-regulation of the production of the four deoxyribonucleotides for DNA synthesis.

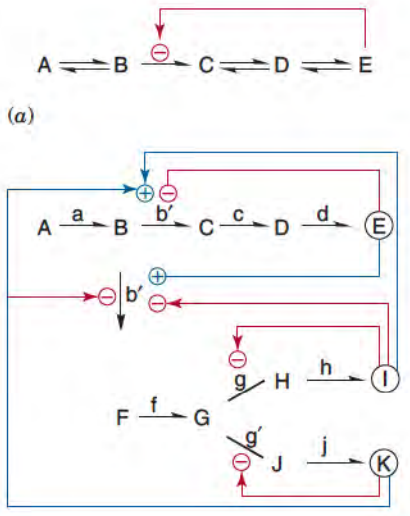

Figure 10.69 Control of metabolic pathways. (*a*) Feedback inhibition. Product E could inhibit the enzyme that catalyzes reaction of B to C. This may be an irreversible or rate-limiting reaction. (*b*) Regulation of a hypothetical complex pathway. Product E could inhibit enzyme b while activating enzyme b'. Similarly, product I and K could inhibit their synthesis by inhibiting enzymes b', g (and g') while activating enzyme b.

Compartmentation

Finally, the activity of a pathway can be regulated by physically partitioning reactions in specific cellular compartments separated by impermeable membranes. The transport of substrates, products, and cofactors across the membrane controls their concentration in the compartment. This regulates their availability and can limit enzyme activity. This is referred to as **compartmentation**. For example, acetyl CoA is formed in the mitochondria and must be transported out to the cytosol for use in fatty acid synthesis. Acetyl CoA carboxylase, the first step in fatty acid synthesis, requires acetyl CoA. The substrate cannot diffuse into the cytosol so a specific transport mechanism is present in the membrane (p. 684). Anabolic and catabolic pathways are often segregated in different organelles in order to better control each pathway. There would be no point for oxidation of fatty acids occurring at the same time and in the same compartment as biosynthesis of fatty acids. By maintaining fatty acid biosynthesis in the cytoplasm and oxidation in the mitochondria, control can be exerted by regulating transport of common intermediates across the mitochondrial membrane.

10.12 • CLINICAL APPLICATIONS OF ENZYMES

Because of their diverse properties enzymes find many uses in therapeutics, clinical analysis, and disease diagnostics. For example, hydrolytic enzymes, such as the proteases pronase and RNases, are used in debridement of wounds. **Streptokinase**, an enzyme mixture prepared from a streptococcus, is useful in clearing blood clots that occur in myocardial infarcts and in the lower extremities. It activates the fibrinolytic preenzyme **plasminogen** (p. 994) that is normally present in plasma. The activated enzyme is **plasmin**, a serine protease that cleaves the insoluble fibrin in blood clots into several soluble components. Another serine protease, human tissue plasminogen activator t-PA, is commercially produced by bioengineered *E. coli* and used in dissolving blood clots in patients suffering myocardial infarction. t-PA also functions by activating plasminogen.

Measurement of Plasma Enzymes

Enzymes found in plasma are of two types: those which are normally present and have a functional role in plasma and those which are released from tissues. The latter have no functional role in the plasma but are used for diagnostic purposes. Normally, the plasma content of intracellular enzymes is low or absent, but when cells are damaged, the contents can appear in blood. A disease process may cause changes in cell membrane permeability or increased cell death, resulting in release of intracellular enzymes. Lower molecular weight components can also diffuse out of cells when there is an abnormal increase in their cellular concentration. Analyzing blood for cellular components represents a convenient way for clinicians to assess damage occurring to specific tissues. In the diagnosis of specific organ involvement in a disease process it would be ideal if there were an enzyme unique to each organ that could be measured in plasma. Unfortunately, identical enzymes are found in most tissues. In some instances, however, different isozymes (p. 379) occur in different organs; these are useful for diagnostic purposes if released from a diseased tissue. For example, an isozyme of alcohol dehydrogenase that is liver specific and an acid phosphatase form found primarily in prostate are useful for specific identification of diseases in these organs. For some enzymes the tissue specific isozymes possess different kinetic properties, so determination of K_m and k_{cat} values can be used to determine from what tissue they arose.

Evaluation of the timing of appearance and disappearance of particular enzymes in plasma permits a diagnosis of specific organ involvement. Figure 10.70 illustrates the time-dependent changes in plasma activities of enzymes from the myocardium following a heart attack. Such profiles allow one to establish when the attack occurred and whether treatment is effective. Clin. Corr. 10.15 describes how diagnosis of a specific enzyme defect led to a rational clinical treatment that restored the patient to health. Another example of how isozymes are used to diagnose diseases is the isozyme pattern for lactate dehydrogenase as a function of time after a myocardial infarction (Figure 10.71, p. 420, and Table 10.2, p. 379). Not only does the total

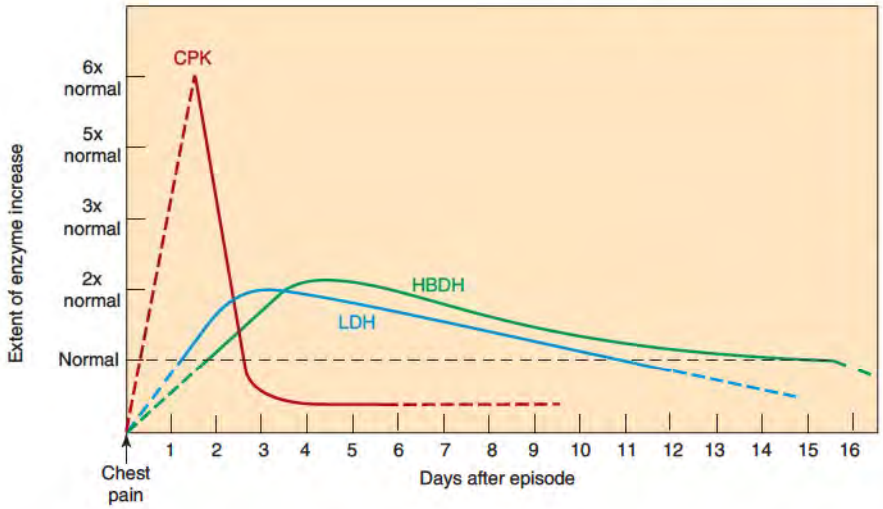

Figure 10.70 Kinetics of release of cardiac enzymes into serum following a myocardial infarction. CPK, creatine kinase; LDH, lactic dehydrogenase; HBDH, α-hydroxybutyric dehydrogenase. Such kinetic profiles allow one to determine where the patient is with respect to the infarct and recovery. *Note:* CPK rises sharply but briefly; HBDH rises slowly but persists. Reproduced with permission from Coodley, E. L. *Diagnostic Enzymes.* Philadelphia: Lea & Febiger, 1970, 61.

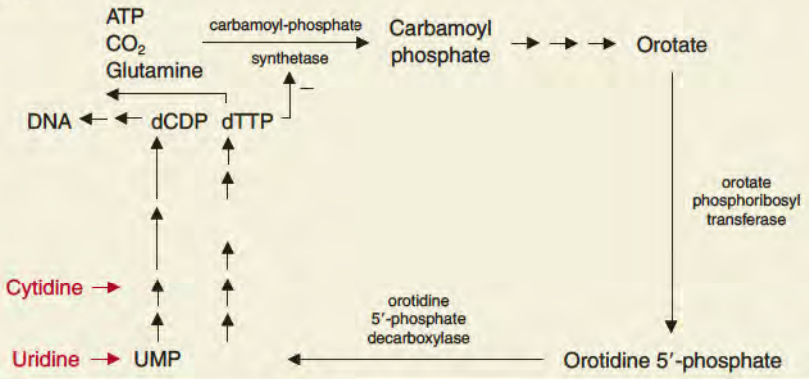
CLINICAL CORRELATION 10.15

Identification and Treatment of an Enzyme Deficiency

Enzyme deficiencies usually lead to increased accumulation of specific intermediary metabolites in plasma and hence in urine. Recognition of the intermediates that accumulate in biological fluids is useful in pinpointing possible enzyme defects. After the enzyme deficiency is established, metabolites that normally occur in the pathway but are distal to the block may be supplied exogenously in order to overcome the metabolic effects of the enzyme deficiency. In hereditary orotic aciduria, there is a double enzyme deficiency in the pyrimidine biosynthetic pathway leading to accumulation of orotic acid. Both orotate phosphoribosyltransferase and orotidine 5′-phosphate decarboxylase are deficient, causing decreased *in vivo* levels of CTP and TTP. The two activities are deficient because they reside in separate domains of a bifunctional polypeptide of 480 amino acids. dCTP and dTTP, which arise from CTP and TTP, are required for DNA synthesis. In these enzyme deficiency diseases, the patients are pale, weak, and fail to thrive. Administration of the missing pyrimidines as uridine or cytidine promotes growth and general well-being and also decreases orotic acid excretion. The latter occurs because the TTP and CTP formed from the supplied uridine and cytidine repress carbamoylphosphate synthetase, the committed step, by feedback inhibition, resulting in a decrease in orotate production.

Webster, D. R., Becroft, D. M. O., and Suttie, D. P. Hereditary orotic aciduria and other diseases of pyrimidine metabolism. In Scriver, C. R., Beaudet, A. L., Sly, W. S., and Valle, D. (Eds.), *The Metabolic and Molecular Bases of Inherited Disease,* 7th ed. New York: McGraw Hill, 1995, 1799.



enzymatic activity increase, but o there is a change in the isozyme pattern. More LDH_1, found primarily in myocardium and red blood cells, is found. In this example, LDH_5 is increased, indicative of liver damage to the patient. Thus secondary complications of heart failure can be monitored. After two weeks the isozyme pattern returns to that of a healthy patient.

Kinetic analyses of both creatine kinase and lactate dehydrogenase are useful for diagnostic purposes. CPK and LDH isozymes are plotted in Figure 10.72 as a function of time

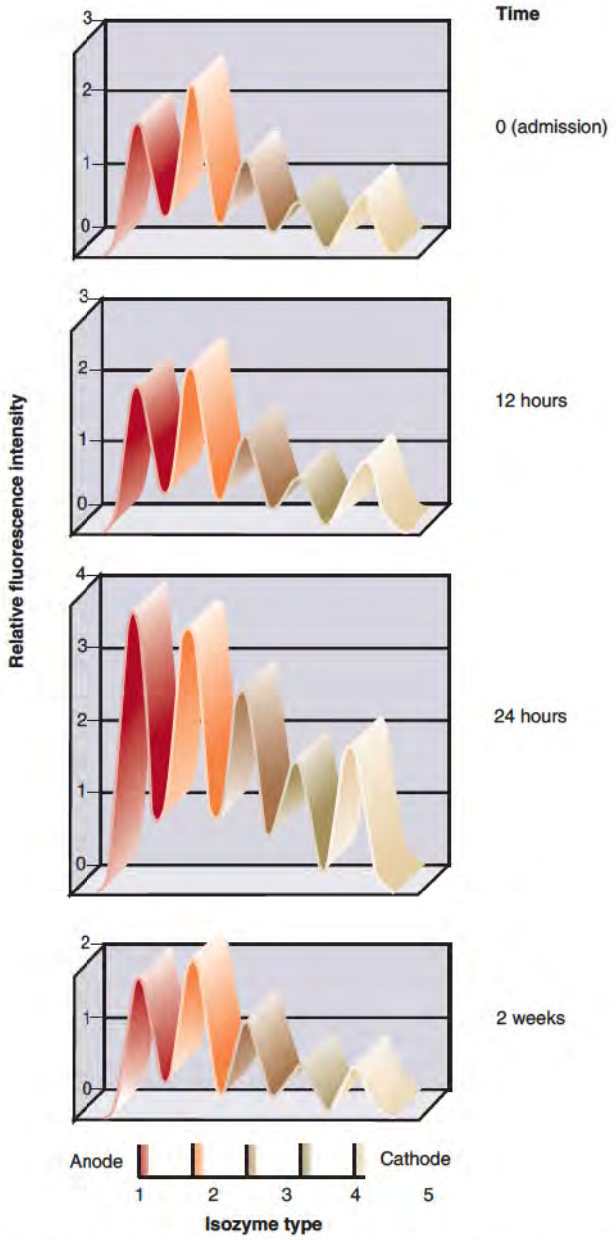


Figure 10.71 Tracings of densitometer scans of LDH isozymes at time intervals following a myocardial infarction. Total LDH increases and LDH1 becomes greater than LDH2 between 12 and 24 h. Increase in LDH5 is diagnostic of a secondary congestive liver involvement. Note the *y*-axis scales are not identical. After electrophoresis on agarose gels, the LDH activity is assayed by measuring the fluorescence of the NADH formed in LDH-catalyzed reaction.
Courtesy of Dr. A. T. Gajda, Clinical Laboratories, University of Arkansas for Medical Science.

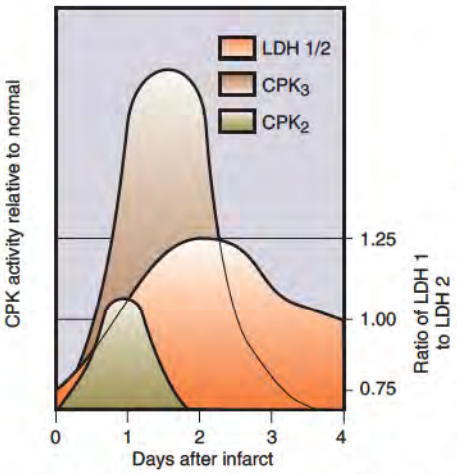

Figure 10.72 Characteristic changes in serum CPK and LDH isozymes following a myocardial infarction. CPK2 (MB) isozyme increases to a maximum within 1 day of the infarction. CPK3 lags behind CPK2 by about 1 day. Total LDH level increases more slowly. The increase of LDH1 and LDH2 within 12–24 h coupled with an increase in CPK2 is diagnostic of myocardial infarction.

after damage to the heart. The tissue damage releases CPK_2 into the blood within the first 6–18 h after an infarct, but LDH release lags behind the appearance of CPK_2 by 1 to 2 days. Normally, the activity of the LDH_2 isozyme is higher than that of LDH_1; however, in the case of infarction, the activity of LDH_1 becomes greater than LDH_2, at about the time CPK_2 levels are back to baseline (48–60 h). The LDH isozyme "switch" coupled with increased CPK_2 is diagnostic of myocardial infarct (MI) in virtually 100% of the cases.

The use of enzymes in the clinical laboratory is described in A Closer Look 10.7 and 10.8.

Metabolomics and Proteomics

With mass spectrophotometers becoming relatively common instruments, many investigators are using them with the hope of finding specific metabolites, proteins, or

A CLOSER LOOK 10.7

Clinical Laboratory Assays Employing Enzymes

Typically enzymes found in organs are not present in serum unless there is damage to the tissue. Hence measurement of serum levels of enzymes can be diagnostic of a diseased state. Assays for measurement-of plasma enzymes-are based on control of the assay system, including temperature, pH, and concentration of substrates, co-substrates, and cofactors. The K_m for the enzyme to be determined must be known. Typically, assays are performed under V_{max} conditions though they need not be. Assay conditions are optimized for the properties of the normal enzyme, which may not correctly measure levels of a variant enzyme because pH optima and/or the K_m for substrate and cofactors may be different from that of the normal enzyme. Enzyme assays measure the concentration of a product formed or substrate remaining as a function of time. In some reactions, the products or substrates absorb light; change in light absorption as a function of time is measured.

Many substrates have been synthesized where they or their products are chromophoric compounds (absorb light or emit fluorescent light). The coenzymes NAD(P) and FAD are easily measured because their reduced forms absorb light in the visible range. Many enzymes that do not directly reduce NAD(P) or FAD generate products that are substrates for NAD(P) or FAD-linked dehydrogenases. By coupling two enzyme reactions, the activity of the enzyme of interest can be determined.

Enzymes, as reagents, are used to measure metabolites in automated clinical analyzers. Glucose oxidase, an enzyme that oxidizes glucose, is used clinically to measure the concentration of glucose in body fluids. Assays for cholesterol employ cholesterol oxidase, and for triacylglycerols lipase is employed. The tests can be completed in a few minutes using small amounts of plasma. The enzymes can be immobilized in a solid bilayer with cofactors and indicator reagents, which become chromophores when reduced. In the case of cholesterol oxidase, hydrogen peroxide is a product of the oxidase reaction and the peroxide formed oxidizes a colorless dye to a colored product mediated by a peroxidase, another enzyme.

A CLOSER LOOK 10.8

Enzyme-Linked Immunoassays Employ Enzymes as Indicators

Modern clinical chemistry has benefited from the merging of enzyme chemistry and immunology. Antibodies specific to a protein antigen are coupled to an indicator enzyme such as horseradish peroxidase to generate a very specific and sensitive assay. After binding of the peroxidase-coupled antibody to the antigen, the peroxidase is used to generate a colored product that is measurable and whose concentration is related to the amount of antigen in a sample. This assay has been given the acronym **ELISA** for **e**nzyme-**l**inked **i**mmunoad**s**orbent **a**ssay. Monoclonal antibodies generate antibodies that are very specific for an antigen, As an example, antibodies to a specific isozyme or to one member of a family of very similar enzymes have been produced allowing their determination by **ELISA**.

Horseradish peroxidase is used as an indicator in ELISA to test for the presence of human immunodeficiency virus (HIV) coat protein antigens. Peroxidase generates many molecules of product per antigen as time progresses. Such amplified enzyme assays allow the measurement of remarkably small amounts of antigens.

enzymes released from tumors. These metabolites and proteins could be employed as markers of specific types of tumors. It is anticipated that unique enzymes and proteins associated with various disease states will be identified in plasma. These enzymes and proteins will have to be purified and characterized to determine their effects on normal cellular activity.

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

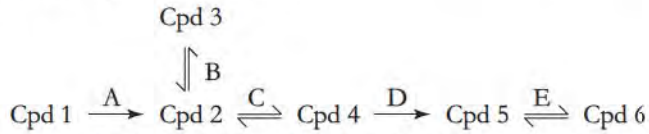
1. In all enzymes the active site
- **A.** contains the substrate binding site.
- **B.** is contiguous with the substrate binding site in the primary sequence.
- **C.** lies in a region of the primary sequence distant from the substrate binding site.
- **D.** contains a metal ion as a prosthetic group.
- **E.** contains the amino acid side chains involved in catalyzing the reaction.

2. When added to a reaction, a catalyst
- **A.** supplies the heats of formation.
- **B.** alters the equilibrium constant K_{eq} to favor the formation of products.
- **C.** increases the rate at which equilibrium is reached.
- **D.** changes the order of the reaction (e.g., first order to second order).
- **E.** alters the ΔG_0 of the reaction.

3. Metal cations may do all of the following except
- **A.** donate electron pairs to functional groups found in the primary structure of the enzyme protein.
- **B.** serve as Lewis acids in enzymes.
- **C.** participate in oxidation-reduction processes.
- **D.** stabilize the active conformation of an enzyme.
- **E.** form chelates with the substrate, with the chelate being the true substrate.

4. An enzyme can facilitate the rate of a reaction by
- **A.** stabilizing the transition state.
- **B.** binding very tightly to the substrate.
- **C.** binding very tightly to the product.
- **D.** preventing the substrate from changing its ionic state.
- **E.** preventing the reaction from proceeding in the reverse direction.

5. In the reaction sequence, below the best point for controlling production of Compound 6 is reaction



A. A **B.** B **C.** C **D.** D **E.** E

6. Turnover number (k_{cat})
- **A.** is a ratio of the rate constants for the formation of ES and of product.
- **B.** has units of 1/time.
- **C.** is inversely related to how fast the reaction is.
- **D.** for a mutant enzyme can change without any change in the K_m of the reaction.
- **E.** has units of substrate concentration.

Questions 7 and 8: A man of Japanese ancestry found himself to be experiencing severe flushing and a very rapid heart rate after consuming one alcoholic beverage. His companion, a Caucasian male, did not have the same symptoms even though he had finished his second drink. These physiological effects are related to the presence of acetaldehyde (CH_3CHO) generated from the alcohol. Acetaldehyde is normally removed by the reaction of mitochondrial aldehyde dehydrogenase which catalyzes the reaction

$$CH_3CHO + NAD^+ \rightleftharpoons CH_3COO^- + NADH + H^+$$

7. Acetaldehyde dehydrogenase is a(n)
- **A.** oxidoreductase.
- **B.** transferase.
- **C.** hydrolase.
- **D.** lyase.
- **E.** ligase.

8. The explanation for the difference in physiological effects is that the Japanese man was missing the normal mitochondrial aldehyde dehydrogenase and had only a cytosolic isozyme. The cytosolic isozyme
- **A.** does not react with CH_3CHO.
- **B.** activates the enzyme that produces CH_3CHO.
- **C.** differs from the mitochondrial enzyme in that it has a higher K_m for CH_3CHO.
- **D.** would be expected to have a greater affinity for the substrate than the mitochondrial enzyme.
- **E.** produces a low steady-state level of acetaldehyde following alcohol consumption.

Question 9 and 10: A research technician who is working with organophosphate compounds is required to have a weekly blood test for acetylcholine esterase activity. Typically, esterase activity remains relatively constant for some time and then abruptly drops to zero. If this happens, the technician must immediately stop working with the organophosphate compounds. The organophosphate compounds form stable esters with a critical serine hydroxyl group in the esterase.

9. In the esterase, serine transfers a proton to a histidine residue. Which of the following is correct?
- **A.** Serine is acting as a general acid.
- **B.** Histidine is acting as a general acid.
- **C.** Serine and histidine form a covalent intermediate.
- **D.** The enzyme would be relatively insensitive to pH changes.
- **E.** Serine is acting as a transition stabilization catalyst.

10. Organophosphate compounds inactivate the esterase by
- **A.** competitive inhibition.
- **B.** uncompetitive inhibition.
- **C.** noncompetitive inhibition.
- **D.** suicide inhibition.
- **E.** irreversible inhibition.

Questions 11 and 12: Gout is a disease in which uric acid is high in blood and urine. One patient who excreted three times normal uric acid had very high blood levels of PRPP, an intermediate in biosynthesis of AMP and GMP, which are precursors of ATP and GTP. Degradation of these products produces uric acid. The patient's PRPP synthetase had normal K_m and V_{max} values but was insensitive to regulation by the end products of the pathway (ATP, GTP). These are negative allosteric modifiers of PRPP synthetase.

11. All of the following statements about allosteric effectors are correct except they
- **A.** may increase the enzyme's affinity for its substrate.
- **B.** may decrease the enzyme's affinity for its substrate.
- **C.** bind at the substrate binding site.
- **D.** cause a conformational change in the enzyme.
- **E.** can change either the K_m or the V_{max} of the reaction.

12. Most allosteric enzymes
- **A.** are monomers.
- **B.** have more then one subunit.
- **C.** exhibit only homotropic interactions.
- **D.** exhibit only heterotropic interactions.
- **E.** bind the allosteric effector with no effect on binding other ligands.

Problems

13. An experiment measuring velocity versus substrate concentration was run, first in the absence of substance A and then in the presence of substance A. The following data was obtained:

[S] μM	*Velocity in absence of A μ mol/min*	*Velocity in presence of A μ mol/min*
2.5	0.32	0.20
3.3	0.40	0.26
5.0	0.52	0.36
10.0	0.69	0.56

Is substance A an activator or an inhibitor? If it is an inhibitor, what kind of inhibitor is it?

14. For the experiment in problem 13, calculate the K_m and V_{max} both in the absence and in the presence of substance A. Are these results consistent with your answer for problem 13?

Answers

1. **E** The active site contains all of the machinery, including the amino acid side chains, involved in catalyzing the reaction. A–D are all possible, but none is necessarily true.
2. **C** A catalyst lowers the energy of the transition state, thus speeding the rate of its formation. A: Heat of formation is the energy to form reactants or products. B: K_{eq} is governed by heats of formation which are constant in a reaction. D: This is determined by the number of reactants. E: ΔG_0 is related to the difference in heats of formation of reactants and products—a constant.
3. **A** Metal cations are electron deficient and may accept electron pairs, serving as Lewis acids, but they do not donate electrons to other functional groups. C: On the contrary, they sometimes accept electron pairs from groups in amino acid side chains. D: In doing so, they may become chelated that may stabilize the appropriate structure. E: Sometimes they are chelated by the substrate, with the chelate being the true substrate.
4. **A** Residues in the enzyme interact with the substrate while it is in the transition state, lowering the energy of activation. B: This would require more energy to reach the transition state. C: It would be difficult for the product to dissociate. D: A key to many reactions is for the enzyme to add or remove protons from the substrate to make the substrate more or less nucleophilic. E: Catalysis is reversible although thermodynamic considerations may make some reactions appear irreversible.
5. **D** Reaction D is irreversible; if it were not controlled, Cpd 5 might build up to toxic levels. A: Control of reaction A would control production of both Cpds 3 and 6. B: Reaction B is not on the direct route. C and E: Reactions C and E are freely reversible, so do not need to be controlled.
6. **B** This is the number of molecules of substrate converted per unit time per molecule of enzyme. A and E: These refer to the K_m. C: The higher the k_{cat}, the faster the reaction. D: k_{cat}/K_m is equal to K_{eq}, so they must both change to maintain the equilibrium.
7. **A** Aldehyde-to-acid conversion is an oxidation. This is of the subclass dehydrogenases as indicated by the presence of the NAD^+.
8. **C** The lower affinity (higher K_m) makes it more difficult for the enzyme to remove CH_3CHO. A: Isozymes, by definition, catalyze the same reaction. B: It is highly unlikely that one enzyme would activate another enzyme. D: With a greater affinity (lower K_m), the reaction would be occurring at a rapid rate, thus removing CH_3CHO. E: These effects are due to a high steady-state concentration.
9. **A** Acids donate protons. General acids are weakly ionized at physiological pH. The environment of the serine in the protein facilitates its ability to transfer a proton and thus act as a nucleophile. B: Bases accept protons. C: No covalent bonds are formed. D: The ability of histidine to accept a proton is very pH dependent. E: This is not likely.
10. **E** The phosphate ester does not dissociate and the enzyme is not restored. A, B, and C: These types of inhibitors bind to the enzyme and/or enzyme substrate complex reversibly. D: A suicide inhibitor is formed from the substrate and remains covalently attached to the enzyme. Organophosphates are not substrates for the esterase.
11. **C** "*Allo*" means other. A and B: Allosteric effectors may be either positive or negative. D: This alters the affinity for the substrate. E: K class alters K_m and V class alters V_{max}.
12. **B** Most are oligomers. A: Only two monomeric allosteric enzymes are known. C and D: Both homotropic and heterotropic interactions are common. E: The principle of allosterism is that binding one ligand affects binding of other ligands.
13. Take the reciprocals of both [S] and v and construct a Lineweaver–Burke plot. You should find that the two curves cross the y-axis at the same point but the curve in the presence of A crosses the x-axis closer to the origin. This pattern indicates that A is a competitive inhibitor.
14.

	$-1/K_m$	K_m	$1/V_{max}$	V_{max}
Absence of A	–0.14	7.1	0.8	1.25
Presence of A	–0.08	12.5	0.8	1.25

With a competitive inhibitor, the V_{max} remains constant (be sure you understand why) but the apparent K_m is larger. It takes more substrate to reach a given velocity because the substrate has to compete with the inhibitor.

Key Concepts

- Cytochromes P450 catalyze incorporation of an oxygen atom into both natural substrates and foreign compounds. They contain heme (iron porphoryrin IX); the iron is reduced by electrons donated by a reductase containing FAD or FMN. Their spectrum derives from the fifth axial ligand of the heme iron to a cysteine residue in each of the proteins.

- The oxygenation of steroids produces regiospecific and stereospecific products that are essential for sexual differentiation (androgens and estrogens) and for metabolic and electrolyte balance (corticosteroids and mineralocorticoids).
- Some cytochromes P450 have less substrate specificity and metabolize exogenous compounds, to produce more polar products for elimination. Some products are more toxic than the original substrate but subsequent metabolism negates these effects. Most drugs are metabolized by several specific cytochromes P450 in the endoplasmic reticulum. Drug–drug interactions occur frequently.
- Some cytochromes P450 can be induced while others are constitutive. There are 57 human cytochromes P450; 50 occur in the endoplasmic reticulum and require NADPH-cytochrome P450 reductase.
- Mitochondrial hydroxylation of steroids requires electrons supplied from NADPH through a FAD-containing reductase to an iron-sulfur protein, adrenodoxin, and finally to cytochrome P450.
- Genetic polymorphisms have been demonstrated in the human population in both cytochromes P450 and NADPH-cytochrome P450 reductase. Mutations can result in reduced metabolism of drugs and abnormal sex steroid metabolism.
- Nitric oxide (NO) is a signaling molecule produced through monooxygenation catalyzed by nitric oxide synthases (NOSs), which contain FAD, FMN, and heme bound in a single molecule that functions as a homodimer. NO is derived from the guanidino group of L-arginine and *N*-hydroxy-L-arginine is an intermediate in the reaction.
- NOSs are composed of two distinct domains, one containing FAD and FMN, and the other heme, connected by a calmodulin binding sequence. Binding of Ca^{+2}-calmodulin is required for electron transfer between the domains. Tetrahydrobiopterin and Zn are also required.
- NOSs are encoded by three genes producing NOSI (neuronal NOS), NOSII (inducible NOS) and NOSIII (endothelial NOS). NOSI is constitutively expressed primarily in skeletal muscle and neurons of the central and peripheral nervous system. It is activated by binding of calmodulin and the NO produced acts as a neurotransmitter and modulator of muscular contractility.
- NOSII is primarily in neutrophils, macrophages, astrocytes, and hepatocytes. It is induced by cytokines; calmodulin is bound under basal physiological conditions. NOSII functions in the early immune response, producing NO as a cytotoxic agent against pathogens.
- NOS III is primarily in vascular endothelial cells, attached to the caveolar membrane through myristoyl and palmitoyl residues. It is constitutively expressed and activated by Ca^{2+}. NOSIII produces NO as a vasodilator, which acts on guanylate cyclase in adjacent smooth muscle cells, ultimately leading to vasorelaxation.

11.1 • INTRODUCTION

Cytochromes P450 constitute a unique family of heme proteins, present in bacteria, fungi, insects, plants, fish, mammals, and primates that catalyze the monooxygenation (i.e., insertion of one atom of molecular oxygen) of a large variety of structurally diverse compounds. Substrates for this enzyme system include both endogenously synthesized compounds, such as cholesterol, steroid hormones, and fatty acids, and exogenous compounds, such as drugs, food additives, components of cigarette smoke, pesticides, and chemicals, that are ingested, inhaled, or absorbed through the skin. The cytochromes P450 are involved in (1) production of steroid hormones; (2) metabolism of fatty acids, prostaglandins, leukotrienes, and retinoids; (3) inactivation or activation of therapeutic agents; (4) conversion of chemicals to highly reactive molecules that may produce unwanted cellular damage; and (5) enzyme inhibition or induction resulting in drug–drug interactions and adverse effects.

The nitric oxide synthases are bidomain enzymes, consisting of a heme-containing (or oxygenase) domain and a flavin-containing (or reductase) domain. These enzymes catalyze the formation of nitric oxide, a highly reactive gaseous free radical molecule that functions in neurotransmission, hemodynamic regulation, or in the immune response, depending on the tissue in which it is produced. Like the cytochromes P450, nitric oxide synthases are heme-containing enzymes that catalyze the monooxygenation of their substrates using similar catalytic mechanisms. The following will discuss both the cytochromes P450 and the nitric oxide synthases in detail, addressing both the similarities and differences between the two systems.

11.2 • CYTOCHROMES P450: PROPERTIES AND FUNCTION

Cytochromes P450 are integral membrane proteins containing a single iron protoporphyrin IX (heme) prosthetic group (p. 791). The heme iron of cytochromes P450 is capable of forming six bonds, four to each of the four pyrrole nitrogen atoms of the porphyrin ring and two to axial ligands. One of the axial (so-called proximal) ligands is a sulfhydryl group

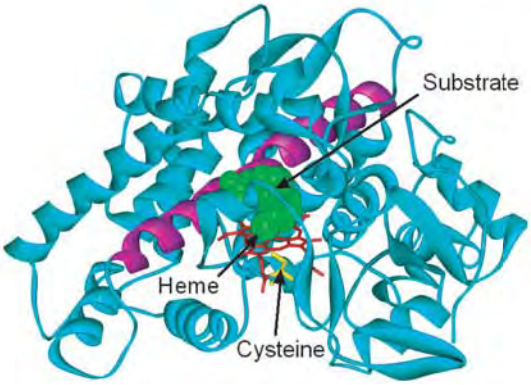

Figure 11.1 Model of the active site of mammalian CYP2C5 showing the protoporphyrin IX prosthetic group (red) with the cysteine thiolate ligand (yellow) attached to the heme iron. The substrate diclofenac, a nonsteroidal anti-inflammatory drug (green), is in the active site of the P450. The I-helix (purple) spans the molecule and is one of the most easily identifiable structural characteristics of cytochromes P450.
Generated from Protein Data Bank file 1NR6, deposited by M. R. Wester, E. F. Johnson, and C. D. Stout, using WebLab Viewer Lite (Molecular Simulations, Inc.).

from a cysteine residue located toward the carboxyl end of the cytochrome P450 molecule (Figure 11.1) and the other (distal) ligand-binding site can be open (producing a penta-coordinated, high-spin heme) or occupied by oxygen, CO, NO, water, or other ligand (producing a hexa-coordinated, low-spin heme). The spin state of the heme is a description of the occupancy of the *d*-electronic shells within the iron atom determined by the ligand state; these can be distinguished spectroscopically.

All cytochromes P450 are triangle-shaped molecules, closely resembling that shown in Figure 11.1. Half of the enzyme consists of α-helical structure and the other half is β-sheet and other structures; a long I-helix runs throughout the enzyme behind the heme. This basic scaffolding is conserved among all known cytochromes P450, although relative placement may differ and some of the minor elements may be missing. The mammalian proteins contain an N-terminal membrane anchor sequence and internal membrane association sequences that result in these proteins being deeply buried in the membrane.

Cytochromes P450 are so called because of the unique absorbance spectrum that is produced when CO is bound to the reduced, ferrous form of the heme. The spectrum exhibits a peak at approximately 450 nm (Figure 11.2); thus the name P450 for a **p**igment with an absorbance at **450** nm. This spectrum is characteristic of a heme thiolate-liganded protein. Much as with the heme iron of hemoglobin, CO binds to the heme iron of cytochromes P450 with a much higher binding affinity than oxygen and thereby is a potent inhibitor of its function.

The general reaction catalyzed by a cytochrome P450 is

$$NADPH + H^+ + O_2 + SH \rightarrow NADP^+ + H_2O + SOH$$

where NADPH is a two-electron donor and the substrate (S) may be a steroid, fatty acid, drug, or other chemical that has an alkane, alkene, aromatic ring, or heterocyclic ring substituent that can serve as a site for oxygenation. The reaction is a monooxygenation, and the enzyme is a monooxygenase as it incorporates only one of the two oxygen atoms into the substrate.

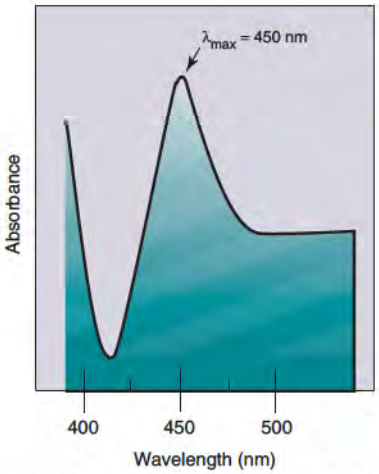

Figure 11.2 The absorbance spectrum of the carbon monoxide–bound cytochrome P450. The reduced form of cytochrome P450 binds carbon monoxide to produce a maximum absorbance at approximately 450 nm.

11.3 • CYTOCHROMES P450 ELECTRON TRANSPORT SYSTEMS

The two electrons required for the overall monooxygenase reaction are provided by NADPH, but a basic mechanistic problem is created in that NADPH is a two-electron donor (p. 562). Cytochrome P450, with its single heme iron, can accept only one electron at a time. This problem is solved by the presence of a NADPH-dependent flavoprotein reductase, which accepts two electrons from NADPH simultaneously but transfers the electrons individually, either to an intermediate iron–sulfur protein or directly to cytochrome P450. The active redox group of the flavoprotein is the isoalloxazine ring, which is uniquely suited to perform this chemical task since it can exist in fully

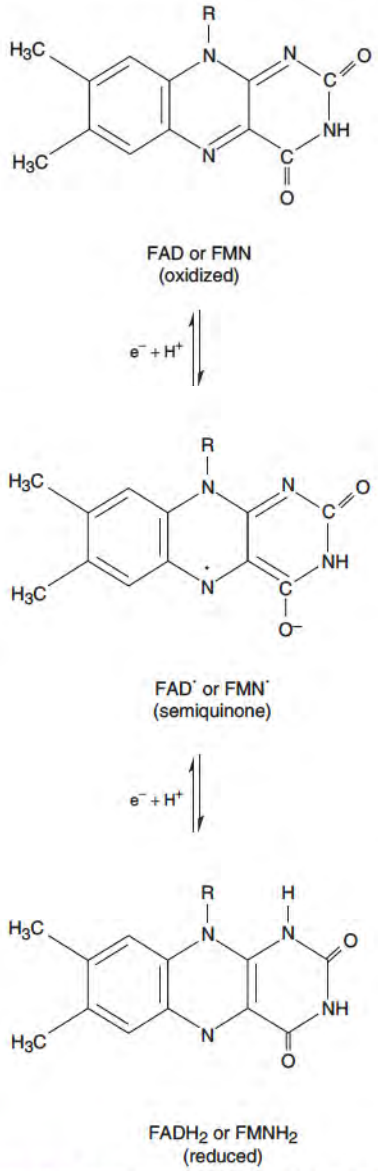

Figure 11.3 Isoalloxazine ring of FMN or FAD in its oxidized, semiquinone (1e⁻-reduced form), or fully reduced (2e⁻-reduced) state.

oxidized or one- or two-electron reduced states (Figure 11.3). The transfer of electrons from NADPH to cytochromes P450 is accomplished by distinct electron transport systems present exclusively in either mitochondria or endoplasmic reticulum (microsomes).

NADPH-Cytochrome P450 Reductase Is the Obligatory Flavoprotein Electron Donor in the Endoplasmic Reticulum

Most mammalian cytochromes P450 are found deeply embedded in the cytoplasmic side of the endoplasmic reticulum (microsomal fraction) of hepatocytes, renal and adrenal cortical cells, ovarian and testicular cells, and cells of the respiratory tract, among others. Fifty of the 57 human cytochrome P450 isoforms are of the microsomal type. These cytochromes P450 use a single NADPH-cytochrome P450 reductase, a peripheral membrane protein of 76.6 kD containing both flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN) as prosthetic groups, for electron delivery. The crystal structure of the human isoform is shown in Figure 11.4. Until the characterization of nitric oxide synthases, the P450 reductase was the only mammalian flavoprotein known to contain both FAD and FMN. NADPH donates electrons to the FAD moiety of P450 reductase and the FMN serves as the exit flavin, transferring two electrons, one at a time, to cytochrome P450. Because a single flavin molecule may exist as a one- or two-electron-reduced form and two flavin molecules are bound per reductase molecule, the enzyme may receive electrons from NADPH and store them between the two flavin molecules before transferring them to one of the numerous microsomal cytochromes P450 (Figure 11.5).

The overall mechanism by which cytochromes P450 catalyze the monooxygenation of their substrates is shown in Figure 11.6. The reaction cycle is initiated by the binding of substrate to the native, low-spin, hexa-coordinate, ferric form of the heme, converting it to a high-spin, penta-coordinate ferric heme. The first electron can be transferred to the heme, reducing it to the high-spin, penta-coordinate ferrous form only after substrate has been bound. Electrons cannot be transferred to the heme in the absence of substrate because the reduction potential of the heme (−300 V) in that state is more electronegative than that of the FMN moiety (−270 mV), making such a transfer thermodynamically unfavorable. Upon substrate binding, there is a conformational change of the protein structure surrounding the heme iron, and the reduction potential of the heme becomes more positive (−230 mV), thus allowing the P450 heme iron to be reduced (Figure 11.6).

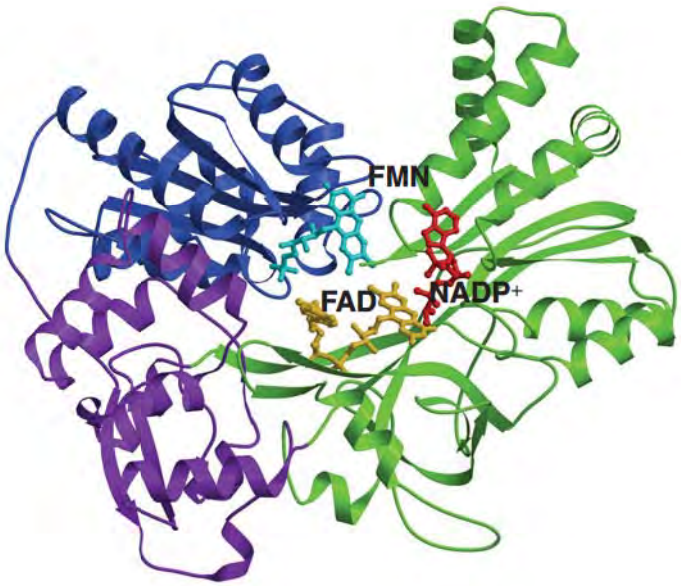

Figure 11.4 Ribbon diagram of human cytochrome P450 reductase based on its crystal structure. Three domains are present: the FMN-binding domain (blue), the FAD/NADPH-binding domain (green), and the intervening connecting domain (purple). Cofactors are shown in stick-and-ball models: blue, FMN; yellow, FAD; and red, $NADP^+$. The figure was rendered using the program Molscript (Kraulis, P. J. Molscript: A program to produce both detailed and schematic plots of protein structures. *J. Appl. Cryst.* 24:946, 1991). Generously supplied by Dr. Jung-Ja P. Kim, Professor of Biochemistry, Medical College of Wisconsin, before publication.

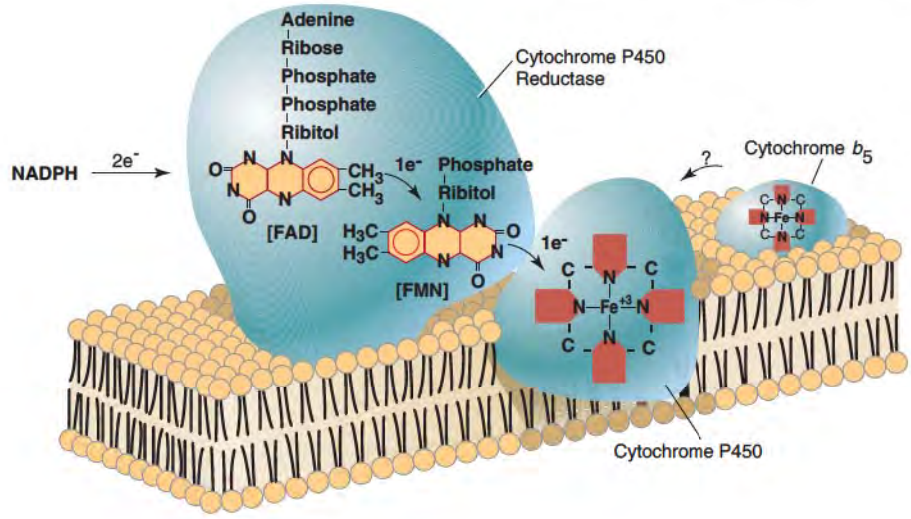

Figure 11.5 Components of the endoplasmic reticulum (microsomal) cytochrome P450 system. NADPH-cytochrome P450 reductase is bound by its hydrophobic tail to the membrane (a peripheral protein) whereas cytochrome P450 is deeply embedded in the membrane (an integral protein). Also shown is cytochrome b_5, which may participate in selected cytochrome P450-mediated reactions.

FAD	–290
FMN	–270
P450 heme	–300
P450 heme + substrate	–230

Figure 11.6 Reaction cycle of cytochrome P450. Diagram shows the binding of substrate, transfer of the first and second electrons from NADPH-cytochrome P450 reductase, and binding of O_2. The reduction potentials of the various components are also shown.

Oxygen can now bind to the ferrous heme and the second electron transfer is facilitated. Subsequently, molecular oxygen is activated and cleaved; one atom is inserted into the substrate (monooxygenation), and the other combines with two protons and two electrons to form H_20.

The binding of the P450 and reductase to one another is electrostatic rather than hydrophobic, and P450 levels exceed those of reductase in liver by a 10:1 to 20:1 ratio. If a particular P450 has a higher affinity for association with reductase, electrons will flow preferentially to those P450s. Consequently, P450s with lower affinities must have mechanisms that allow them to receive electrons. In some cases, the binding of substrate increases both the affinity and the rate of association of the P450/reductase complex; this mechanism makes sense as an "empty" P450 monopolizing the reductase would be non-productive.

In some reactions, transfer of the second electron may not be directly from the P450 reductase, but may occur from cytochrome b_5, a small heme protein (15.2 kDa) that can be reduced by either the P450 reductase or another microsome-bound flavoprotein, NADH-cytochrome b_5 reductase. Some reactions catalyzed by specific cytochromes P450 require cytochrome b_5 for optimal enzymatic activity possibly because cytochrome b_5: (1) alters the affinity of the P450/reductase interaction, (2) alters the affinity of the P450 for a particular substrate, or (3) increases the rate of transfer of the second electron to the P450 heme.

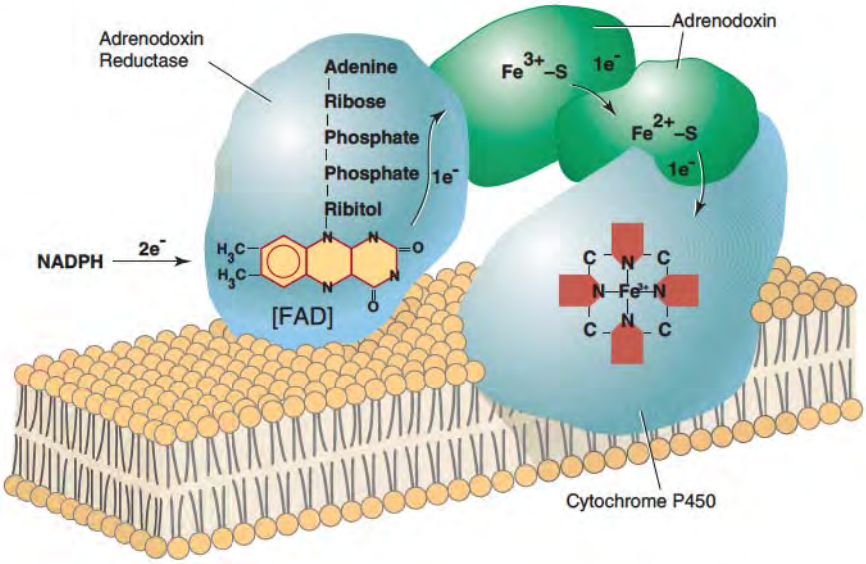

Figure 11.7 Components of mitochondrial cytochrome P450 system. Cytochrome P450 is an integral protein of the inner mitochondrial membrane. NADPH-adrenodoxin reductase and adrenodoxin are peripheral proteins, not embedded in the membrane.

NADPH-Adrenodoxin Reductase Is the Flavoprotein Electron Donor in Mitochondria

The mitochondrial cytochromes P450 are found in the inner membrane of mitochondria and are involved in steroid hydroxylation reactions. Seven of the 57 human isoforms are of this type. This electron transfer system requires two additional proteins, the NADPH-adrenodoxin reductase (51 kD), which contains a single FAD prosthetic group, and adrenodoxin, a 12.5 kD iron–sulfur protein, for product formation (Figure 11.7). Adrenodoxin reductase is only weakly associated with the inner mitochondrial membrane and cannot directly transfer either the first or second electron to the heme iron of cytochrome P450. A second protein, adrenodoxin, which is also weakly associated with the inner mitochondrial membrane, contains an iron–sulfur cluster that serves as a redox center for this molecule and functions as an electron shuttle between the FAD of adrenodoxin reductase and the heme iron of a mitochondrial cytochrome P450. One adrenodoxin molecule receives an electron from its mitochondrial flavoprotein reductase and interacts with a second adrenodoxin, which then transfers its electron to a specific cytochrome P450. Components of the mitochondrial cytochrome P450 system are synthesized in the cytosol as larger molecular weight precursors, transported into mitochondria, and processed by proteases into smaller molecular weight, mature proteins.

11.4 • CYTOCHROMES P450: NOMENCLATURE AND ISOFORMS

Because of the large number of cytochromes P450 that have been identified (over 7000, as of February 2008), a system for classification of the enzymes into functional groups and nomenclature had to be developed. The system chosen is based on classification according to the relative identity of the amino acid sequences of the enzymes. The superfamily of cytochromes P450 is thus divided initially into families in which the amino acid sequence identity of the members is greater than 40%. The family is designated by the prefix "CYP", for cytochrome P450, followed by an Arabic numeral (e.g., CYP1, CYP2, CYP3, etc.) The families are further divided into subfamilies in which the amino acid sequence identity of the members is greater than 55%. The subfamily is identified by an additional capital letter (e.g., CYP1A, CYP1B, CYP1C, etc.). The individual members of each subfamily are then numbered in the order in which they were identified (e.g., CYP1A1, CYP1A2, CYP1A3, etc.). Although cytochromes P450 are enzymes, the term *isoenzyme* or *isozymes* is generally not used to describe these proteins; rather, the term *form* or *isoform* is used.

Tables 11.1 and 11.2 list the known human P450 isoforms. There are 57 isoforms split into 18 families and 41 subfamilies. The human genome also encodes for 58 CYP pseudogenes

TABLE 11.1 • Human Cytochromes P450 Involved in Exogenous Metabolism

that do not form active protein. Table 11.1 lists the isoforms that utilize primarily exogenous compounds, that is, drugs and xenobiotics; these isoforms each metabolize a wide variety of substrates. Table 11.2 lists the isoforms involved in metabolism of endogenous compounds; these isoforms generally recognize only one or two specific substrates and these are listed in the table.

11.5 • CYTOCHROMES P450: SUBSTRATES AND PHYSIOLOGICAL FUNCTIONS

Cytochromes P450 metabolize a variety of lipophilic compounds of endogenous or exogenous origin. As shown in Figure 11.8 (p. 433), cytochromes P450 may catalyze hydroxylation of the carbon atom of a methyl group, the methylene carbon of an alkane, hydroxylation of an aromatic ring to form a phenol, or addition of an oxygen atom across a double bond to form an epoxide. They may also catalyze dealkylation reactions in which alkyl groups attached to oxygen, nitrogen, or sulfur atoms are removed. Oxidation of nitrogen, sulfur, and phosphorus atoms and dehalogenation reactions are also catalyzed by cytochrome P450 forms.

Both endogenous and exogenous substrates are metabolized by the cytochromes P450. Endogenous substrates include cholesterol, steroids, prostaglandins, and fatty acids. In these cases, the reactions are more stereo- and regiospecific and the cytochromes P450 bind only specific substrates. Exogenous substrates (*xenobiotics,* meaning "foreign to life") include many drugs, chemicals, environmental contaminants, and food additives. Cytochromes P450 in this group are less discriminating among substrates and oxidize these primarily lipophilic (hydrophobic) compounds to make them more water soluble (hydrophilic) for excretion.

TABLE 11.2 • Human Cytochromes P450 Involved in Endogenous Metabolism

CYP Family	*Isoforms*	*Substrate(s)*	*Activity*

51	51A1	Lanosterol	14-α-Demethylase

Cytochromes P450 Participate in the Synthesis of Steroid Hormones and Oxygenation of Endogenous Compounds

The importance of cytochrome P450-catalyzed reactions with endogenous substrates is illustrated by the synthesis of steroid hormones from cholesterol in the adrenal cortex and sex organs. Both mitochondrial and microsomal (endoplasmic reticulum) cytochrome P450 systems are required to convert cholesterol to aldosterone and cortisol in adrenal cortex, testosterone in testes, and estradiol in ovaries.

Cytochromes P450 are responsible for several steps in the adrenal synthesis of aldosterone, the mineralocorticoid responsible for regulating salt and water balance, and cortisol, the glucocorticoid that governs protein, carbohydrate, and lipid metabolism. In addition, adrenal cytochromes P450 catalyze the synthesis of small quantities of the androgen androstenedione, a regulator of secondary sex characteristics and a precursor of both estrogens and testosterone. Figure 11.9 presents a summary of these pathways.

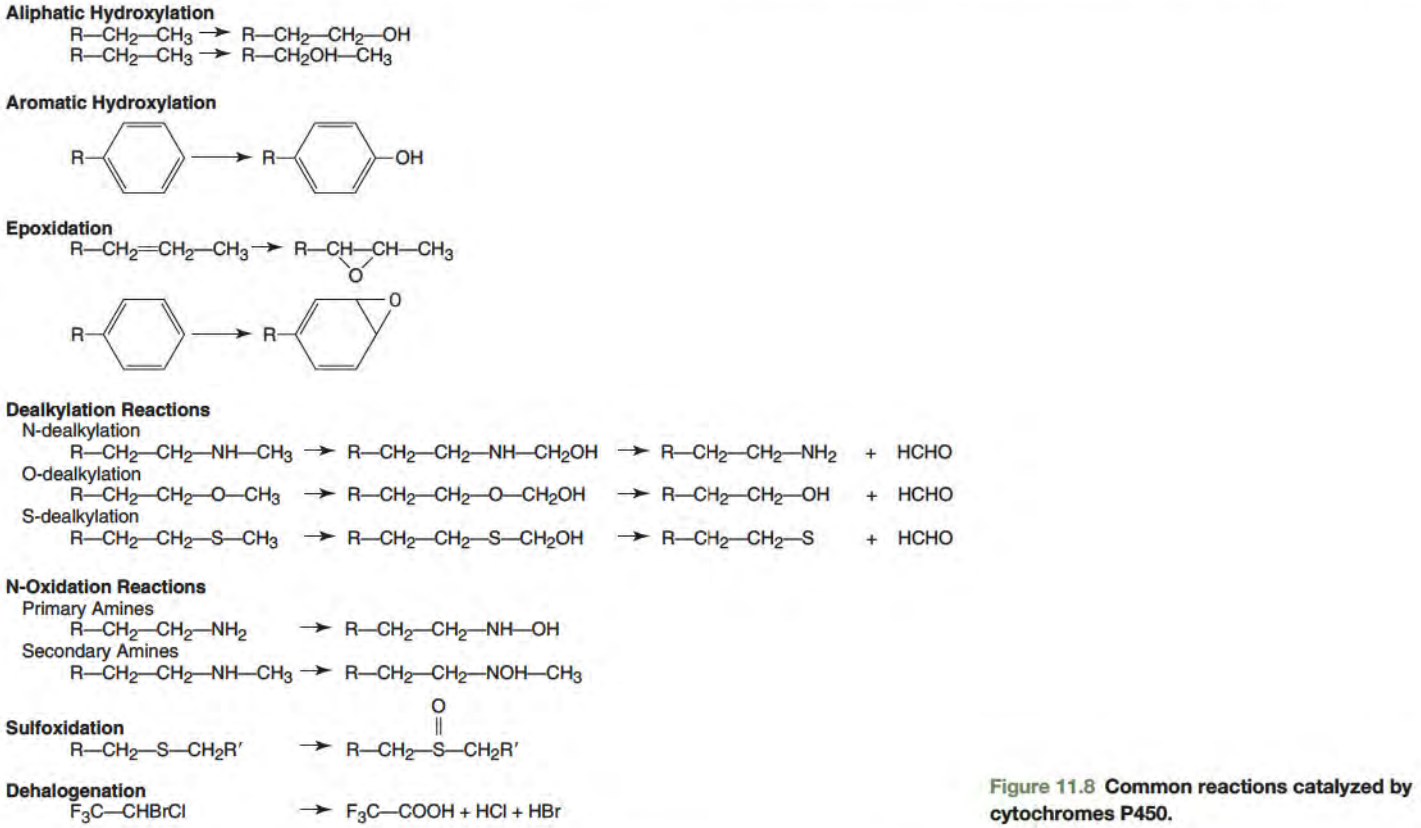

Figure 11.8 Common reactions catalyzed by cytochromes P450.

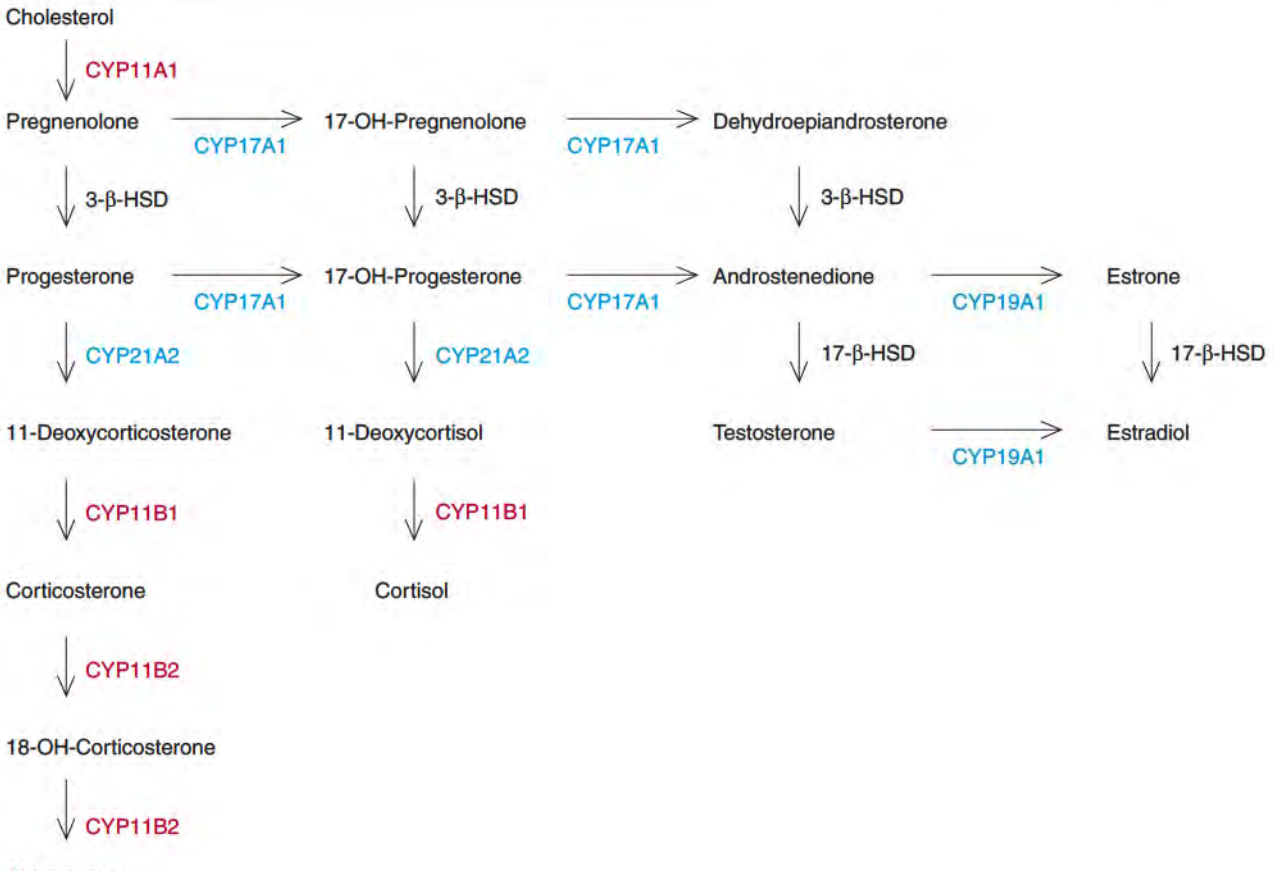

Figure 11.9 Steroid hormone synthesis in the adrenal gland. The cytochromes P450 involved are CYPs 11A1, 11B1, and 11B2 in the mitochondria (red) and CYPs 17A1, 19A1, and 21A2 in the endoplasmic reticulum (blue). The other enzymes shown, 3-β-HSD and 17-β-HSD, are hydroxysteroid dehydrogenases.

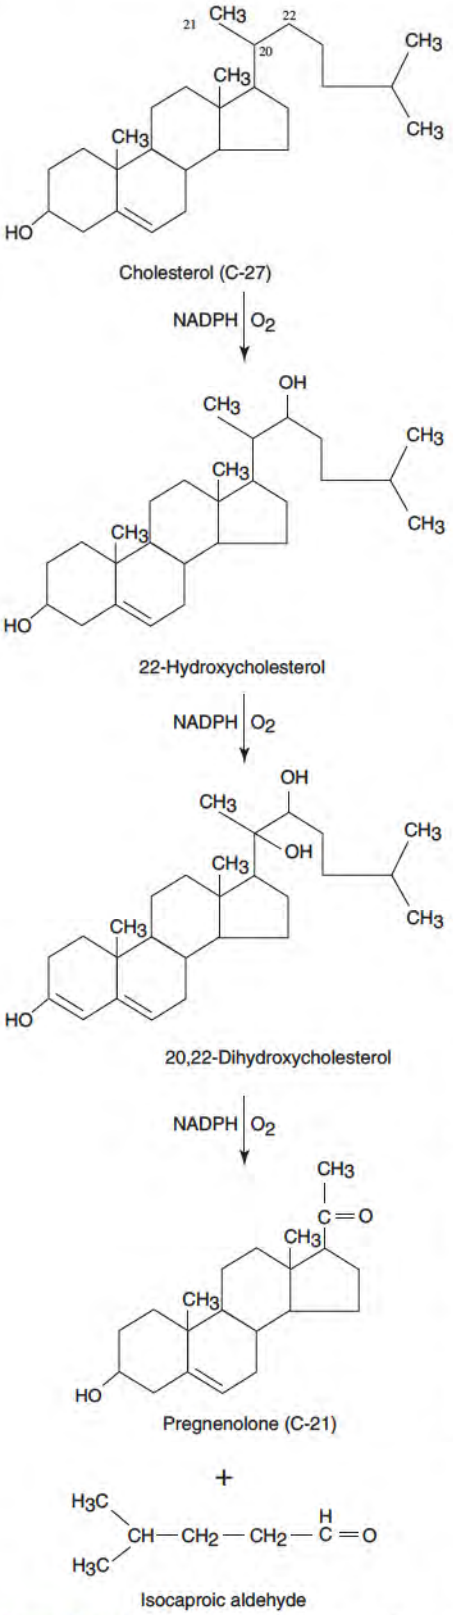

Figure 11.10 Side chain cleavage reaction of cholesterol. Three sequential reactions are catalyzed by CYP11A1 to produce pregnenolone and isocaproic aldehyde.

In adrenal mitochondria, a cytochrome P450 (CYP11A1) catalyzes the side chain cleavage reaction converting cholesterol to pregnenolone, a committed step in steroid biosynthesis. This reaction involves sequential hydroxylation at carbon atoms 22 and 20 to produce 22-hydroxycholesterol and then 20, 22-dihydroxycholesterol, respectively (Figure 11.10). CYP11A1 then cleaves the carbon–carbon bond between C20 and C22 to produce pregnenolone, a 21-carbon steroid. This reaction sequence requires three NADPH and three O_2 molecules, and it is catalyzed completely by CYP11A1.

Pregnenolone is produced in mitochondria, but is moved to the cytosol where it is oxidized by 3-β-hydroxysteroid dehydrogenase $\Delta^{4,5}$-isomerase to progesterone. Progesterone is hydroxylated at the C21 position of the steroid nucleus to deoxycorticosterone (DOC) by the microsomal P450 CYP21A2. DOC is subsequently hydroxylated at C11 by the mitochondrial P450 CYP11B1 to form corticosterone, which can then be hydroxylated by another mitochondrial cytochrome P450 enzyme, CYP11B2, at C18 to form the mineralocorticoid aldosterone (Figure 11.9 and p. 433).

Cortisol is synthesized from either pregnenolone or progesterone beginning with the hydroxylation of C17 by microsomal P450 CYP17A1. Hydroxylation at C21 of 17α-hydroxyprogesterone by CYP21A2 produces 11-deoxycortisol, which is transported into the mitochondrion where it is further hydroxylated by CYP11B1 at C11 to form cortisol (Figure 11.9, p. 433). Congenital deficiencies resulting from mutations in the gene that codes for CYP21A2 are discussed in Clin. Corr. 11.1.

Synthesis of steroids containing 19 carbon atoms from 7α-hydroxypregnenolone or 17α-hydroxyprogesterone proceeds with the loss of the acetyl group at C17. This deacetylation reaction is catalyzed by CYP17A1 (via a 17,20-lyase reaction), the same cytochrome P450 that hydroxylates steroids at C17. The factors that determine whether this cytochrome P450 performs only a single hydroxylation step to produce the 17-hydroxy product or proceeds further to cleave the C17–C20 bond have not been determined, although the presence of cytochrome b_5 in gonadal tissues appears to allow CYP17A1 to catalyze the cleavage reaction. The products formed after removal of the acetyl group are dehydroepiandrosterone (DHEA) from 17α-hydroxypregnenolone or androstenedione from 17α-hydroxyprogesterone. DHEA may be dehydrogenated at the 3-OH group to androstenedione, a potent androgenic steroid that serves as the immediate precursor of testosterone.

The estrogens are synthesized from the androgens in a reaction called aromatization because an aromatic ring is produced in ring A of the steroid product. In this complex reaction, multiple hydroxylation reactions are catalyzed by a single cytochrome P450 enzyme, CYP19A1 or aromatase, to form the aromatic ring with removal of the methyl group at C19. Figure 11.11, p. 436, details the aromatization reaction. Two sequential hydroxylation reactions at the methyl C19 result in the introduction of an aldehyde group. The final step may involve a peroxidative attack at C19 with the loss of the methyl group and elimination of the hydrogen atom to produce the aromatic ring. All three hydroxylation reactions are catalyzed by CYP19A1. The complexity of steroid hormone production during pregnancy and the role of P450 forms are illustrated in Clin. Corr. 11.2.

Cytochromes P450 also metabolize other endogenous compounds that are involved in physiological processes and thus regulate their activity. For example, arachidonic acid is metabolized by cytochromes P450 to form 19- and 20-hydroxyeicosatetraenoic acids (HETEs), epoxyeicosatetraenoic acids (EETs), and dihydroxyeicosatetraenoic acids (DiHETEs). These metabolites function in the regulation of vascular, renal, pulmonary, and cardiac systems and in inflammatory and growth responses. 20-HETE, formed by the metabolism of arachidonic acid by CYP4As and CYP4Fs in humans, is a potent vasoconstrictor. The EETs, formed by CYP1A, 2B, 2C, and 2J in humans, are endothelium-derived vasodilators. The CYP4As also catalyze the hydroxylation of prostaglandins and fatty acids, thus activating or inactivating these important regulatory factors.

Cytochromes P450 produce vital metabolites for maintenance of homeostasis in other systems as well. CYP7A1 catalyzes the first and rate-limiting step of bile acid synthesis in the liver (pp. 728 and 1053). In liver, CYP27B1 catalyzes the 1-hydroxylation of 25-hydroxy-vitamin D3, formed in kidney, to produce the 1,25-dihydroxy metabolite, which is the active form of this hormone, important in developing and maintaining bone

CLINICAL CORRELATION 11.1

Congenital Adrenal Hyperplasia: Deficiency of CYP21A2

The adrenal cortex, a major site of steroid hormone production during fetal and adult life, is metabolically more active in fetal life and may produce 100–200 mg of steroids per day in comparison to 20–30 mg in the nonstressed adult adrenal gland. Enzyme deficiencies have been reported at all steps of cortisol production. Diseases associated with insufficient cortisol production are referred to as congenital adrenal hyperplasias (CAH). The most common enzyme deficiency in CAH is in CYP21A2, a 21-hydroxylase, resulting in the failure to metabolize 17α-hydroxyprogesterone to 11-deoxycortisol, which is converted by CYP11B1 to cortisol. Because there is not enough cortisol, secretion of ACTH, the pituitary hormone that regulates production of cortisol, increases. Prolonged periods of elevated ACTH levels cause adrenal hyperplasia and an increased production of the androgenic hormones, dehydroepiandrosterone (DHEA) and androstenedione.

Clinical problems arise because the additional production of androgenic steroids causes virilization in females, precocious sex organ development in prepubertal males, or diseases related to salt imbalance because of decreased levels of aldosterone. Clinical consequences of severe 21-hydroxylase deficiency may be recognizable at birth, particularly in females, because the excessive buildup of androgenic steroids may cause obvious irregular development of their genitalia. In male newborns, a deficiency in 21-hydroxylase activity may be overlooked, because male genitalia appear normal, but there will be precocious masculinization and physical development later on. In late onset CAH, clinical symptoms may vary considerably from early development of pubic hair, early fusion of epiphyseal growth plates causing premature cessation of growth, or male baldness patterns in females.

Donohoue, P. A., Parker, K. and Migeon, C. J. Congenital adrenal hyperplasia. In Scriver, C. S.,, Beaudet, A. L., Sly, W. S., and Valle, D. (Eds.), *The Metabolic and Molecular Bases of Inherited Disease*. New York; McGraw Hill, 7th ed., Vol. 2, 1995, Chap. 94, 2929; and White, P. C. and Speiser, P. W. Congenital adrenal hyperplasia due to 21-hydroxylase deficiency. *Endocrine Reviews* 21: 245, 2000.

CLINICAL CORRELATION 11.2

Steroid Hormone Production during Pregnancy

Cytochromes P450 play a major role in estrogen synthesis. During pregnancy, a unique interaction among cytochromes P450 in different organs is needed to synthesize the large quantities that are required. Steroid hormone production increases dramatically and, at term, reaches 15–20 mg of estradiol, 50–100 mg of estriol, and approximately 250 mg of progesterone per day, amounts that are 1000 times greater than those produced by premenopausal, nonpregnant women.

The corpus luteum of the ovary is the major site for estrogen production in the first few weeks of pregnancy, but at approximately 4 weeks of gestation, the placenta begins synthesizing and secreting progesterone and estrogens. After 8 weeks of gestation, the placenta becomes the dominant source of progesterone. The human placenta lacks CYP17, which catalyzes both the 17α-hydroxylation reaction and the cleavage of the C17–C20 bond and thus cannot synthesize estrogens from cholesterol. The placenta, however, can catalyze the side-chain cleavage reaction to form pregnenolone from cholesterol and oxidizes pregnenolone to progesterone, which is secreted into the maternal circulation. How then does the placenta produce estrogens if it cannot synthesize DHEA or androstenedione from progesterone? The fetal adrenal gland, a highly active steroidogenic organ, catalyzes the synthesis of DHEA from cholesterol and releases it into the fetal circulation. A large proportion of fetal DHEA is metabolized by the fetal adrenal and liver to 16α-hydroxy-DHEA, which is converted by CYP19 in the placenta to the estrogen estriol. This is an elegant demonstration of the cooperativity of the cytochrome P450-mediated hydroxylating systems in the fetal and maternal organ systems leading to the progressive formation of estrogens during gestational development.

Cunningham, F. G., MacDonald, P. C. Gant, N. F., Leveno, K. J., et al. The placental hormones. In *Williams Obstetrics*, 20th ed. East Norwalk, CT: Appleton & Lange, 1997, Chapt.6, 125.

(p. 1067), while CYP24A1 is involved in degradation or inactivation of vitamin D metabolites. In the immune system, leukotriene B4 is a polymorphonuclear leukocyte chemoattractant that is hydroxylated by CYP4F3 to the less active 20-hydroxy-leukotriene B4, vital in the inactivation of the immune response. Retinoic acid is metabolized by CYP26A1 to the 4-hydroxy derivative, which may have greater activity than retinoic acid in certain organs, where it plays a role in cell cycling and signaling. Table 11.2, p. 432, lists the human cytochromes P450 that metabolize endogenous substrates and details their substrate specificities and functions.

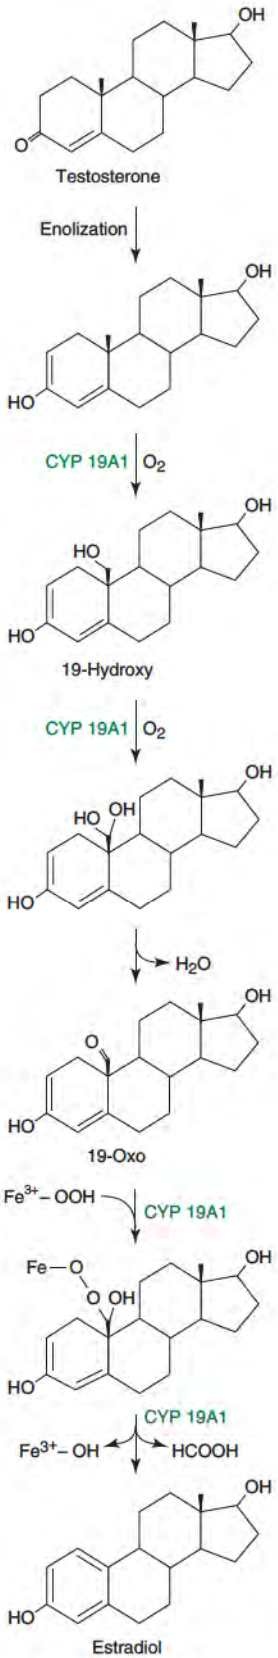

Figure 11.11 The sequence of reactions leading to the aromatization of androgens to estrogens. Adapted from Graham-Lorence, S., Amarneh, B., White R. E., Peterson, J. A., and Simpson E. R., A three dimensional model of aromatase cytochrome P450. *Protein Science* 4: 1065, 1995.

Cytochromes P450 Oxidize Exogenous Lipophilic Substrates

Exogenous substrates metabolized by cytochromes P450 include therapeutic drugs, chemicals used in the workplace, industrial byproducts that become environmental contaminants, and food additives. The human cytochromes P450 involved in xenobiotic metabolism are listed in Table 11.1, p. 431. These cytochromes P450 exhibit broad substrate specificities, oxidizing a wide variety of xenobiotics, particularly lipophilic compounds. Addition of a hydroxyl group makes the compound more polar and, therefore, more soluble in the aqueous environment of the cell. Many exogenous compounds are highly lipophilic and will accumulate within cells over time, potentially interfering with cellular function, unless they are metabolized to more hydrophilic products.

It is estimated that CYP3A4 metabolizes approximately 50% of therapeutic drugs, CYP2D6 approximately 20%, CYP2C9 and 2C19 approximately 15%, and CYP1A2, CYP2A6, CYP2B6, and others metabolize the remaining 15% of the drugs. CYP3A4 is the major drug-metabolizing P450 in the human. It is present in the gastrointestinal tract as well as the liver and is responsible for the poor oral bioavailability of many drugs. Because cytochromes P450 have such broad substrate specificities, a compound may be metabolized by more than one cytochrome P450 isoform and/or at different sites, as shown in Figure 11.12 for the compound diazepam.

Drugs and xenobiotics are metabolized primarily via two pathways, Phase I (oxidative functionalization reactions) and Phase II (biosynthetic reactions). They may be metabolized by either or both pathways. In Phase I metabolism, a functional group, such as a hydroxyl group, is introduced into or exposed on the drug by cytochromes P450 (among other enzymes; Table 11.3). The enzymes in Phase II metabolism, in many cases, then connect this functional group to an endogenous species such as glucuronic acid, sulfate, glutathione, amino acids, or acetate. The net effect of either or both of these modifications is to make the foreign compound more water soluble and thus easier to excrete, generally through

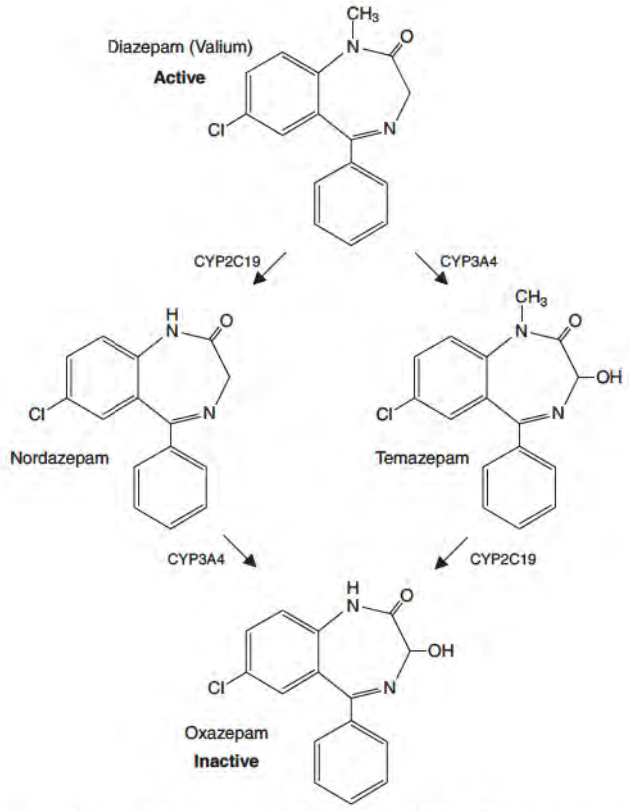

Figure 11.12 The metabolism of diazepam by CYPs 3A4 and 2C19. Diazepam may be metabolized by more than one P450. The metabolites formed from a compound will be affected by the amount of P450 forms that are expressed in tissues.

TABLE 11.3 • Xenobiotic-Metabolizing Reactions and Enzymes

Type of Reaction	*General Enzyme Name*	*General Enzymatic Reaction*
Oxidation	Dehydrogenases	Oxidation of alcohol or aldehyde groups
	Flavin-containing monooxygenases (FMO)	Oxidation of primary, secondary, and tertiary amines, nitrones, thioethers, thiocarbamates and phosphines.
	Monoamine oxidases	Removal of an amine by oxidative deamination
	Cytochrome P450	See Tables 11.1 and 11.2 and Fig. 11.7 for reactions catalyzed by P450 enzymes
Reduction	Aldehyde and ketone reductases	Reduction of carbonyl group to a hydroxyl group
	Azoreductases	Reduction of azo group to form primary amines
	Quinone reductases	Reduction of quinones to hydroquinones
Hydrolysis	Epoxide hydrolases	Addition of water to arene oxide or epoxide groups to form vicinal hydroxy groups
	Carboxylesterases Amidases	Addition of water to an ester bond Addition of water to an amide bond
Conjugation	*N*-acetyltransferases	Addition of CoA from acetyl CoA to aromatic amines or compounds containing hydrazines
	UDP-glucuronosyl transferases	Addition of glucuronic acid from uridine-5′-diphosphate (UDP)–glucuronic acid to carboxyl, phenolic, aliphatic hydroxyl, aromatic or aliphatic amines, or sulfhydryl groups
	Sulfotransferases	Addition of sulfate group from phosphoadenosyl phosphosulfate to phenolic groups, aliphatic alcohols or aromatic amines
	Methyltransferases	Addition of methyl group from S-adenosyl methionine to compounds containing phenolic, catechol, aliphatic or aromatic amines, or sulfhydryl groups
	Glutathione *S*-transferase	Conjugation of compounds containing electrophilic heteroatoms, nitrenium ions, carbonium ions, free radicals, epoxide, or arene oxide groups

the kidneys, but also through the intestines via excretion into bile. Cytochromes P450 are involved in Phase I, but not Phase II, metabolism. General examples of xenobiotic-metabolizing enzymes and their reactions are shown in Table 11.3.

Metabolism of xenobiotics by cytochromes P450 can have one of three effects on the compound: **inactivation**, **activation**, or **formation of a toxic metabolite**. In inactivation,

CLINICAL CORRELATION 11.3

Cytochrome P450 Inhibition: Drug–Drug Interactions and Adverse Effects

The roles that cytochromes P450 play in drug metabolism and the serious consequences of drug–drug interactions were clearly shown for two drugs, terfenadine (Seldane) and cisapride (Propulsid), when their metabolism was inhibited by other drugs. A small percentage of users experienced severe adverse effects that forced their manufacturers and the Food and Drug Administration (FDA) to issue warnings that the drugs should not be taken with other drugs that inhibit CYP3A4. The seriousness of these adverse effects forced the FDA to have both drugs removed from the market.

The FDA approved terfenadine, a second-generation H1 antihistamine, in 1985 to treat seasonal allergies. Terfenadine is rapidly metabolized in the liver by CYP3A4 to fexofenadine, as shown in Figure 11.12, resulting in low levels of the parent drug soon after ingestion, but the therapeutic effects of terfenadine are actually affected by fexofenadine. Because many other drugs are substrates or inhibitors of CYP3A4, the metabolism of terfenadine is potentially inhibitable. Individuals who took terfenadine with the macrolide antibiotic, erythromycin, or the antifungal agent, ketoconazole, both strong inhibitors of CYP3A4, had significantly elevated plasma levels of terfenadine. In a small percentage of these terfenadine users, serious cardiac problems developed because the parent drug caused alteration in cardiac potassium channels and increased the risk of a rare ventricular tachycardia called Torsades de Pointes. Some individuals died from cardiac problems that developed after taking terfenadine with erythromycin or ketoconazole. Since the therapeutic properties of terfenadine were associated with its nontoxic metabolite, fexofenadine, the manufacturer tested fexofenadine as a new medication and sought FDA approval for this metabolite, now marketed as Allegra.

Cisapride was approved in 1993 for patients who suffer from nighttime heartburn as a result of gastroesophageal reflux disease or GERD. The elimination of this drug from the body is dependent on CYP3A4 metabolism, and when administered alone or with other drugs that do not inhibit CYP3A4, the parent drug does not accumulate in the plasma. However, when taken with drugs that are substrates or inhibitors of CYP3A4, cisapride metabolism is reduced, and it accumulates with subsequent intake. In some individuals, increased cisapride levels cause cardiac arrhythmias, and, by the end of 1999, heart rhythm abnormalities were reported in 341 patients taking cisapride, resulting in 80 deaths. Accordingly, the manufacturer of cisapride stopped marketing this drug in the United States after 2000.

the active form of a drug is converted to an inactive form, thus decreasing bioavailability or, in the case of harmful xenobiotics, decreasing potential harmful effects (e.g., phenobarbital). Diazepam (brand name Valium, prescribed as a sedative), for example, is metabolized by CYPs 2C19 (*N*-dealkylation) and 3A4 (hydroxylation) to the biologically inactive oxazepam (Figure 11.12), which then undergoes Phase II conjugation with glucuronic acid before elimination.

Other drugs are biologically inactive until metabolized by a cytochrome P450 to a biologically active form. The drug terfenadine (brand name Seldane, a histamine H1 receptor antagonist prescribed for seasonal allergies) is an inactive form of a drug, or a prodrug, that is activated by sequential CYP3A4 hydroxylation to fexofenadine, the functional, desired form (Figure 11.13). Problems associated with interference of terfenadine activation are detailed in Clin. Corr. 11.3.

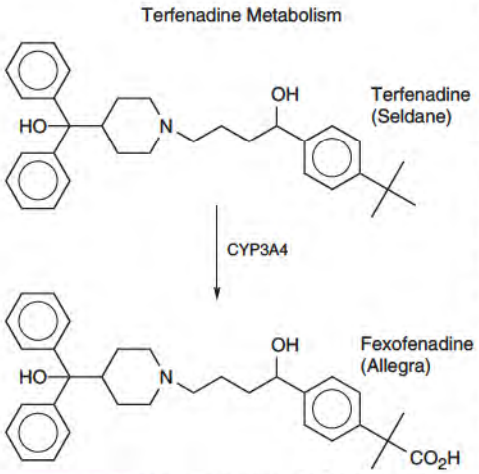

Figure 11.13 The metabolism of terfenadine to fexofenadine, the bioactive compound.

In addition to xenobiotic activation or inactivation, cytochrome P450 metabolism can inadvertently cause the formation of toxic metabolites. Benzo[a]pyrene is a weak carcinogen produced from the burning of coal, combustion of materials in tobacco products, food barbecued on charcoal briquettes, and industrial processing. It is converted by CYPs 1A1, 1A2, and 1B1 to benzo[a]pyrene-7,8-dihydrodiol-9,10-epoxide, a much more potent carcinogen (Figure 11.14). Benzo[*a*]pyrene is converted to the 7,8-epoxide form by CYP1A1. Subsequent hydrolysis by epoxide hydrolase forms the vicinal hydroxy derivative, benzo[*a*]pyrene-7,8-dihydrodiol, and a second epoxidation reaction by CYP1A1 or 3A4 forms benzo[*a*]pyrene-7,8-dihydrodiol-9,10-epoxide, which can form guanine adducts on DNA, causing disruption of gene function leading to mutations. The interaction of benzo[*a*]pyrene-7,8-dihydrodiol-9,10-epoxide with the p53 gene is a critical step in the mechanism by which benzo[*a*]pyrene is carcinogenic in humans. Benzo[a]pyrene also binds to the aryl hydrocarbon receptor (AhR) and induces these P450 forms, thus increasing its own metabolism.

Acetaminophen, commonly used as an analgesic and antipyretic, is converted by CYP2E1 to *N*-acetyl-*p*-benzoquinone imine (NAPQI), a highly reactive compound leading

to protein adducts, oxidative stress, and toxicity. Normally, acetaminophen is primarily metabolized by glucuronidation and sulfation pathways to polar, inactive conjugates that are readily excreted (Figure 11.15, upper and lower pathways, respectively). Acetaminophen is also metabolized by CYP2E1 to a highly reactive NAPQI (Figure 11.15, middle pathway). The amount of acetaminophen that is metabolized by CYP2E1 is normally low in comparison to that of glucuronidation and sulfation. Whatever small amounts of NAPQI formed are rapidly conjugated by glutathione (p. 789) to a nontoxic metabolite. However, if glutathione levels are depleted, NAPQI will escape glutathione conjugation and react with liver cell components to cause cell damage. Normally, the levels of CYP2E1 are low in comparison to other P450 forms, and the production of NAPQI, when normal doses of acetaminophen are taken, is small. However, intake of large quantities of acetaminophen will cause an increase in the production of NAPQI that may cause severe liver damage. Another factor in acetaminophen-induced liver toxicity is that the consumption of alcoholic beverages induces CYP2E1, which will increase the production of NAPQI. However, alcohol is also a substrate for this cytochrome P450 and will inhibit the metabolism of other CYP2E1 substrates. The extent of liver damage thus depends on the timing and amount of acetaminophen taken. Acetaminophen overdose results in more calls to poison control centers in the United States than any other pharmacological substance. In addition, according to the American Liver Foundation, 35% of cases involving liver failure are caused by acetaminophen poisoning. A description of the effects of alcohol on acetaminophen metabolism is presented in Clin. Corr. 11.4.

As exemplified by benzo[*a*]pyrene and acetaminophen, the P450 system can produce toxic metabolites. Formation of toxic compounds by the cytochromes P450, however, does not mean that cell damage or a tumor will occur. Other cellular processes will determine the extent of cellular damage; for example, conjugation of the benzo[*a*]pyrene-7,8-dihydrodiol-9,10-epoxide by glutathione transferases plays a key protective role in inhibiting DNA adduct formation and reducing its carcinogenic activity. The actions of various detoxification

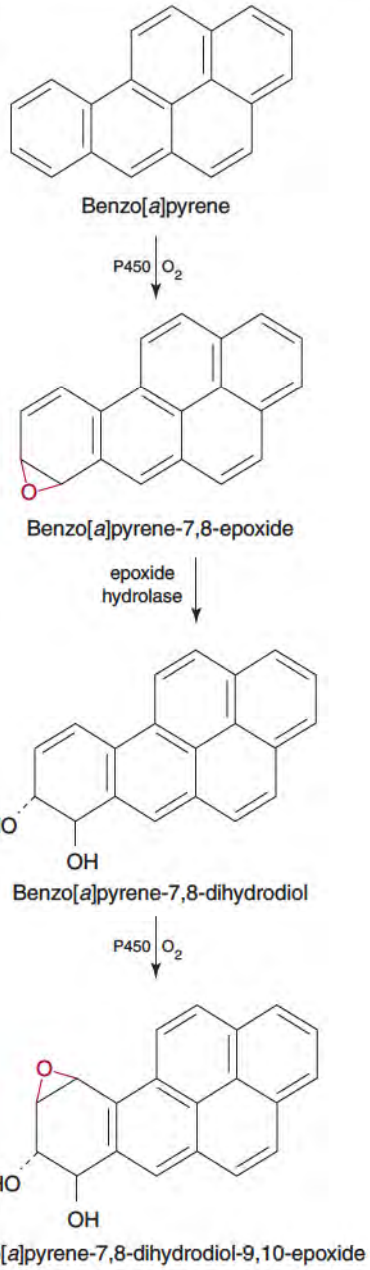

Figure 11.14 The metabolism of benzopyrene by cytochrome P450 and epoxide hydrolase to form benzopyrene-7,8-dihydrodiol-9,10-epoxide.

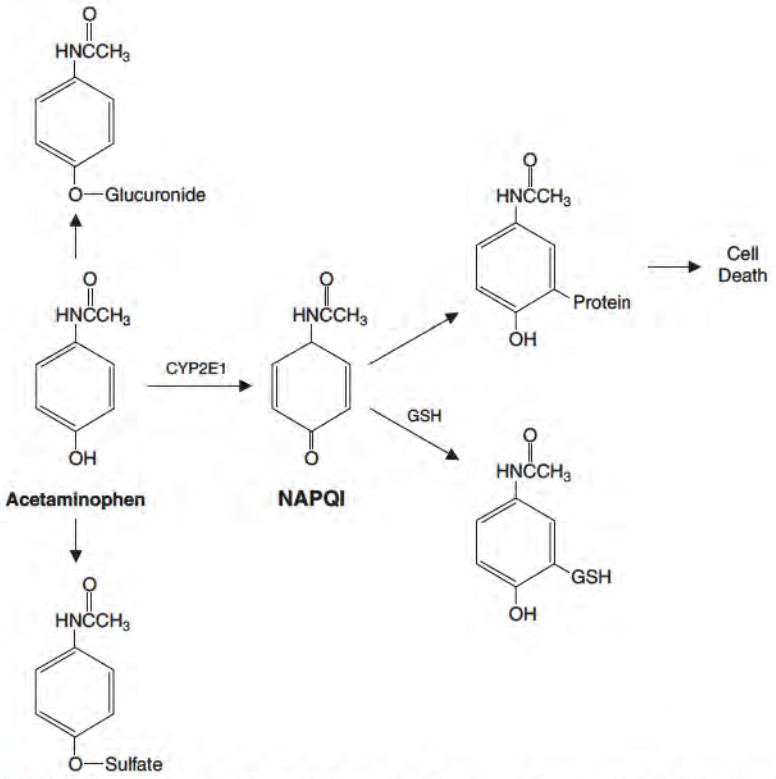

Figure 11.15 Acetaminophen may be metabolized by the phase II enzymes sulfotransferase and glucuronsyl transferase and by CYP2E1. Metabolism by CYP2E1 will lead to the formation of *N*-acetyl-*p*-benzoquinoneimine (NAPQI). When NAPQI formation is low, NAPQI can be conjugated by glutathione to a nontoxic metabolite; however, if NAPQI is formed in excessive amounts, it may escape glutathione conjugation and react with liver cell components to cause cell damage.

CLINICAL CORRELATION 11.4

Role of Cytochrome P450 2E1 in Acetaminophen-Induced Liver Toxicity

Acetaminophen is one of the most commonly used analgesic (pain-relieving) and antipyretic (fever-reducing) over-the-counter medications. It is available alone or as a component of more than 100 other nonprescription medications. The pathway of acetaminophen metabolism is shown in Figure 11.15. The consumption of alcohol, an inducer and substrate of CYP2E1, has a profound effect on acetaminophen metabolism. Alcohol consumption equivalent to drinking a 750-ml bottle of wine, six 12-oz cans of beer, or 9 oz of 80-proof liquor over a 6- to 7-hour period causes a 22% increase in CYP2E1-mediated metabolism of acetaminophen that manifests several hours post alcohol intake. Thus, the timing between the last consumption of alcohol and acetaminophen intake may be very critical in the development of acetaminophen-induced liver injury. In a person drinking alcohol, metabolism of acetaminophen taken concomitantly or shortly after cessation of drinking is delayed because ethanol, like acetaminophen, is a substrate for CYP2E1 and therefore competes for binding. In chronic alcohol consumption, CYP2E1 is induced and greater amounts of *N*-acetyl-*p*-benzoquinoneimine (NAPQI) are produced; however, alcohol may actually protect the liver from acetaminophen-induced injury if taken at the same time or shortly before. If acetaminophen is taken several hours post alcohol intake, the alcohol has already been metabolized and increased levels of CYP2E1 are then available to metabolize acetaminophen to NAPQI, increasing the risk of liver damage.

The length of time and amount of alcohol consumed daily affect the amount of CYP2E1 expressed in hepatocytes. The amount of acetaminophen consumed is also a major determining factor for risk, as normally recommended doses do not usually generate sufficient NAPQI to produce liver cell damage. Higher doses of acetaminophen increase the risk of liver cell injury as more drug will be metabolized through the CYP2E1 pathway. Both the sulfation and glucuronidation pathways are essential in determining the amount of acetaminophen that will be metabolized by CYP2E1. In addition, the levels of intracellular glutathione are critical as glutathione forms conjugates with NAPQI to protect the liver from this reactive metabolite. In the presence of high levels of NAPQI, glutathione is rapidly depleted and can no longer protect against damage.

enzyme systems, including conjugation reactions such as glucuronidation and sulfation, the status of the immune system, nutritional state, genetic predisposition, and exposure to various environmental chemicals all play key roles in determining the extent of P450-mediated cell damage and toxicity. Although it seems counterproductive for mammalian systems to possess enzymes that potentially create highly toxic compounds, the purpose of the cytochrome P450 system is to add or expose functional groups making the molecule more polar and/or more susceptible to metabolism by other detoxification enzyme systems; the creation of toxic metabolites is an unintended consequence of this process.

Although the vast majority of the substrates for these cytochromes P450 (Table 11.1, p. 431) are exogenous compounds, some endogenous functions have also been postulated. CYP1A1 and 1A2 appear to be involved in heme catabolism and estradiol metabolism, respectively. There is also evidence that members of the CYP2A, 2B, 2C, and 3A subfamilies are involved in testosterone metabolism and those of the 2D and 2E subfamilies are involved in catecholamine metabolism and gluconeogenesis, respectively.

11.6 • CYTOCHROMES P450: INDUCTION AND INHIBITION

Clearly, the levels and activity of the cytochromes P450 in any given person will greatly influence the effect of a particular drug or xenobiotic on the system. Thus, compounds that inhibit or induce P450 activity, as well as polymorphisms occurring in a P450 gene, can produce unexpected results.

Drug–Drug Interactions

Many drugs induce the formation of the cytochrome P450 that metabolizes them. Other drugs cause inhibition of P450 activity. Altering the metabolism of a particular drug from its predicted rate may cause unexpected and adverse effects and is of particular concern for

individuals who take a combination of drugs. For drugs that are dependent on P450 metabolism for elimination from the body, inhibition will lead to accumulation of the parent drug to concentrations that may be toxic. Conversely, induction of the P450 isoform required to metabolize a particular drug may lead to over-metabolism and sub-effective concentrations.

The unintended effects that can occur when levels of cytochromes P450 are induced or inhibited by other drugs are called drug–drug interactions. If these inducing or inhibiting drugs are given with other drugs that are normally metabolized by P450 enzymes, the lifetime of these other drugs will be altered. If these drugs affect critical systems, the result can be fatal. For example, CYP2E1 is induced by alcohol or isoniazid. It also metabolizes anesthetics, such as halothane and enflurane, to compounds that damage liver proteins. The immune system then attacks these abnormal proteins, producing a form of hepatitis. People with higher than normal CYP2E1 activity produced by alcohol intake are at higher risk for this sort of hepatitis reaction to an anesthetic.

Drug–drug interactions also occur with CYP3A4, the most important drug metabolizing P450 and the P450 most abundantly present in liver and small intestine. CYP3A4 levels are induced by rifampicin, anticonvulsants such as carbamazepine and phenytoin, and glucocorticoids such as dexamethasone and are inhibited by antifungals such as ketoconazole, HIV protease inhibitors, calcium channel blockers, cyclosporine, antibiotics such as erythromycin, SSRI antidepressants, and even grapefruit juice. A very few of the many compounds metabolized by this enzyme are listed in Table 11.1, p. 431.

It is readily apparent that mixing inducers and/or inhibitors of CYP3A4 with various drugs (which can themselves be inducers or inhibitors) may have unintended or even fatal effects. Taking rifampicin, a CYP3A4 inducer, with oral contraceptives, which are metabolized by CYP3A4, has resulted in lower efficacy of the contraceptives, leading to unintended pregnancies. Taking ketoconazole or even drinking grapefruit juice, both of which inhibit CYP3A4, along with the anticoagulant warfarin, could lead to excessive bleeding. Clinical consequences that relate to inhibition or induction of drug-metabolizing enzymes are presented in Clin. Corr. 11.3, p. 438, and Clin. Corr. 11.5.

The mechanisms of induction of cytochromes P450 are at either the transcriptional or posttranscriptional (e.g., stabilization of mRNA or a decrease in protein degradation) level. It is not possible to predict the mode of induction on the basis of the inducing compound. The complexity of the induction process is illustrated with CYP2E1 in the human versus rat liver. CYP2E1 protein is induced in both species by small organic molecules, such as ethanol, acetone, or pyrazole, or under fasting or diabetic conditions. In humans, the levels of mRNA for the protein are unaffected and the induction is likely due to stabilization of human CYP2E1 from proteolytic degradation. However, in diabetic rats the sixfold induction of CYP2E1 protein is accompanied by a 10-fold increase in mRNA without involving an increase in gene transcription, suggesting stabilization of the mRNA.

Specific cytosolic receptor proteins have been indicated for some inducing agents. One of the most extensively studied is the aryl hydrocarbon (or Ah) receptor, which interacts with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and causes induction of CYP1A1, CYP1A2, and CYP1B1. This is an example of a compound that persists in the lipid environments of the cell for extended periods of time and can induce carcinogenesis. Polycyclic aromatic hydrocarbons are ligands for the Ah receptor, and they produce a ligand-receptor complex that is translocated into the nucleus by the **Ah** receptor **n**uclear **t**ranslocator (Arnt) where it binds to specific response elements in the upstream regulatory regions of cytochrome P450 genes. Figure 11.16, p. 442, illustrates this process.

Another receptor system of P450 genes is the pregnane X receptor (PXR) which regulates the CYP3A gene. Pregnane refers to 21-carbon steroids such as the progesterone metabolite 5α-pregnane-3, 20-dione, which is a ligand for PXR and a potent inducer of the human CYP3A4 gene. In addition to 21-carbon steroids, other structurally dissimilar compounds such as carbamazepine (a drug used for the treatment of convulsions) and rifampin (an antituberculosis drug), as well as St. John's wort (a nonprescription herbal agent used to treat mood disorders) are ligands for PXR. PXR binds the retinoid X receptor (RXR) to form a heterodimeric complex (PXR-RXR) that binds specific response elements in the 5′-flanking region of CYP3A genes. Recall that approximately 50% of prescription drugs are metabolized by this cytochrome P450 form.

CLINICAL CORRELATION 11.5

Cytochrome P450 Induction: Drug–Drug Interactions and Adverse Effects

Induction of specific cytochromes P450 may decrease the therapeutic effects of drugs, because increases in liver P450 levels increase rates of metabolism and, therefore, inactivation and/or excretion of drugs. Induction of the P450 system may also have adverse effects due to the increased formation of toxic metabolites (also Clin. Corr. 11.4).

Induction of CYP3A4 by, for example, the antituberculosis drug rifampin, may greatly increase elimination of the oral contraceptive ethinyl estradiol, causing subeffective plasma levels of the drug, which increases the risk of pregnancy. Treatment with the anticonvulsant drugs, phenytoin and carbamazepine, may also induce CYP3A4 and reduce the contraceptive potency of ethinyl estradiol. It is imperative that a woman taking ethinyl estradiol as an oral contraceptive simultaneously with a CYP3A4 inducer increase the dose of the contraceptive or use an alternative contraceptive method or drug.

The widely used herbal agent St. John's wort, which can be purchased without a prescription, also induces CYP3A4 activity, raising concerns that individuals who ingest the herb may not receive the therapeutic benefits of drugs that are CYP3A4 substrates. A reduction in plasma levels of oral contraceptives, HIV antiprotease drugs, the immunosuppressive drug cyclosporin, or certain statin drugs, used to lower cholesterol levels, can occur because each of these drugs is a substrate for CYP3A4. Because St. John's wort is considered a natural substance, rather than a drug, individuals may take this agent without notifying their physician or knowing its effects on the efficacy of other drugs they are taking.

Roby, C. A., Anderson, G. D., Kantor, E., Dryer, D. A., and Burstein, A. H. St. John's wort: Effect on CYP3A4 activity. *Clin. Pharmacol. Ther.* 67:451, 2000; and Shader, R. I. and Oesterheld, J. R. Contraceptive effectiveness: Cytochromes and induction. *J. Clin. Psychopharmacol.* 20:119, 2000.

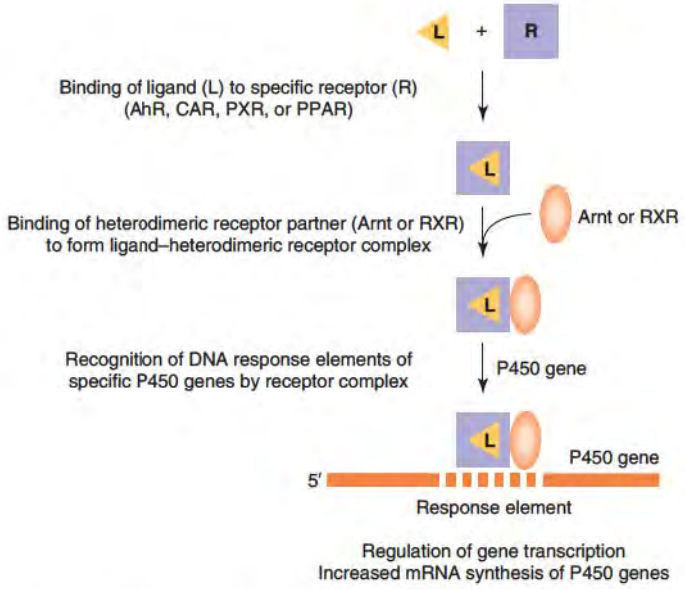

Figure 11.16 The interaction of a ligand with its receptor and receptor partner to form the heterodimeric receptor complex initiates induction of cytochrome P450 forms.

Another inducer of cytochrome P450 genes is phenobarbital. This induction is mediated by the constitutive androstane receptor (CAR), which also forms a heterodimeric complex with RXR to interact with its specific response element in the 5′-flanking region of CYP2B genes. Two endogenous androstane steroids, androstanol and androstenol, are also ligands for CAR and, when either ligand is bound to CAR, they prevent the interaction of the CAR-RXR receptor complex with the protein, SRC-1. SRC-1 is a coactivator of nuclear receptors and is required for transcriptional activation by CAR. Administration of phenobarbital or other phenobarbital-like inducers displaces the androstane ligands, permitting SRC-1 binding and transcription of the CYP2B gene.

Cytochrome P450 Genetic Polymorphisms

In addition to exposure to various inducing agents that may change the cytochrome P450 expression pattern in the liver and other organs, individuals may differ in their metabolism rates for particular drugs because of unique cytochrome P450 genes or alleles they possess, *i.e.*, polymorphisms. A polymorphism is a difference in DNA sequence found at 1% or higher in a population. These differences in DNA sequence can lead to differences in drug metabolism. Since these are genetic variations, many of them are present in specific ethnic groups, which may, therefore, experience more frequent adverse effects with certain drugs. It is estimated that 40% of the different human cytochrome P450 forms that metabolize xenobiotics are polymorphic.

Genetic polymorphisms in CYP2D6 have been studied extensively and 65 different alleles have been identified. The population can be divided into *extensive metabolizers* or *poor metabolizers,* depending on the levels of CYP2D6 expression. If there is no other way to clear a particular drug from the system, poor metabolizers may be at risk for adverse drug reactions. Alternatively, extensive metabolizers may find many drugs to be ineffective.

Many persons of Ethiopian and Saudi Arabian origin exhibit high expression of CYP2D6. This isoform metabolizes a variety of drugs, making them ineffective; many antidepressants and neuroleptics are important examples. Conversely, prodrugs will be extensively activated; codeine will be converted very quickly to high amounts of morphine.

In contrast, many individuals lack functional 2D6. These patients will be predisposed to drug toxicity caused by antidepressants or neuroleptics, but will find codeine to be ineffective due to lack of activation. Perhexiline (a calcium channel blocker) was withdrawn from the market due to the neuropathy it caused in 2D6 inactive patients. Even beta-blocker removal may be impaired (for example, propranolol) in 2D6-deficient people. Clin. Corr. 11.6 discusses polymorphism effects.

Although genetic polymorphism of a particular cytochrome P450 may affect metabolism of a discrete set of compounds, genetic polymorphisms of the cytochrome P450 reductase, the sole and obligate electron donor to the 50 members of the microsomal class

CLINICAL CORRELATION 11.6

Genetic Polymorphisms of P450 Enzymes

Multiple alleles have been demonstrated for approximately 40% of human P450 genes. These genetic polymorphisms may produce defective P450 proteins. A description of the polymorphic CYP21 and its importance in the metabolism of an endogenous compound was given in Clin. Corr. 11.1. The absence of a cytochrome P450 activity may cause many problems due to the accumulation of therapeutic drugs that cannot be metabolized. The discovery of exaggerated hypotensive effects with the antihypertensive drug debrisoquine led to the characterization of individuals who inefficiently metabolized CYP2D6 substrates. Approximately 5% to 10% of the Caucasian, 8% of the African and African-American, and 1% of the Asian populations are deficient in catalytically active CYP2D6. In addition to debrisoquine, other drugs that are metabolized by CYP2D6 are sparteine, amitriptyline, dextromethorphan, and codeine. In the case of codeine, CYP2D6 in normal individuals catalyzes the *O*-demethylation of approximately 10% of the codeine to morphine. Individuals who lack functional CYP2D6 are unable to catalyze this reaction and so do not achieve the analgesic effects of codeine.

A genetic polymorphism associated with CYP2C19 has been demonstrated in individuals who are poor metabolizers of mephenytoin, a drug used in the treatment of epilepsy; CYP2C19 hydroxylates C4 of the S-enantiomer of mephenytoin to inactivate the physiological effect. Poor metabolizers of this drug suffer greater sedative effects at normal dosages. Approximately 14% to 22% of the Asian, 4% to 7% of the African and African-American, and 3% of the Caucasian populations lack the active form of CYP2C19.

CYP2C9 polymorphisms occur in less than 0.003% of the African or African-American, 0.08% of the Asian, and 0.36% of the Caucasian populations. The absence of a functional CYP2C9 may have serious consequences in the metabolism of S-warfarin, an orally administered drug used to inhibit blood coagulation in patients who have suffered a heart attack or a stroke to prevent the reoccurrence of life-threatening clots. Plasma levels of the drug must be maintained within a specific range because excessive amounts will cause uncontrolled bleeding and, possibly, death. Warfarin is metabolized by CYP2C9 for elimination. CYP2C9*3 is an allelic variant in which isoleucine is substituted for leucine at residue 359, resulting in substantial loss of enzymatic activity. Individuals deficient in CYP2C9 may require only 0.5 to 1 mg of warfarin per week in contrast to the 4 to 5 mg per day prescribed for an individual with normal CYP2C9. If a 5-mg dose of warfarin was taken by someone lacking functional CYP2C9, uncontrollable bleeding could result from a simple cut.

Ingelman-Sundberg., M., Oscarson, M., and McLellan, R. A. Polymorphic human cytochrome P450 enzymes: An opportunity for individualized drug treatment. *Trends Pharm. Sci.* 20:342, 1999.

CLINICAL CORRELATION 11.7

Genetic Polymorphisms of NADPH-Cytochrome P450 Reductase: Antley–Bixler Syndrome (OMIM 207410)

Mutations have been found in human NADPH-cytochrome P450 reductase that result in a patient phenotype of skeletal malformations characterized by craniosynostoses, radio-ulnar or radio-humeral synostoses, and/or bowed femora, a set of clinical features known as Antley–Bixler syndrome. These patients also exhibit disordered steroidogenesis and congenital adrenal hyperplasia (CAH). As described in Clin. Corr. 11.1, a defect in CYP21A2 is the most common cause of CAH. Because cytochrome P450 reductase deficiency potentially affects the activities of three steroidogenic cytochromes P450 (CYPs 19A and 17A, as well as CYP21A, Figure 11.8), variable and abnormal patterns of steroid hormones are observed in these cases, resulting in overvirilized females and undervirilized males. The pathways involved in embryonic skeletal development were also clearly affected in some cytochrome P450 reductase-deficient patients, and cytochrome P450-mediated drug metabolism was compromised in at least some of these patients. Because there is no redundancy in the electron-transferring portion of the microsomal cytochrome P450 system, defects in the cytochrome P450 reductase would be expected to have variable and pleotropic effects, depending on the severity of the effect on its activity. In addition, various cytochromes P450 could interact with different surface residues of the reductase, and thus be affected differentially by mutations in such residues. Therefore, depending on the locus of the mutation in the structure of the reductase (Figure 11.4), and the resultant alteration of enzymatic activities or protein–protein interactions, the mutations may vary greatly in resulting severity and phenotype.

Fluck, C. E., Tajima, T., Pandey, A. V., Arlt, W., et al. Mutant P450 oxidoreductase causes disordered steroidogenesis with and without Antley–Bixler syndrome. *Nat. Genet.* 36:228, 2004: and Scott, R. R. and Miller, W. L. Genetic and clinical features of P450 oxidoreductase deficiency. *Horm. Res.* 69:266, 2008.

of cytochromes P450, might be expected to have more global and dramatic effects on metabolism of both endogenous and xenobiotic substrates. Indeed, completely knocking out the cytochrome P450 reductase gene in an animal model is embryonically lethal to these animals. Recently, human mutations that alter activity in this gene have been described to have profound effects (Clin. Corr. 11.7).

Therapeutic Inhibition of Cytochrome P450

Because cytochromes P450 are present in almost all organisms and because they play such important roles in cellular homeostasis, selective inhibition of these enzymes is of clinical importance. Azole inhibitors (ketoconazole, itraconazole, and fluconazole), for example, are used to control yeast infections contracted by AIDS patients, cancer patients undergoing chemotherapy, and patients who are treated with immunosuppressive drugs. In yeast, CYP51 catalyzes the demethylation of sterol molecules in the synthesis of ergosterol, an important membrane lipid. In humans, a related P450 form, CYP51A1, catalyzes the demethylation of lanosterol, a reaction that is essential to cholesterol synthesis. Although the human and yeast CYP51 proteins are similar, sufficient differences exist that azole antifungal agents are effective inhibitors of ergosterol formation. As discussed earlier, however, these agents may also induce or inhibit native human cytochromes P450, possibly leading to drug–drug interaction phenomena.

Certain tumors, such as breast tumors, are dependent on estrogen for their growth. Thus, the prevention of estrogen synthesis without inhibiting production of other steroid hormones might serve as a selective chemotherapeutic tool to reduce and eliminate tumors. CYP19A1, the cytochrome P450 that catalyzes estradiol formation from androstenedione, is an attractive target for this type of intervention. A particularly selective type of inhibitor is a mechanism-based, or suicide, inhibitor. These compounds bear strong resemblance to a substrate of an enzyme but form an irreversible inhibition product during catalytic turnover with the enzyme prosthetic group or protein. Such inhibitors would be highly specific for a particular cytochrome P450 form and would, therefore, be a good tactical approach to drug design.

It is readily apparent that without an understanding of drug metabolism and drug interactions mediated by the cytochrome P450 system, medication cannot be safely prescribed, particularly when multiple medications are required, as in older patients. It is critical to determine how therapeutic drugs are metabolized and whether cytochrome P450 forms can be inhibited by different compounds. The Food and Drug Administration's (FDA's) drug approval process requires that extensive information be submitted on the metabolism of drugs before they are finally approved for general human use.

11.7 • NITRIC OXIDE SYNTHASES: PROPERTIES AND ENZYMATIC FUNCTION

The nitric oxide synthases (NOSs) are heme- and flavin-containing enzymes that catalyze the synthesis of nitric oxide (NO) through two serial monooxygenase reactions analogous to those of the cytochrome P450 systems. The NOSs are functional dimers and consist of two major domains, a heme-containing oxygenase domain, which is structurally unrelated to cytochrome P450s, and a flavin-containing reductase domain, which structurally resembles the P450 reductase (Figure 11.17). Electrons are transferred from NADPH into the reductase domain of one monomer, through the flavins FAD and FMN, to the heme iron of the other monomer where molecular oxygen is bound and activated. The domains are connected by a calmodulin-binding site, occupation of which by calmodulin is required for electron transfer from the reductase to the oxygenase domain.

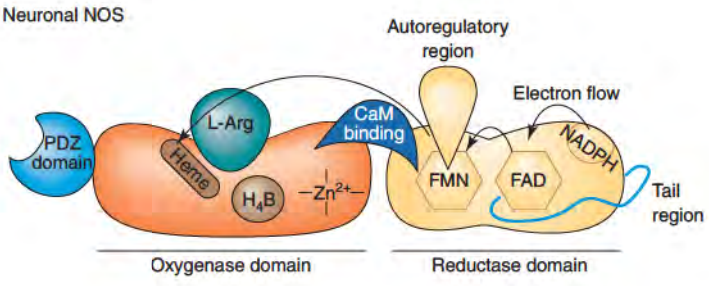

Figure 11.17 A modular structure of neuronal nitric oxide synthase showing approximate locations of prosthetic groups and cofactors.

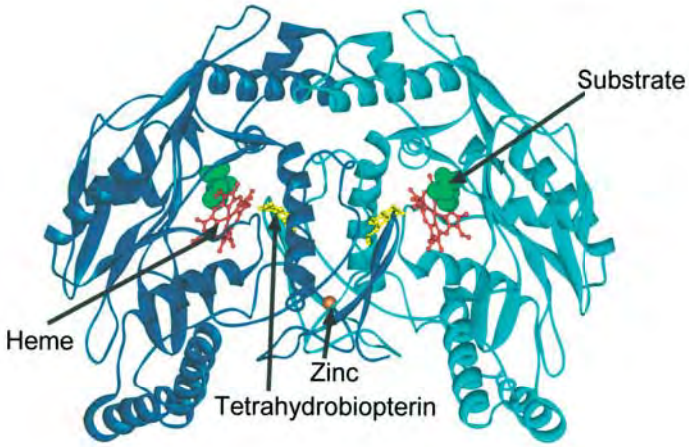

Figure 11.18 Model of the dimeric structure of bovine NOSIII heme domain showing the protoporphyrin IX (red) and tetrahydrobiopterin (yellow) prosthetic groups. The two monomers are depicted in light blue and dark blue, respectively. The substrate L-arginine (green) is in the active site of the NOSIII. A zinc atom is at the interface between the two monomers.
Generated from Protein Data Bank file 2NSE, deposited by C. S. Raman, H. Li, P. Martasek, V. Kral, B. S. Masters, and T. L. Poulos, using WebLab Viewer Lite (Molecular Simulations, Inc.).

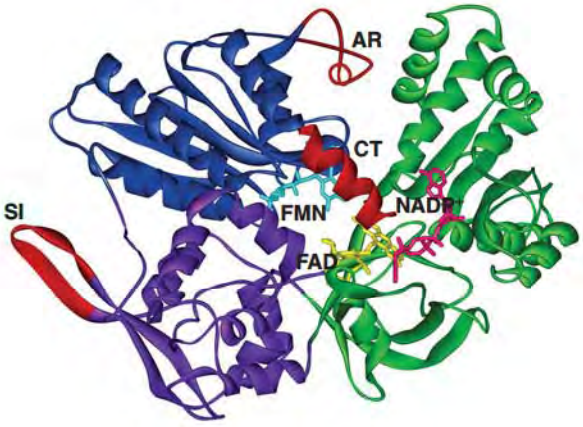

Figure 11.19 Ribbon diagram of nNOS reductase domain derived from its crystal structure. Similar to cytochrome P450 reductase, several subdomains are present—the FMN-binding domain (blue), the FAD/NADPH-binding domain (green), and the intervening connecting domain (purple). Unlike the P450 reductase, the nNOS reductase contains a calmodulin-binding site (not evident in the diagram), and regulatory regions (red) at the C-terminus (CT), in the FMN domain (AR), and in the connecting domain (SI). Cofactors are shown in stick models: blue, FMN; yellow, FAD; and red, $NADP^+$.
Generated from Protein Data Bank file 1TLL, deposited by E. D. Garcin, C. M. Bruns, S. J. Lloyd, D. J. Hosfield, et al., using WebLab Viewer Lite (Molecular Simulations, Inc.).

The heme moiety of the NOSs resembles that of cytochromes P450 in that it forms a thiolate ligand with a cysteine in the NOS protein, and it yields the same type of absorbance spectrum when CO is bound to the reduced, ferrous form of the heme, that is, an absorbance peak at about 450 nm. The NOS oxygenase domain is, however, structurally very different from the cytochromes P450 (compare the NOS oxygenase domain crystal structure in Figure 11.18 with that of the cytochrome P450 in Figure 11.1, p. 431). In addition to the heme moiety and substrate-binding site, the oxygenase domains of NOSs also contain a binding site for tetrahydrobiopterin, which apparently functions in electron transfer, and a tetra-coordinated zinc atom, which is important for structural integrity.

The NOS reductase domain is structurally very similar to that of cytochrome P450 reductase (compare the nNOS reductase domain crystal structure in Figure 11.19 with that of the cytochrome P450 reductase in Figure 11.4, p. 428). They share almost 60% sequence homology, and the overall architecture and subdomain structures, the FMN domain, the connecting domain, and the FAD/NADPH binding domain, closely resemble each other. The primary structural difference between the two is the inclusion in the NOS reductase domain of various regulatory elements, which are only partially visible in the crystal structure due to their extreme flexibility.

The general reaction catalyzed by the NOSs is sequential monooxygenation of the amino acid L-arginine to form NO and citrulline, as shown in Figure 11.20. The reaction cycle is initiated by the binding of calmodulin to "open the gate" between the reductase and oxygenase domains. The electron donor is NADPH, which donates two electrons to

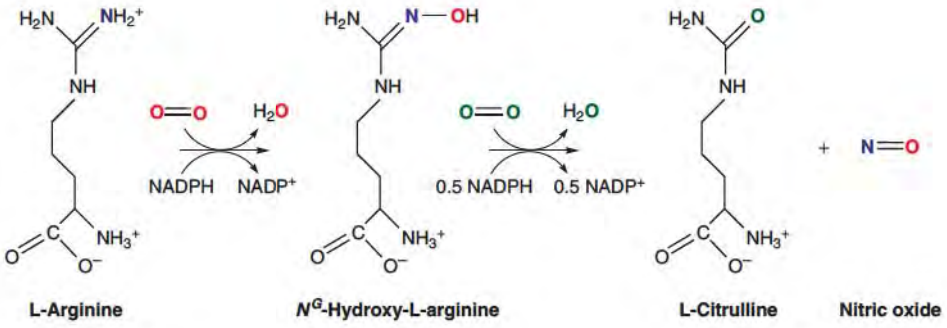

Figure 11.20 Production of nitric oxide. NOSs catalyze the formation of NO from L-arginine through two sequential monooxygenation steps which appear to be mechanistically similar to that of the microsomal cytochrome P450 system. The nitrogen atom (blue) of NO is derived from the guanidino group of the L-arginine side chain, and the oxygen atom (red) of NO is derived from molecular oxygen.

FAD, which, in turn, reduces FMN. The FMN reduces the heme iron to its ferrous form, to which oxygen can bind. In the first step, arginine is oxidized to the stable intermediate *N*-hydroxy-L-arginine. In the second step, *N*-hydroxy-L-arginine is oxidized to NO and citrulline. Note that the source of NO is the guanidino group of the substrate, arginine. This entire process requires 2 oxygen molecules and 1.5 molecules of NADPH and, like that of the cytochromes P450, is inhibited by carbon monoxide.

The overall electron transfer chain and mechanism by which the NOSs form NO is similar to that of the cytochromes P450, but there are some significant differences in regulation of the electron transfer process. The most obvious is the requirement of the constitutive NOSs for calmodulin binding. Calmodulin is not bound to the enzyme at intracellular, basal calcium levels. It requires an influx of calcium to raise the calcium concentration, increasing the binding of calcium to calmodulin (p. 493). The calcium–calmodulin complex binds to and activates NOSs. In the absence of calmodulin binding, heme reduction occurs only very slowly and does not support NO formation, and transfer between FAD and FMN is also slow. Calmodulin binding causes a conformational change in the enzyme, potentiating electron transfer between the flavins and allowing productive heme reduction. The reductase domains of the NOSs also contain several regulatory regions, shown in Figure 11.17, p. 444 and Figure 11.19, p. 445, which are involved in transducing the signal of calmodulin binding through the enzyme. In addition to the calmodulin-binding site, the regulatory regions present in the NOSs include a C-terminal extension of the FAD/NADPH binding domain, an insert of 45–50 residues in the FMN domain, and a small insertion in the connecting domain. All NOS isoforms include the C-terminus, but only the so-called constitutive isoforms contain the FMN and connecting domain inserts.

Another difference between the NOSs and P450s is that substrate binding is not required by the NOSs to initiate the reaction cycle, and the binding of substrate does not alter the reduction potential of the heme. If substrate is not present, the electron transferred to the heme can activate molecular oxygen, forming the oxy–ferrous complex, which can decay and be released as superoxide. If the second electron is transferred before the release occurs, the peroxy form of oxygen is generated, which will dissociate as hydrogen peroxide. Thus, if substrate is not present, but the NOS is active, potentially destructive reactive oxygen species may be formed. In addition, a tetrahydrobiopterin cofactor is required for NO synthesis by NOS, but is not required by any known cytochrome P450. Tetrahydrobiopterin serves as an electron donor to the oxy–ferrous complex (i.e., the one-electron reduced, oxygen-bound form of the heme) of NOS, delivering the second electron to the heme much faster than the relatively slow interdomain transfer of an electron from the NOS FMN. Thus, in the absence of tetrahydrobiopterin, NOS will produce superoxide due to the autoxidation of the oxy–ferrous complex. In the presence of tetrahydrobiopterin, but in the absence of substrate, NOS can also form hydrogen peroxide, due to the formation and subsequent decay of the peroxy–ferrous complex. The formation of these reduced oxygen species has been implicated in several inflammatory disease processes, such as endothelial dysfunction, and also in ischemia/reperfusion injury, where tissues are first depleted of oxygen and then reperfused with oxygen-rich blood. This type of injury occurs in cerebral thrombosis and in tissues removed for transplantation.

TABLE 11.4 • Properties of the NOS Isoforms

Property	*NOSI*	*NOSII*	*NOSIII*
Molecular mass	160 kD	130 kD	135 kD
Expression	Constitutive	Inducible	Constitutive
Cell fraction	Cytoplasmic	Cytoplasmic	Membrane-bound
Dependence on calcium influx	Dependent	Independent	Dependent
Physiological action	Neurotransmission	Cytotoxicity	Vasodilation

11.8 • NITRIC OXIDE SYNTHASE ISOFORMS AND PHYSIOLOGICAL FUNCTIONS

There are three major NOS isoforms, neuronal (NOSI or nNOS), inducible (NOSII or iNOS), and endothelial (NOSIII or eNOS), although variations of each of these types occur in many different organisms. Properties of these isoforms are summarized in Table 11.4.

Many of the physiological functions of NO are mediated through activation of soluble guanylate cyclase, a heterodimeric (α/β) heme-containing protein that converts GTP to cGMP. cGMP is a second messenger involved in many signal transduction cascades (p. 530). The inactive form of soluble guanylate cyclase has a penta-coordinate heme, bound by a histidine on the β-subunit. NO binds as the sixth ligand to form a hexa-coordinate heme and causes breakage of the heme–histidine bond, yielding the active, penta-coordinate nitrosyl complex of soluble guanylate cyclase (Figure 11.21). Activation of soluble guanylate cyclase causes up to a 400-fold increase in the rate of cGMP formation. The cGMP levels are regulated by a balance between guanylate cyclase activity and the phosphodiesterases (PDE), particularly PDE5, which is specific for cGMP, that hydrolyze cGMP to 5′-GMP, thus turning off the signal.

NOSI

NOSI is found primarily in skeletal muscle and in neurons of both the central and peripheral nervous systems. It is a soluble enzyme, although it is localized to the membrane via protein–protein interactions with a host of regulatory and localization proteins. It is constitutively expressed, meaning that it is not normally induced at the transcriptional level and is activated by the influx of calcium. In the case of NOSI (and NOSIII, p. 450), calmodulin (p. 493) is not bound to the enzyme at intracellular, basal calcium levels. It requires an influx of calcium to raise the calcium concentration intracellularly, allowing calmodulin to bind, and thus activating NO formation. The amount of NO synthesized in the activated state is very low, that is, picomolar. The NO produced serves as a neurotransmitter in the central and peripheral nervous systems. In skeletal muscle, NO also serves as a mediator of contractile force.

In the central nervous system, NO is produced generally by nNOS in the postsynaptic neuron, but diffuses back across the synapse to the presynaptic neuron. NO synthesis is regulated by the influx of calcium through receptor-dependent channels, that is, following postsynaptic stimulation of *N*-methyl-D-aspartate (NMDA) receptors by the excitatory neurotransmitter glutamate. Guanylate cyclase is activated by NO, producing cGMP, which

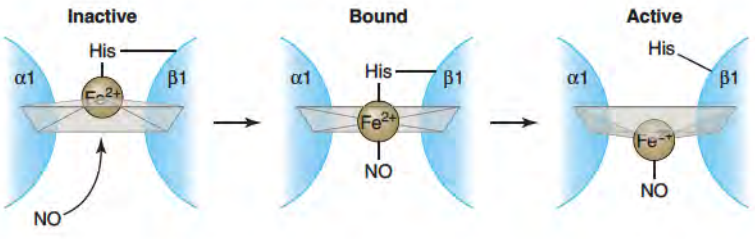

Figure 11.21 Activation of soluble guanylate cyclase by NO.
Redrawn based on figure in Bellamy, T. C. and Garthwaite, J. The receptor-like properties of nitric oxide-activated soluble guanylate cyclase in intact cells. *Mol. Cell. Biochem.* 230: 165, 2002.

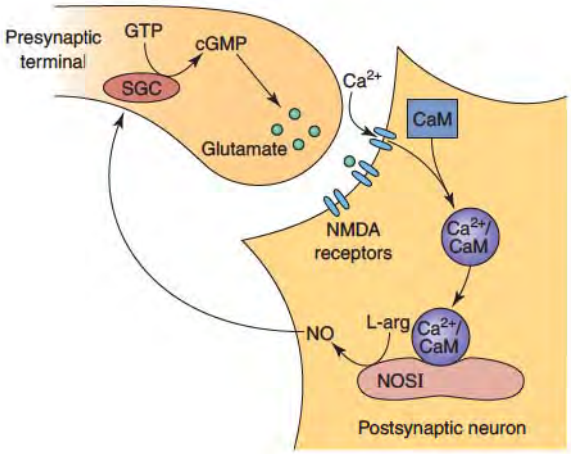

Figure 11.22 NO produced by NOSI in the central nervous system. In this instance, NO is produced by the postsynaptic cell and travels to the presynaptic cell where it activates sGC, creating cGMP that activates PKG. PKG phosphorylates proteins on the neurotransmitter vesicles, leading to more neurotransmitter release and potentiation of the signal.

regulates synthesis of the neurotransmitters norepinephrine and glutamate, thus enhancing NO production (Figure 11.22) in a positive feedback manner. NO has been implicated in neural signaling, neurotoxicity, synaptic plasticity, learning and memory, and perception of pain.

In addition to its oxygenase and reductase domains, NOSI has an *N*-terminal 300–amino acid PDZ domain, which mediates its interaction with other proteins. In the central nervous system, the PDZ domain of NOSI interacts with the postsynaptic density protein PSD-95. The NMDA receptor also interacts with PSD-95, thus bringing NOSI and the NMDA receptor into close proximity, so that NOSI is directly exposed to the calcium entering the ion channel of the activated NMDA receptor.

NO is very different from other known neurotransmitters (p. 942). NO is synthesized on demand and cannot be stored in lipid vesicles, as it freely diffuses across membranes. The action of NO is not terminated by degradation or reuptake but is removed by interaction with its target, which is an intracellular second messenger rather than a membrane-bound receptor.

In the peripheral nervous system, NO is produced by nNOS in myenteric neurons of the gastrointestinal, pulmonary, vascular, and urogenital systems. In the gastrointestinal system, NO is involved in gut motility and control of the pyloric sphincter. NO mediates the main bronchodilator pathway in the human pulmonary system and is involved in neural control of the vascular system, particularly important in cerebral blood flow. In the urogenital system, NO is involved in urethra and bladder control and in penile erection. During sexual excitement, NO is released from nerves adjacent to the blood vessels of the penis. Relaxation of these vessels causes blood to engorge the corpus cavernosum, producing erection. NOSI is activated in these systems by the influx of calcium through voltage-dependent calcium channels (p. 481). It diffuses to a neighboring smooth muscle cell causing activation of soluble guanylate cyclase. The smooth muscle relaxes via the mechanism described below for vascular smooth muscle. Clin. Corr. 11.8 describes the therapeutic manipulation of cGMP levels for treatment of erectile dysfunction.

High levels of NOSI are expressed in the skeletal muscle, where it is involved in mediation of contractile force, innervation of developing muscle, and perhaps glucose uptake. Skeletal muscle relaxation by NO also occurs through the cGMP pathway via the mechanism described in the following for vascular smooth muscle. NOSI is targeted to the sarcolemma of the muscle due to its association with α-syntrophin, a member of the muscle dystrophin complex. NOSI is activated by influx of calcium through voltage-dependent calcium channels, as well as from the sarcoplasmic reticulum.

NOSII

NOSII is found primarily in activated neutrophils and macrophages, astrocytes, and hepatocytes and is involved in the early immune response. It is a soluble enzyme and is induced at the transcriptional level by cytokines, such as interferon-γ, interleukin 1, and tumor

CLINICAL CORRELATION 11.8

Mechanism of Action of Sildenafil

The levels of cyclic nucleotides (cGMP and cAMP) present in the cell are dependent not only on their formation by adenylate or guanylate cyclases but also on their degradation by phosphodiesterases (PDEs), which hydrolyze them to 5′-nucleotides and so play a critical role in the modulation of these second messenger signaling pathways. The inhibition of PDE destruction of cyclic nucleotides would thus prolong the physiological response elicited by the cyclic nucleotides. Sildenafil (Viagra), a drug prescribed for erectile dysfunction in males, is a potent inhibitor of PDE5, which is specific for cGMP and is found primarily in the human corpus cavernosum and in vascular and gastrointestinal smooth muscle. In the penis, NO produces erection via a cGMP-dependent pathway, as discussed in the text. As the cGMP is degraded by PDE5, the vasodilatory signal attenuates and the erection subsides. Sildenafil inhibits PDE5, delaying cGMP degradation and thus prolonging erection.

Sildenafil is highly selective for PDE5 over PDE3, a cAMP-specific PDE involved in the regulation of cardiac contractility. This is important because inhibition of PDE3 increases the incidence of cardiac arrhythmias and decreases long-term mortality in heart failure patients. Interestingly, Sildenafil also inhibits, to a lesser extent, PDE6, which is localized to photoreceptors in the retina, and one of the side effects sometimes reported with Sildenafil use is a blue-green tint in the patient's vision.

Because PDE5 is present in vascular smooth muscle, Sildenafil causes a mild, clinically insignificant reduction in blood pressure due to vasodilation but, more importantly, it greatly exacerbates the effects of nitrates and external NO donors such as nitroglycerin, taken for angina, causing potentially fatal hypotension. These hypotensive effects occur regardless of the sequence and/or timing of the drugs. Sildenafil is therefore contraindicated in patients using nitrates in any form. In addition, Sildenafil is metabolized by both the CYP2C9 and 3A4 pathways. Inhibition of these pathways by other drugs may increase the plasma concentration of Sildenafil, intensifying side effects.

necrosis factor-α, or endotoxins, such as lipopolysaccharides. Induction occurs over several hours via the inflammatory NFκB pathway. Calmodulin is bound to NOSII under basal physiological conditions, that is, independent of calcium influx, so the enzyme is always activated once it is synthesized. The amount of NO synthesized by NOSII is in the nanomolar range, approximately 1000 times greater than that of either NOSI or NOSIII.

The NO produced by NOSII is a potent cytotoxin, and its principal role is to destroy pathogens engulfed by neutrophils and macrophages. NOSII controls such intracellular pathogens as parasites, for example, plasmodia (malaria), schistosoma (schistosomiasis), leishmania (leishmaniasis), and toxoplasma (toxoplasmosis), as well as microbials, for example, bacteria and mycobacteria (tuberculosis and leprosy), fungi, and even tumor cells. The cellular targets for the NO produced by NOSII are metal-containing heme proteins, such as cytochromes P450, and iron-sulfur proteins, such as aconitase and mitochondrial complexes I and II, all of which are inhibited. NO also reacts with thiol groups and tyrosines, causing nitrosation or oxidation of proteins, and with oxygen or superoxide, forming highly reactive nitrogen oxide compounds, for example, peroxynitrite. These reactive intermediates cause a variety of DNA alterations including strand cleavage and deamination. These modifications thus affect many crucial metabolic enzymes, leading to cytostatic or cytotoxic effects against these pathogens.

Although NO is essential for the antimicrobial function of the macrophage, overproduction of NO by NOSII has been implicated in septic/cytokine-induced circulatory shock. Septic shock is characterized by a systemic inflammatory response to microbial infection in which blood pressure drops precipitously, mediated by the overproduction of NO, causing decreased tissue perfusion and oxygen delivery and, eventually, multiple organ failure. Hypotension in these patients is often refractory to conventional vasoconstrictor drugs. The role of NO in septic shock and therapeutic intervention by NOS inhibitors is discussed in Clin. Corr. 11.9.

In addition to being produced during acute inflammation, NO is generated by NOSII during chronic inflammation. NOSII is present and active in a number of chronic inflammatory conditions including rheumatoid arthritis, Crohn disease, and asthma, where it may potentially exacerbate some situations, although protective effects have also been reported.

CLINICAL CORRELATION 11.9

Nitric Oxide Overproduction in Septic Shock

Although NO is essential in tumoricidal and bactericidal functions of macrophages, overproduction of NO (by NOSII) has been implicated in septic/cytokine-induced circulatory shock in humans. In septic shock, production of too much NO leads to massive systemic vasodilation and a precipitous and often fatal drop in blood pressure, which causes an insufficient blood and oxygen supply to peripheral organs, eventually leading to multiple organ failure. Septic shock is associated with an extremely high mortality rate of 50%–70%; more people die annually from septic shock than from myocardial infarction, stroke, trauma, or lung or breast cancer. NO-induced hypotension in these patients occurs through the mechanism for smooth muscle relaxation, that is, activation of guanylate cyclase. Therapeutic intervention by NOS inhibitors has been investigated for treatment of septic shock. Interestingly, although NOS inhibition successfully and rapidly raises blood pressure and systemic vascular resistance, it also led to a progressive fall in cardiac output and exacerbated organ dysfunction, leading to increased mortality in clinical trials. Thus, NO plays a detrimental role in septic shock, due to its mediation of hypotension, but may also play a beneficial role in survival, perhaps due to localized vasodilation or the antiplatelet aggregation, antileukocyte adhesion, antiapoptotic or antioxidative properties of NO.

NOSIII

NOSIII is found primarily in vascular endothelial cells, which line all blood vessels, and cardiac myocytes. It is localized to the membrane due to co-translational myristoylation and posttranslational palmitoylation of the *N*-terminus. Like NOSI, it is constitutively expressed and is activated by the influx of calcium, which binds to calmodulin facilitating its binding to both NOSI and NOSIII for activation. The amount of NO synthesized in the activated state is very low, that is, picomolar, and the NO produced serves as a vasodilator of vascular smooth muscle, both ligand mediated and flow dependent. The NO also serves antithrombotic and anti-inflammatory functions by inhibiting platelet and leukocyte adhesion and aggregation. In addition, NO also inhibits angiotensin II, a vasoconstrictor.

NO synthesis by NOSIII is activated in response to an increase in calcium following the binding of ligands such as acetylcholine, bradykinin, histamine, or insulin or following shear stress, the mechanical force of blood flow on the luminal surface of the vascular endothelium. Increased blood flow velocity thus stimulates calcium release and increased NOSIII activity, leading to vasodilation.

NO diffuses out of the endothelial cell and into adjacent smooth muscle cells where it binds to and activates soluble guanylate cyclase, which makes cGMP (Figure 11.23). cGMP activates protein kinase G, a cGMP-dependent kinase that phosphorylates a variety of channels, including L-type calcium channels, and receptors, all leading to inhibition of calcium influx into the smooth muscle cell. Vasoconstriction in vascular smooth muscle requires the influx of calcium, which binds to calmodulin that, in turn, activates muscle light chain kinase (MLCK). MLCK then phosphorylates myosin light chain (MLC), leading to cross-bridge formation between the myosin heads and the actin filament, resulting in contraction

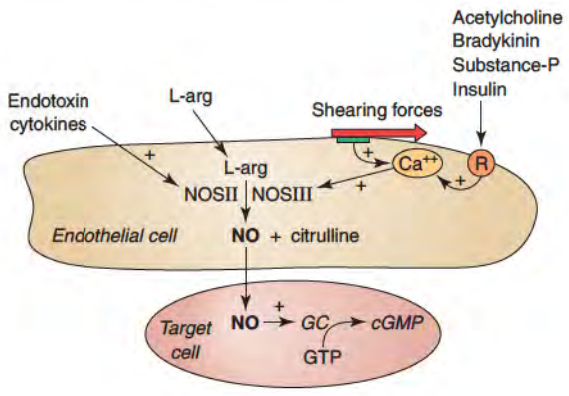

Figure 11.23 NO produced by NOSIII in the endothelial cell. Calcium concentration in the endothelial cell rises due to ligand binding or shear stress leading to activation of NO production by NOSIII. The NO diffuses across the membrane of the endothelial cell to a smooth muscle cell where it activates sGC.

CLINICAL CORRELATION 11.10

History and Biological Effects of Nitroglycerin

Nitroglycerin, more correctly called glyceryl trinitrate (GTN), was first synthesized by Ascanio Sobrero in 1846. Because GTN was extremely explosive and many fatal accidents occurred, Alfred Nobel developed a procedure in 1864 to stabilize GTN by mixing it with diatomaceous earth. The fortune he made from dynamite is the basis of the Nobel Prizes, awarded yearly in Sweden for outstanding contributions to the fields of physics, chemistry, physiology or medicine, literature, economics, and world peace. Shortly thereafter, in 1867, Sir Thomas Lauder Brunton first reported the use of inhaled amyl nitrate in his patients with chest pains, and in 1879, William Murrell published an article describing the use of the longer-lasting and more convenient compound GTN to better alleviate the pain of angina pectoris. GTN works by dilating the arteries of the heart, thus allowing more oxygenation of the tissue. Ironically, Murrell died in 1912 from untreated heart failure having never taken GTN, and Nobel refused to take it when prescribed by his doctor for heart disease.

It was not until 1987, over a century after Murrell's publication, that nitric oxide released from GTN metabolism was postulated to be the active agent in the dilation of the coronary blood vessels. It was not until 15 years later that the mechanism of nitric oxide release from nitroglycerin was elucidated. The mitochondrial aldehyde dehydrogenase (ALDH2) metabolizes GTN to 1,2-glycerol dinitrite and nitrite. The nitrite is further reduced to form NO. The mechanism of this reduction is unclear, but ALDH2 may also be involved in this step, and members of the mitochondrial electron transport chain have also been shown to reduce nitrite to NO. Alternatively, a major mechanism of nitrite reduction may be through direct reaction with deoxygenated hemoglobin or myoglobin.

When used over a long period of time for chronic conditions, GTN gradually loses its efficacy. Several mechanisms have been proposed to explain patient tolerance to this drug. Impaired biotransformation of GTN by ALDH2, which occurs on depletion of an ALDH2 reductant, or an increase in oxidative stress due to impaired mitochondrial metabolism are both possibilities.

(p. 978). Inhibition of calcium influx leads to decreased calmodulin stimulation of MLCK and decreased phosphorylation of MLC, causing diminished development of smooth muscle tension and, thus, vasodilation. Increased cGMP also directly causes MLC dephosphorylation by activation of MLC phosphatase. As with NOSI, cGMP levels are regulated by a balance between guanylate cyclase activity and the phosphodiesterases, which hydrolyze cGMP to 5′-GMP and thus turn off protein kinase G activity and vasodilation. Several therapeutic treatments are based on the administration of NO, either directly or in a precursor form. Clin. Corr. 11.10 discusses the history and use of nitroglycerin for vasodilation, and Clin. Corr. 11.11 discusses the use of direct NO administration as a therapeutic treatment.

NOSIII has a unique *N*-terminal sequence that undergoes myristoylation at one site and palmitoylation at two other sites within this sequence, localizing the enzyme to the membrane where it is targeted to plasmalemma caveolae. The caveolae are small invaginations of the plasma membrane, characterized by the presence of proteins called caveolins that serve to organize and attach signaling molecules such as receptors, *G*-proteins, and NOS to plasma membranes. At low cytoplasmic calcium concentrations, caveolin-1 binds to and inhibits NOSIII, maintaining it in an inactive state. On calcium influx, calmodulin competitively displaces the caveolin from NOSIII, resulting in activation of NOS synthesis.

Also localized to the caveolae are several other proteins important for NOSIII activity. The cationic amino acid transporter CAT-1, present in caveolae, is involved in the uptake of L-arginine, thus ensuring a supply of substrate for NO synthesis. NOSIII interacts with porin, a voltage-dependent anion/cation channel, which localizes NOSIII near a source of calcium influx. The bradykinin B2 receptor is also present, and it binds to and inactivates NOSIII. On stimulation with bradykinin, this complex dissociates, and NOSIII becomes activated. Localization to the caveolae is an important regulator of NOSIII activity; if palmitoylation is inhibited, NOSIII is not found in the caveolae, and synthesis of NO does not occur in those cells. Palmitoylation is a reversible process that is influenced by some agonists and is essential for membrane localization; cellular relocalization resulting in deactivation may occur on depalmitoylation.

CLINICAL CORRELATION 11.11

Therapeutic Uses of Inhaled Nitric Oxide

Systemically delivered nitric oxide causes systemic hypotension, severely limiting its usefulness as a therapeutic agent. On the other hand, nitric oxide that is inhaled would theoretically relax the pulmonary vasculature, but any excess NO that reached the bloodstream would be scavenged by oxy-hemoglobin, thereby preventing systemic vasodilation. Indeed, studies have shown that NO inhalation increased the systemic oxygenation of hypoxemic newborns with persistent pulmonary hypertension of the newborn (PPHN). Inhaled NO also decreased the incidence and mortality of bronchopulmonary dysplasia (BPD) in premature infants. In adults, chronic obstructive pulmonary disease (COPD) has been successfully treated with a combination of supplemental oxygen and NO; such a regimen reduced pulmonary arterial pressure and pulmonary vascular resistance and increased cardiac output in treated patients.

Many patients do not respond to inhaled NO therapy, however. In addition, the effects of NO are transient and disappear when treatment is discontinued, requiring continuous therapy. Approximately 70% of inhaled NO is excreted in the urine in the form of nitrate within 48 h. Several studies have described the use of Sildenafil, a drug used to treat erectile dysfunction, to augment or prolong the vasodilatory effects of inhaled NO. As discussed in Clin. Corr. 11.8, Sildenafil inhibits the breakdown of cGMP by inhibiting the cGMP-specific phosphodiesterase, PDE5, an isoform highly expressed in penile, retinal, and lung tissue. In patients with pulmonary hypertension, inhaled-NO-mediated pulmonary vasodilation was both augmented and prolonged by cotreatment with Sildenafil.

Interestingly, although inhaled NO has no effect on systemic blood pressure, other systemic effects have been reported, including platelet and leukocyte inhibition, which result in decreased thrombosis and reduced ischemia/reperfusion injury. It is believed that these systemic effects are mediated by blood-borne low- and high-molecular-weight thiols, which react with NO and transport it in a stable form throughout the body. *S*-nitrosylated hemoglobin and serum albumin, as well as other nitrosamines, iron-nitrosyls, and nitrated lipids are proposed mediators.

Bloch, K. D., Ichinose, F., Roberts, J. D., Jr., and Zapol, W. M. Inhaled NO as a therapeutic agent. *Cardiovascular Res.* 75: 339, 2007; and Griffiths, M. J. D. and Evans, T. W. Inhaled nitric oxide therapy in adults. *N. Engl. J. Med.* 353: 2683, 2005.

Many disease processes, such as hypertension, hypercholesterolemia, and diabetes lead to endothelial dysfunction, which is characterized by compromise of the normal functions of the endothelial cells, including vasodilation and mediation of platelet adhesion. One of the major hallmarks of endothelial dysfunction is the decreased bioavailability of NO, due to decreased function of NOSIII. Clin. Corr. 11.12 discusses some possible roles of NO in and mechanisms of endothelial dysfunction.

CLINICAL CORRELATION 11.12

The Role of eNOS in Endothelial Dysfunction

Nitric oxide derived from eNOS in the vascular endothelial cells is responsible for regulation of vascular tone, inhibition of platelet and leukocyte aggregation and adhesion, decreasing expression of proinflammatory genes, and limiting vascular smooth muscle cell proliferation. Impairment of endothelial function, endothelial dysfunction, is characterized by reduced NO synthesis leading to increased vasospasm, vascular inflammation, and thrombosis and is very often seen concomitant with other cardiovascular risk factors, such as diabetes, hypertension, atherosclerosis, or hypercholesteremia. It is believed that vascular oxidative stress, due to increased production of radical oxygen species, particularly superoxide, contributes to endothelial dysfunction due, in part, to reaction of superoxide with NO to form peroxynitrite. Not only is less NO available for its protective biological function, but peroxynitrite is a powerful oxidant and nitrating agent, which can damage protein, DNA, and lipid molecules. Covalent nitration of tyrosine residues in proteins by reactive oxygen species is often used as a marker of oxidative stress. Peroxynitrite is also responsible for depletion of tetrahydrobiopterin, which leads to uncoupling of eNOS electron transfer, causing eNOS to produce superoxide rather than nitric oxide, further exacerbating oxidative stress. In the absence of NO and in the presence of oxidative stress, several proinflammatory and proatherosclerotic pathways are activated; this is the primary molecular basis of endothelial dysfunction.

Treatment with antioxidant drugs, such as vitamin C or E, does not restore bioavailable NO levels, nor does it improve cardiovascular outcome, perhaps because the vitamins do not scavenge the superoxide before it reacts with NO. One of the most effective class of drugs is the statins, which function both by decreasing oxidative stress, via inhibition of NADPH oxidase activity, a prominent source of superoxide production, and by increasing NO production by eNOS, via both protein expression and phosphorylation. Angiotensin-converting-enzyme (ACE) inhibitors and angiotensin II receptor agonists also effectively improve cardiovascular outcome. These drugs decrease the formation/action of angiotensin II, a protein that activates the NADPH oxidases, thus reducing oxidative stress.

All of the NOSs produce NO, which serves such diverse functions as neurotransmission, vasodilation, muscle relaxation, and cytotoxicity. The consequences of NO can be beneficial, as in maintenance of vascular tone, acquisition of memory and learning, and protection against pathogen invasion, as well as detrimental, as with septic shock or chronic inflammatory and mutagenic responses. The net effect of the NO produced is dependent on where it is being produced, regulation of its production, how much is being produced, and which other reactive species are present.

cGMP
guanylate cyclase
protein kinase G
vasodilation
phosphorylation
neurotransmission

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. All of the following are correct about a molecule designated as a cytochrome P450 except it
   A. contains a heme as a prosthetic group.
   B. catalyzes the hydroxylation of a hydrophobic substrate.
   C. may accept electrons from a substance such as NADPH.
   D. undergoes a change in the heme iron on binding a substrate.
   E. comes from the same gene family as all other cytochromes P450.

2. Flavoproteins are usually intermediates in the transfer of electrons from NADPH to cytochrome P450 because
   A. NADPH cannot enter the membrane.
   B. flavoproteins can accept two electrons from NADPH and donate them one at a time to cytochrome P450.
   C. they have a more negative reduction potential than NADPH so accept electrons more readily.
   D. production of NADPH in the cytosol is the only source of electrons.
   E. they contain iron–sulfur centers.

3. NADPH-cytochrome P450 reductase
   A. uses both FAD and FMN as prosthetic groups.
   B. binds to cytochrome P450 by strong hydrophobic interactions.
   C. requires an iron–sulfur center for activity.
   D. always passes its electrons to cytochrome b_5.
   E. can use NADH as readily as NADPH.

4. Reactions after the 21-hydroxylation leading to cortisol and androgens occur in mitochondria which require NADPH-adrenodoxin reductase and adrenodoxin; NADPH-adrenodoxin reductase
   A. contains both FAD and FMN.
   B. passes its electrons to a protein with iron–sulfur centers.
   C. is an integral protein of the membrane.
   D. reacts directly with cytochrome P450.
   E. reacts directly with cytochrome b_5.

5. Genetic polymorphism in genes for cytochromes P450 could cause
- **A.** an individual to metabolize poorly certain drugs.
- **B.** an individual to metabolize certain drugs more rapidly than normal.
- **C.** a specific ethnic group to experience more effects with certain drugs.
- **D.** all of the above.
- **E.** none of the above.

6. In the presence of active nitric oxide synthase but absence of substrate,
- **A.** electrons cannot be transferred to heme.
- **B.** calmodulin cannot bind Ca^{2+}.
- **C.** the oxygenase and reductase domains dissociate.
- **D.** cGMP production is increased.
- **E.** superoxide and/or hydrogen peroxide will be formed.

Questions 7 and 8: Acetaminophen, an analgesic and antipyretic, is available alone or as a component of many nonprescription medications. Acetaminophen overdose, which can lead to liver damage, is a significant health problem. Consumption of alcoholic beverages can exacerbate the problem, especially if the acetaminophen is taken several hours post-alcohol intake. Acetaminophen, in normal doses, is nontoxic because it is metabolized using normal mechanisms for increasing water solubility.

7. Normally, acetaminophen is primarily metabolized by
- **A.** oxidation by cytochrome P450 (CYP2E1).
- **B.** conjugation with glucuronide or sulfate.
- **C.** conjugation with glutathione.
- **D.** addition of an –OH to the ring.
- **E.** reduction with NADPH.

8. Alcohol is both an inducer and substrate for CYP2E1. Alcohol taken at the same time as acetaminophen may protect the liver from injury. Which of the following is correct?
- **A.** CYP2E1 metabolizes alcohol but not acetaminophen.
- **B.** CYP2E1 is increased and converts acetaminophen to a nontoxic form.
- **C.** Taken at the same time, alcohol and acetaminophen compete for CYP2E1 so less toxic metabolite is formed.
- **D.** With the longer time gap, only alcohol reacts with CPY2E1.
- **E.** None of the above.

Questions 9 and 10: Because herbal remedies are not prescription drugs, many patients fail to inform their physicians that they are using such products. A patient was told by his physician that his blood cholesterol levels were not responding to the usually effective statin drug he was taking. The patient was also taking St. John's wort, an herbal agent, to improve his mood. St. John's wort induces a cytochrome P450 (CYP3A4) activity. Statins are one of the many drugs that are metabolized by CYP3A4.

9. The induction of cytochromes P450
- **A.** occurs only by exogenous compounds.
- **B.** occurs only at the transcriptional level.
- **C.** necessarily results from increased transcription of the appropriate mRNA.
- **D.** necessitates the formation of an inducer-receptor protein complex.
- **E.** may occur by posttranscriptional processes.

10. Statins could be considered xenobiotics (exogenous substances metabolized by the body). Many xenobiotics are oxidized by cytochromes P450 in order to
- **A.** make them carcinogenic.
- **B.** increase their solubility in an aqueous environment.
- **C.** enhance their deposition in adipose tissue.
- **D.** increase their pharmacological activity.
- **E.** all of the above.

Questions 11 and 12: Some patients show profound hypotension after abdominal surgery complicated by bacterial infections that produce endotoxins. Such hypotension is often refractory to treatment with conventional vasoconstrictor drugs. This hypotension may be caused by an overproduction of nitric oxide by the induced form of nitric oxide synthase (NOS). Administration of NOS inhibitors specific to this form might be an appropriate treatment for such patients.

11. Nitric oxide
- **A.** is formed spontaneously by a reduction of NO_2.
- **B.** is synthesized only in macrophages.
- **C.** is synthesized from arginine.
- **D.** acts as a potent vasoconstrictor.
- **E.** has three isoforms.

12. Nitric oxide synthase
- **A.** catalyzes a dioxygenase reaction.
- **B.** is similar to cytochromes P450 in binding zinc and tetrahydrobiopterin.
- **C.** accepts electrons from NADH.
- **D.** uses a flow of electrons from NADPH to FAD to FMN to heme-iron.
- **E.** is inhibited by Ca^{+2}.

Problems

13. Phenobarbital is a potent inducer of cytochrome P450. Warfarin, an anticoagulant, is a substrate for cytochrome P450 so the drug is metabolized more rapidly than normal. If phenobarbital is given to a patient, with no change in warfarin dosage, what would happen? What would happen if the warfarin dosage were adjusted for a proper response, and then phenobarbital withdrawn without adjusting the warfarin dosage?

14. Congenital adrenal hyperplasia (CAH) occurs because of a deficiency in CYP21A2, a 21-hydroxylase of endoplasmic reticulum. The disease results in decreased cortisol, increased ACTH, increased androgenic hormones, and problems related to salt balance. Explain why these should be so.

Answers

1. **E** Several gene families are known. A: All cytochromes are heme proteins. B: The types of substrates are hydrophobic. It is classified as a monooxygenase. C: This is the usual electron donor. D: The change from hexa- to penta-coordinated gives the compound a more positive reduction potential.
2. **B** Heme can accept only one electron at a time whereas NADPH always donates two at a time. A: NADPH passes only electrons; it does not have to enter the membrane. C: If this were true, the flow of electrons would not occur in the way it does. D: NADPH is required for both endoplasmic reticulum and mitochondrial mediated cytochrome P450 reactions. E: Iron–sulfur centers play a role in some, but not all, systems.
3. **A** This enzyme is one of two mammalian proteins known to do so. B: The binding is electrostatic. C: Some reductases do so but not this one. D: Only certain reactions catalyzed by the enzyme do. E: There are NADH-dependent reductases, but they are different enzymes.
4. **B** The iron–sulfur protein is adrenodoxin. A: It has only FAD. C: It is weakly associated with the membrane. D and E: Adrenodoxin acts as an electron shuttle between the reductase and heme of cytochrome P450.
5. **D** A: This occurs if the allelic variants code for inactive or less active proteins. B: If there is gene duplication, an individual may have larger amounts of active protein. C: There may be greater expression of specific allelic variants in specific ethnic populations.
6. **E** O_2 is activated leading to these toxic products. A: Superoxide results from the transfer. B and C: These do not happen. D: NO increases cGMP, and NO is not formed in absence of substrate.
7. **B** These are common mechanisms for increasing water solubility. A: This occurs but normally in small amounts; the product, NAPQ1, is the toxic metabolite. C: Glutathione is conjugated with NAPQ1 and renders it nontoxic. D and E: These do not occur.
8. **C** The competition lowers the production of NAPQ1, the toxic metabolite. A: Both are substrates. B: CYP2E1 converts acetaminophen to the toxic metabolite. D: Alcohol is metabolized more rapidly so the CYP2E1 it has induced is available to metabolize acetaminophen.
9. **E** There may be a stabilization of mRNA or decrease in the degradation of the protein. A: Both endogenous and exogenous substances can induce cytochromes P450. B and C: Transcriptional modification is only one of the mechanisms of induction. D: This has been shown with induction of some compounds but not all.
10. **B** Xenobiotics oxidized by cytochrome P450 are usually highly lipophilic but must be excreted in the aqueous urine or bile. A: This may happen but is certainly not the purpose. C: They do that prior to oxidation. D: Oxidation tends to reduce pharmacological activity.
11. **C** The other product is citrulline. A: It is formed from arginine. B: One of the isoforms of NO synthase has been found in macrophages, but neuronal and endothelial isoforms also exist. D: Nitric oxide is a vasodilator. E: Three isoforms of nitric oxide synthase have been identified but nitric oxide is a specific compound.
12. **D** This is one of two mammalian enzymes that use both FAD and FMN. A: The reaction is a monooxygenation. B: Cytochromes do not bind these. C: The donor is NADPH. E: The system requires Ca^{+2}-calmodulin, at least the neuronal and endothelial isoforms.
13. If warfarin is metabolized and cleared more rapidly by cytochrome P450, its therapeutic efficiency is decreased. At the same dosage, it will be less effective as an anticoagulant. If the phenobarbital is withdrawn, the cytochrome P450 levels will decrease with time to the uninduced level. With no change in the warfarin level, eventually there will be an increased possibility of hemorrhaging.
14. This enzyme converts 17-OH-progesterone to 11-deoxycortisol, the precursor of cortisol. It also converts progesterone to 11-deoxycorticosterone, a precursor of aldosterone which regulates salt balance. The decreased cortisol leads to an increased secretion of ACTH because of a decrease in feedback control. Prolonged elevated ACTH causes adrenal hyperplasia and an increased production of the androgenic hormones. Abnormalities in sexual development are common in infants with CAH.

Key Concepts

- Major biological membrane lipids are glycerophospholipids, sphingolipids, and cholesterol. Specific lipid composition varies with the source of the membrane.
- In aqueous medium, amphipathic lipids can form spheres (micelles) and vesicles (liposomes), which have a membrane consisting of a bilayer of randomly distributed lipids. Polar groups are in contact with the aqueous medium. Biological membranes have a similar structure.
- Membranes proteins are classified as integral (tightly bound) or peripheral (easily dissociated). Integral proteins have a single segment or multiple amino acid domains spanning the lipid bilayer. Some form homo- or hetero-oligomeric structures. Peripheral proteins have various means of attachment to the surface of the bilayer. Protein composition varies depending on function of the membrane.
- Lipids and proteins readily diffuse laterally in the bilayer but not transversely. Biological membranes have a chemical asymmetry. There are lipid–protein microdomains in membranes with specific roles.
- Membrane protein receptors interact with growth factors, hormones, and other small molecules initiating a cellular response. Some receptors are ion channels, while others initiate enzymatic reactions or intracellular protein–protein interactions.
- Specific protein structures in membranes facilitate translocation across the membrane of non-diffusable ions and compounds. They are classified as protein channels/pores or transporters. Transporters facilitate translocation without input of metabolic energy. Others require energy from hydrolysis of ATP or a $[Na^+]$ or $[H^+]$ gradient for translocation of a substrate.
- Some toxins form pores in membranes. Ionophores facilitate movement of ions across membranes.

Figure 12.1 Electron micrograph of the erythrocyte plasma membrane showing the trilaminar appearance. A clear space separates the two electron-dense lines. Electron microscopy has demonstrated that the inner dense line is frequently thicker than the outer line. Magnification about 150,000×.

12.1 • INTRODUCTION

Membranes of eukaryotic or prokaryotic cells have the same classes of chemical components, are similar in structural organization, and have many properties in common. They have a trilaminar appearance when viewed by electron microscopy (Figure 12.1), with two dark bands on each side of a light band. Most mammalian membranes have a width of 7–10 nm and a dense inner layer often thicker than an outer dense layer. Intracellular membranes are usually thinner than plasma membranes. Membranes have a chemical asymmetry and their surfaces are dotted with protruding globular proteins. They are dynamic structures that permit cells and subcellular structures to adjust their shape and to change position. The lipid is in a fluid state, in which both proteins and lipids are able to diffuse and interact.

Cellular membranes control the composition of space they enclose by excluding a variety of ions and molecules and by the presence of selective transport systems for transmembrane movement of substances. Concentrations of substances in cellular compartments are modulated by controlling translocation of substrates, cofactors, and ions across membranes. Extracellular regulators of cellular function bind to protein receptors on plasma membranes and their signal is transmitted from the membrane receptors to the appropriate metabolic pathway. Plasma membranes have a role in cell–cell recognition, in maintenance of cell shape, and in cell locomotion.

12.2 • CHEMICAL COMPOSITION OF MEMBRANES

Lipids and proteins are the major components of all membranes. Their concentrations vary greatly between membranes (Figure 12.2). Proteins are responsible for the function of membranes, and depending on the source, different membranes have very specific complements of proteins. A small amount of various polysaccharides, as either glycoproteins or glycolipids, are present in membranes but there is no free carbohydrate.

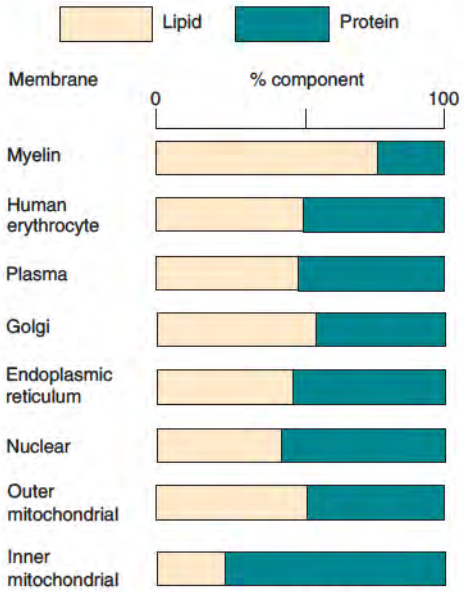

Figure 12.2 Percentage of lipid and protein in various cellular membranes. Values are for rat liver, except for the myelin and human erythrocyte plasma membrane. Values for liver from other species, including human, indicate a similar pattern.

Lipids Are Major Components of Membranes

Glycerophospholipids, sphingolipids, and cholesterol are the three major lipid components of eukaryotic membranes. Glycerophospholipids and sphingomyelin, a sphingolipid that contains phosphate, are classified as **phospholipids**. Bacteria and blue-green algae contain glycerolipids in which a carbohydrate is attached directly to the glycerol. Some membranes contain small quantities of other lipids, such as triacylglycerol and diol derivatives (p. 687 for structures), as well as lipids covalently linked to protein. Lipids have a structural role, but many also have other cellular functions.

Glycerophospholipids Are the Most Abundant Lipids of Membranes

Glycerophospholipids (phosphoglycerides) have a glycerol molecule with a phosphate esterified at the α-carbon (Figure 12.3) and two long-chain fatty acids esterified to the remaining carbon atoms (Figure 12.4). Glycerol does not contain an asymmetric carbon, but the α-carbon atoms are not stereochemically identical. Esterification of a phosphate to an α-carbon makes the molecule asymmetric. Naturally occurring glycerophospholipids are designated by the stereospecific numbering (sn) system (Figure 12.3) discussed on p. 708.

1,2-Diacylglycerol 3-phosphate, or **phosphatidic acid**, is the parent compound of the glycerophospholipids. **A phosphodiester bridge to glycerol attaches choline, ethanolamine, serine, glycerol, and inositol** (Figure 12.5). **Phosphatidylethanolamine (ethanolamine glycerophospholipids** or **cephalin)** and **phosphatidylcholine (choline glycerophospholipid** or **lecithin)** are the most common glycerophospholipids in membranes (Figure 12.6). **Phosphatidylglycerol phosphoglyceride** (Figure 12.7) **(diphos-**

phatidylglycerol or **cardiolipin**) contains two phosphatidic acids linked by a glycerol and is found nearly exclusively in mitochondrial inner membranes and bacterial membranes. Inositol, a hexahydroxy alcohol, is esterified to phosphate in **phosphatidylinositol** (Figure 12.8). Different phosphorylated derivatives are localized in different membranes; phosphatidylinositol 4-phosphate predominates in Golgi, phosphatidylinositol 4,5-bisphosphate in plasma membranes, and phosphatidylinositol 3-phosphate and phosphatidylinositol 3,5-bisphosphate in endosomes (A Closer Look 12.1).

Two fatty acids are esterified to C1 and C2 of glycerol in glycerophospholipids; the major ones are presented in Table 12.1. A saturated fatty acid is usually on C1 of glycerol and an unsaturated fatty acid on C2. There are 500 to 1000 molecular species of lipids in membranes principally because of the number of possible combinations of fatty acids in the different phospho- and sphingolipids. Designation of the different classes of phospholipids does not specify which fatty acids they contain. Phosphatidylcholine usually contains palmitic or stearic on C1 and a C_{18} unsaturated fatty acid, oleic, linoleic, or linolenic, on C2.

Phosphatidylethanolamine contains palmitic or oleic on C1 but a long-chain polyunsaturated fatty acid, such as arachidonic, on the C2 position. Each type of cell membrane has a distinctive composition of fatty acyl groups in its glycerophospholipids. The fatty acid composition of lipids has a significant impact on membrane function. Fatty acyl groups of

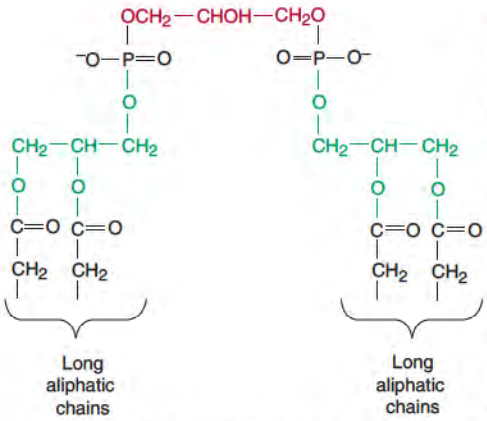

Figure 12.7 Phosphatidylglycerol phosphoglyceride (cardiolipin).

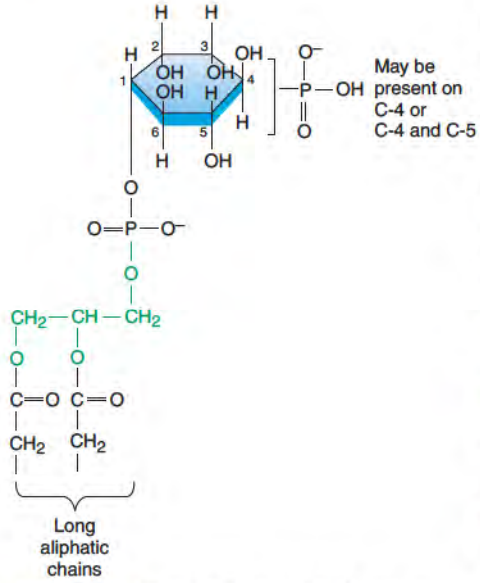

Figure 12.8 Phosphatidylinositol. Phosphate groups are also found on C4 or C4 and C5 of the inositol. The additional phosphate groups increase the charge on the polar head of this glycerophospholipid.

the same tissue in different species are very similar. Acyl group composition can change under different nutritional and pathophysiological conditions.

A saturated fatty acid is a straight chain, as is a *trans* unsaturated fatty acid. *Cis* double bonds, which occur in most naturally occurring fatty acids, create a kink in the hydrocarbon chain (Figure 12.9). The presence of unsaturated fatty acids in the phospholipid has a marked effect on the fluidity of the membrane (p. 472).

Glycerol ether phospholipids contain a long aliphatic chain in ether linkage to the glycerol at the C1 position (Figure 12.10). Ether phospholipids contain an alkyl group (alkyl acyl glycerophospholipid) or an α,β-unsaturated ether, termed a **plasmalogen**. Plasmalogens containing ethanolamine (**ethanolamine plasmalogen**) or choline (**choline plasmalogen**) esterified to the phosphate are abundant in nervous tissue and heart but not in liver. More than 50% of the ethanolamine glycerophospholipids in human heart are plasmalogens. High levels of ether-linked lipids in plasma membranes of metastatic cancer cells have been reported, suggesting a role for the lipids in the invasive properties of these cells.

Glycerophospholipids Are Amphipathic

Glycerophospholipids are **amphipathic**, containing a polar and nonpolar end. The charge on the polar end (head group) consists of a charged phosphate (pK ~2), which is negatively charged at pH 7.0, and any charge of the groups (bases) on the phosphate (Table 12.2). Choline and ethanolamine glycerophospholipids are **zwitterions** at pH 7.0, with a negative charge on phosphate and a positive charge on nitrogen. Phosphatidylserine has a positive charge on the α-amino group of serine and two negative charges, one on phosphate and one on the carboxyl group of serine, with a net charge of –1. In contrast, glycerophospholipids containing inositol and glycerol have only one negative charge on phosphate. The 4-phosphoinositol and 4,5-bisphosphoinositol derivatives are very polar compounds with negative charges on phosphate. The nonpolar end of glycerophospholipids consists of the hydrophobic hydrocarbon chains of the fatty acyl groups.

Sphingolipids Are Present in Membranes

The amino alcohols **sphingosine** (D-4-sphingenine) and **dihydrosphingosine** (Figure 12.11) are the basis for the **sphingolipids**. A saturated or unsaturated long-chain fatty acyl group in amide linkage with the amino group of sphingosine (Figure 12.12) is a **ceramide**, which is similar in structure to diacylglycerol. Various substitutions are found on the hydroxyl group at C1 of sphingosine. The **sphingomyelins**, the most abundant sphingolipids in mammalian tissues, have phosphorylcholine esterified at C1 (Figure 12.13) and are classified as phospholipids. Sphingomyelin and choline glycerophospholipid are similar in structure and have many properties in common; both are amphipathic. The fatty acid composition of sphingomyelin varies from tissue to tissue; myelin sphingomyelin contains predominantly longer-chain fatty acids (C_{24}).

A CLOSER LOOK 12.1

Phosphatidylinositols Have Many Functions

Phosphatidylinositols in cells have a variety of functions. They are involved in membranes as the source of second messengers (p. 534), in activation of membrane ion channels (p. 477), in activation of enzymes, involvement in endo- and exocytosis, and as anchors of proteins (p. 471). Phosphatidylinositol 4,5-bisphosphate is the source of the second messengers inositol trisphosphate and diacylglycerol (p. 535) that are involved in the action of some hormones. Phosphatidylinositol 3-phosphate and phosphatidylinositol 3,5-bisphosphate are presumed to be involved in control of membrane traffic in endosomes. They are also involved in the cytoskeleton and control of cell shape and motility and have been implicated in cytosolic and nuclear functions. Enzymes metabolizing phosphatidylinositols have been linked to human diseases.

Figure 12.11 Structures of sphingosine and dihydrosphingosine.

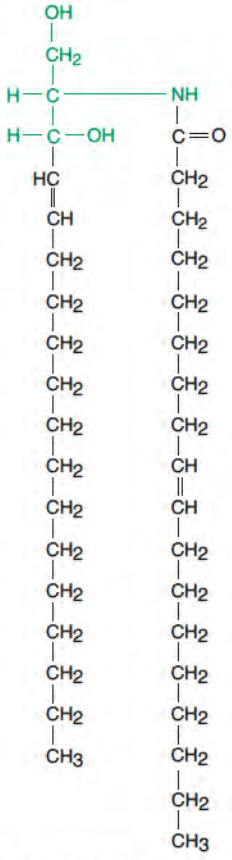

Figure 12.12 Structure of a ceramide.

Glycosphingolipids contain a sugar linked by a β-glycosidic bond to C1 OH group of a ceramide; they lack phosphate and are uncharged. A subgroup is the **cerebrosides**, which contain either glucose (**glucocerebrosides**) or galactose (**galactocerebrosides**). **Phrenosine** (Figure 12.14, p. 464) is a galactocerebroside that contains a C_{24} fatty acid in amide linkage. Galactocerebrosides predominate in brain and nervous tissue, whereas glucocerebrosides occur in small quantities in nonneural tissues. Galactocere-broside containing a sulfate group esterified on the C3 of the sugar are classified as **sulfatides** (Figure 12.15, p. 464). Cerebrosides and sulfatides usually contain fatty acids with 22–26 carbons. Neutral glycosphingolipids often have 2 (dihexosides), 3 (trihexosides), or 4 (tetrahexosides) sugar residues attached to the 1-OH group of ceramide. The usual sugar components are diglucose, digalactose, ***N*-acetyldiglucosamine**, and ***N*-acetyldigalactosamine**.

Gangliosides, the most complex glycosphingolipids, contain an oligosaccharide group with one or more residues of ***N*-acetylneuraminic acid (sialic acid)** (see p. 657 for structure); they are amphipathic compounds with a negative charge at pH 7.0 and represent 5%–8% of the total lipids in brain. Some 20 different types have been identified that differ in the number and relative position of the hexose and sialic acid residues. A detailed description of gangliosides is presented on p. 733. The carbohydrate moiety of gangliosides that extends beyond the surface of the membrane is involved in cell–cell recognition and binding of hormones and bacteria toxins, such as **cholera toxin** (p. 527).

Cholesterol Is an Important Component of Plasma Membranes

Cholesterol is a compact, rigid, hydrophobic molecule (Figure 12.16, p. 464), with four fused rings and a C8-branched hydrocarbon chain attached to the D ring at position 17. It has a polar hydroxyl group at C3. The presence of cholesterol in membranes alters the fluidity and reduces permeability.

Lipid Composition Varies between Membranes

Plasma and intracellular membranes have distinctive lipid compositions (Figure 12.17, p. 464). The membranes of a specific tissue, for example, liver, in different species contain very similar classes of lipids. The plasma membrane exhibits the greatest variation in percentage composition because cholesterol content is affected by the nutritional state of the animal. Myelin membranes of neuronal axons are rich in sphingolipids and have a high proportion of glycosphingolipids. Intracellular membranes, for example endoplasmic reticulum, contain primarily glycerophospholipids and little sphingolipids. The membrane lipid composition of mitochondria, nuclei, and rough endoplasmic reticulum is similar, with that of the Golgi complex being somewhere between that of intracellular and plasma membranes. Cardiolipin is high in inner mitochondrial membrane and low in outer membrane with essentially none in other membranes. The choline containing lipids, phosphatidylcholine and sphingomyelin, are most common, followed by phosphatidylethanolamine. The constancy of composition

of various membranes suggests a relationship between lipids and the specific functions of those membranes.

Membrane Proteins

Membrane proteins have a variety of functions, including a structural role to maintain the shape of the cell, as receptors for the binding of hormones and growth factors, as facilitators of transmembrane movement of solute and ions, and as enzymes involved in transduction of signals (p. 507). About 30% of genes in mammalian cells encode membrane proteins.

Membranes proteins are classified on the basis of the ease of separation of the protein from the lipid of the membrane. Isolation of **integral (intrinsic) membrane proteins** requires disruption of the membrane by detergents or organic solvents, and when isolated, they usually contain tightly bound lipid. These proteins are immersed in the lipid milieu of the membrane (p. 468). They contain sequences of hydrophobic amino acids, which constitute the segments of the protein in contact with the lipids of the membrane. The hydrophobic nature of these proteins, thus their water insolubility, has made it difficult to determine their three-dimensional structure and to study their functional properties.

Peripheral (extrinsic) membrane proteins are loosely attached to the surface of the lipid membrane. Treatment with salt solutions of different ionic strength, acidic or basic pHs of the medium, or cleavage of covalently bound lipid releases these proteins. Peripheral membrane proteins are subclassified on the basis of their mode of attachment to a membrane (p. 468). Many loosely attached peripheral proteins are typical water-soluble globular proteins.

Proteolipids are hydrophobic lipoproteins soluble in chloroform and methanol but insoluble in aqueous systems. They are present in many membranes but particularly in myelin, where they represent about 50% of the protein component. **Lipophilin**, a major lipoprotein of brain myelin, contains over 65% hydrophobic amino acids and covalently bound fatty acids. (See p. 470 for a discussion of localization and attachment of membrane proteins.)

Membrane Carbohydrates Are Part of Glycoproteins or Glycolipids

Carbohydrates are present in membranes as oligosaccharides covalently attached to proteins (glycoproteins) and to lipids (glycolipids). The sugars in the oligosaccharides include glucose, galactose, mannose, fucose, *N*-acetylgalactosamine, *N*-acetylglucosamine, and ***N*-acetylneuraminic acid** (sialic acid) (Figure 12.18 and Appendix). Structures of glycoproteins and glycolipids are presented on pages 659 and 732, respectively. The carbohydrate is on the extracellular surface of plasma membrane and luminal surface of endoplasmic reticulum. The roles for protein-bound carbohydrates include cell–cell recognition and adhesion, and receptor action. There is little or no free carbohydrate in membranes.

12.3 • MICELLES, LIPID BILAYERS, AND LIPOSOMES

Lipids Form Vesicular Structures

The basic structural characteristic of membranes is due to the physicochemical properties of the glycerophospholipids and sphingolipids. These amphipathic compounds with a hydrophilic head and a hydrophobic tail (Figure 12.19*a*) interact in aqueous systems to form spheres, termed **micelles** (Figure 12.19*b*). The charged polar head groups are on the outside of the sphere while the hydrophobic tails interact to exclude water. Micelles have only one polar surface, which is the side presented to the aqueous phase. Micelles that contain a single lipid or a mixture of lipids can be prepared. The concentration of lipid required for

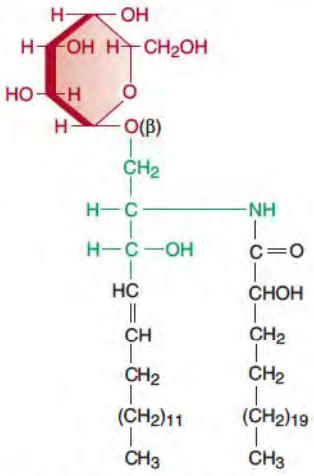

Figure 12.14 **Structure of a galactocerebroside containing a C_{24} fatty acid.**

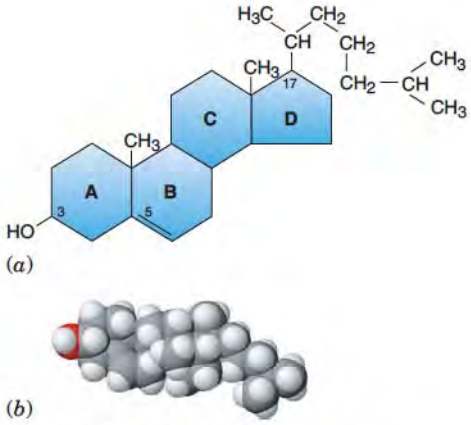

Figure 12.16 **Cholesterol.** (*a*) Structure of cholesterol. (*b*) Space-filling model. See Figure 12.3 for color scheme.
(*b*) Courtesy of Dr. Daniel Predecki, Shippensburg University, PA.

micelle formation is the **critical micelle concentration** (p. 1058). Formation of micelles also depends on the temperature and, if a mixture of lipids is present, on the ratio of concentrations of the different lipids. The structure of a micelle is very stable because of hydrophobic interactions between hydrocarbon chains and attraction of the polar head groups to water. Micelles are important in intestinal digestion and absorption of lipids (p. 1058).

Synthetic Lipid Bilayers and Liposomes

Amphipathic lipids, such as glycerophospholipids, can also form a bilayer structure with two layers of lipid. In this structure there is minimal contact of hydrocarbon chains with water. Polar head groups are at the interface between aqueous medium and lipid, and hydrophobic tails interact creating an interior hydrophobic environment that excludes water (Figure 12.19*c*). This bilayer configuration is the basic lipid structure of biological membranes. Lipid bilayers are extremely stable. They are held together by hydrophobic forces of the hydrocarbon chains and ionic interactions of charged head groups with water. Lipid bilayers self-seal if disrupted.

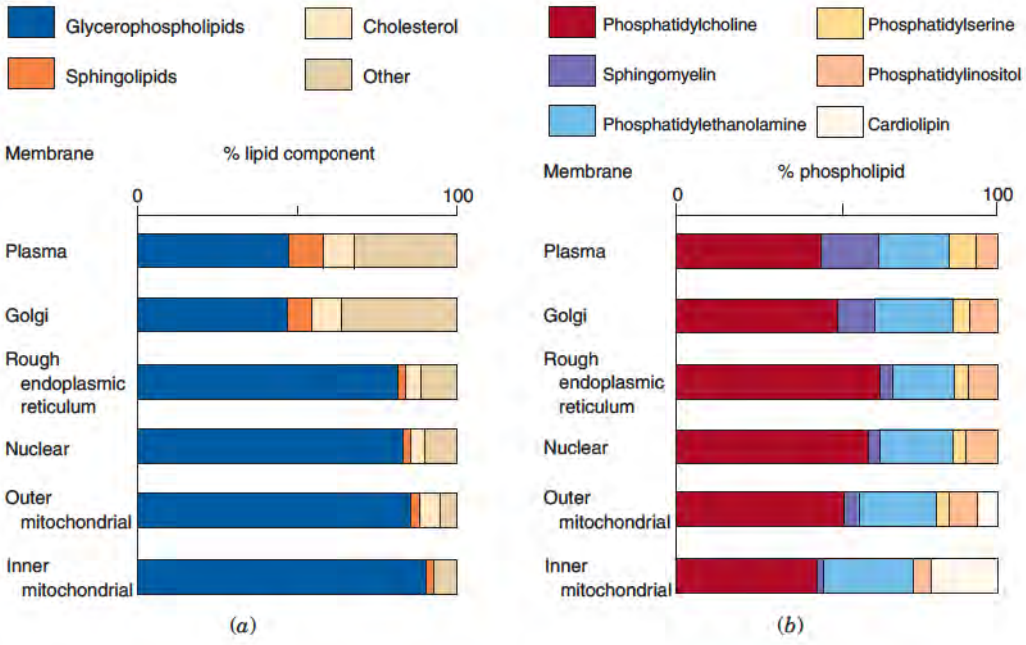

Figure 12.17 **Lipid composition of cellular membranes isolated from rat liver.** (*a*) Amount of major lipid components as percentage of total lipid. The area labeled "Other" includes mono-, di-, and triacylglycerol, fatty acids and cholesterol esters. (*b*) Phospholipid composition as a percentage of total phospholipid. Values from Harrison, R., and Lunt, G. G. *Biological Membranes.* New York: Wiley, 1975.

A lipid bilayer will form a spherical vesicle, separating the external environment from an internal aqueous compartment. Such vesicles, termed **liposomes** (Figure 12.19*d*), have been prepared using purified lipids and mixtures of lipids from biological membranes. Depending on the procedure, unilamellar and multilamellar (vesicles within vesicles) vesicles of various sizes (20 to 1000 nm in diameter) are prepared. The ability of amphipathic lipids to self-assemble into bilayers is an important property for formation of cell membranes.

General Properties of Lipid Bilayers

Phospholipid molecules readily exchange places with neighboring molecules in the separate monolayers, leading to rapid lateral diffusion in the plane of the membrane (Figure 12.20). In the preparation with different lipids of artificial membranes, lipids distribute randomly between monolayers. Rotation occurs around the carbon–carbon bonds in fatty acyl chains; in fact, there is a greater degree of rotation nearer the methyl end, leading to greater motion at the center than at the surface of the lipid bilayer. Individual lipid molecules do not flip-flop readily from one monolayer to the other because of thermodynamic constraints on movement of a charged head group through the lipophilic core. In addition, lipids do not readily escape from the bilayer. Lipid bilayers, therefore, have an inherent stability in which individual molecules move rapidly in their own monolayer but do not readily exchange with an adjoining monolayer.

Interaction of lipids in a bilayer is very different from that illustrated in Figure 12.19*c*. The interior of membrane bilayers is very fluid and in constant motion. Acyl chains of glycerophospholipids and sphingolipids have a random motion, intercalating with chains in the opposing monolayer. The viscosity is higher closer to the lipid head groups. Cholesterol in the bilayer reduces the fluidity near the surface of the membrane because cholesterol does not extend into the layer as far as the acyl chains of phospholipids. Figure 12.21 is a computer representation of the arrangement of phospholipids in a bilayer at a moment in time. Several layers of ordered water molecules on the surface of membranes influence the environment of the membrane.

The lipid bilayer is essentially impermeable to nonlipid (as an example, carbohydrates) and charged molecules but not to neutral hydrophobic molecules. Inorganic ions (Na^+, K^+, Cl^-, etc.), charged organic molecules, and macromolecules outside liposomes do not have access to the interior of liposomes. During liposome formation, nonpermeable solutes, however, can be trapped in the aqueous interior. Thus, both the external and internal environments of liposomes can be manipulated, and properties, including ability to exclude molecules, interaction with various substances, and stability under different conditions can be evaluated. Liposomes are an important tool in studying aspects of natural membrane structure and function. Proteins isolated from biological membranes have been incorporated into liposome membranes for study of their function. With some limited success, liposomes of varying lipid and protein composition have been tested in both animals and humans as a replacement for red cell, to deliver encapsulated drugs, and as vectors for gene therapy (Clin. Corr. 12.1).

CLINICAL CORRELATION 12.1

Liposomes as Carriers of Drugs, Proteins, and Nucleic Acids

Liposomes have been used for administration of a variety of therapeutic substances in order to target specific organs or tissues. Both hydrophilic and hydrophobic compounds can be carried, the former in the aqueous interior and the latter in the liposome membrane. Liposomes prepared from purified phospholipids are nontoxic and biodegradable. Cationic liposomes have been evaluated that will interact with the cell membrane surface charge, and others with specific proteins to bind specific cellular membrane receptors. Uptake of liposomes can be by fusion with the cell membrane or by endocytosis. Liposomes have found a use with drugs that are metabolized very rapidly. Incorporation of the drug in liposomes permits release over a longer time period, thus increasing their effectiveness. Antibiotic, antineoplastic, antimalarial, antiviral, antifungal, and antiinflammatory agents are effective when administered in liposomes. It may be possible to prepare liposomes with a high degree of tissue specificity so that drugs and perhaps even enzyme replacement may be possible with this technique. Liposomes have been tested as a vehicle to introduce nucleic acids into cells for gene therapy and treatment with small RNAs. In another use, liposomes containing concentrated hemoglobin have been tested with some success as a transfusion alternative in place of red blood cells.

12.4 • STRUCTURE OF BIOLOGICAL MEMBRANES

Mosaic Model of Biological Membranes

All plasma and intracellular membranes are lipid bilayers, with amphipathic lipids and cholesterol oriented so that their hydrophobic portions interact to minimize contact with water or other polar groups. Their polar head groups are at the interface with the aqueous environment. Proteins are distributed on the surface or immersed in the lipid bilayer and can diffuse laterally in the **sea of lipid**. There is, however, molecular organization of biological membranes, including constraints on random diffusion of lipids and proteins in some domains. Figure 12.22 is a model of a biological membrane, indicating a degree of organization. The general characteristics of lipid bilayers explain many of the properties of cellular membranes, including fluidity, flexibility that permits change of shape and form, ability to self-seal, and impermeability.

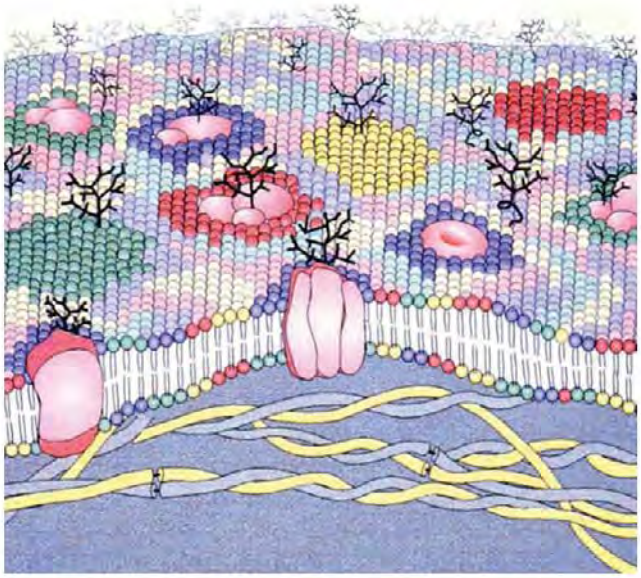

Figure 12.22 Model of a mammalian plasma membrane. The various lipids are different colored spheres; they would be more random than indicated. Proteins are represented by globular structures, and carbohydrates are attached to proteins by the black trees on the external surface of the membrane. The fiber network underneath the membrane represents the cytoskeleton and its association with the membrane.
Figure very generously supplied by Professor P. Kinnunen, University of Helsinki, Finland.

Lipids Are Asymmetrically Distributed in Membranes

Lipids are distributed asymmetrically in the two bilayers of biological membranes. Each layer has a different composition of glycerophospholipids and sphingolipids. The asymmetric distribution of lipids of the plasma membrane of the human erythrocyte is presented in Figure 12.23. Sphingomyelin is predominant in the outer layer, whereas phosphatidylethanolamine is predominant in the inner lipid layer. Phosphatidylinositols are not shown in Figure 12.23 because of their low amounts but are located primarily in the inner layer; the amount varies depending on the tissue. The transbilayer distribution of cholesterol is not known. Lipids in intracellular membranes are also distributed asymmetrically but not with

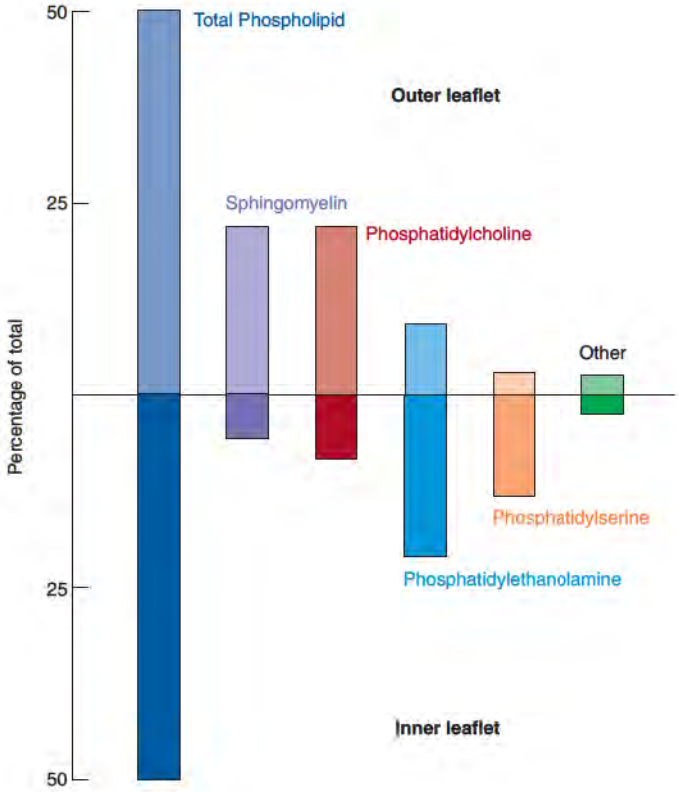

Figure 12.23 Distribution of phospholipids between inner and outer layers of the human erythrocyte membrane. Values are percentage of each phospholipid in the membrane. Others include phosphatidylinositol, phosphatidylinositol 4-phosphate, phosphatidylinositol 4,5-phosphate, and phosphatidic acid.
Data from Verkeij, A. J., Zwaal, R. F. A., Roelofsen, B. Comfurius, P. et al. *Biochim. Biophys. Acta* 323: 178, 1973; and Zachowski, A. *Biochem. J.* 294: 1, 1993.

the same pattern as in the plasma membrane. The asymmetry accounts for some of the functional differences in the two layers.

The asymmetry of lipids is established during biosynthesis of membranes on the endoplasmic reticulum. Uncatalyzed transverse movement (flip-flop) between bilayers of membrane lipids is slow but does occur. Asymmetry of lipids is maintained by **lipid transporters**, which catalyze unidirectional movement of specific lipids from one layer to the other sometimes against their concentration gradient. A subclass of ATP-dependent lipid transporters, **aminophospholipid translocases** or **flippases**, specific for phosphatidylserine and phosphatidylethanolamine catalyze the transport of these aminoglycerolipids from the extracellular to the cytoplasmic layer. They are responsible for maintaining low concentrations of these phospholipids in the outer layer of plasma membranes. An outward-directed ATP-dependent transporter, termed **floppase**, is nonspecific for phospholipids. A third type of lipid transporter, **phospholipid scramblase**, facilitates bidirectional mixing of phospholipids between the two leaflets, thus randomizing the phospholipids between the layers. It is nonspecific with respect to phospholipids, not ATP dependent, and is stimulated by increases in intracellular Ca^{2+}. Phospholipid scramblase 1 (PLSCR 1) can be reversibly palmitoylated-depalmitoylated and contains a protein kinase C phosphorylation site for control of activity (p. 535). Scramblases have an important role in the cell-mediated coagulation cascade (p. 984), and recognition by the reticuloendothelial system of dying cells (p. 1010). In both responses, the movement of phosphatidylserine from the inner to the outer leaflet leads to exposure of phosphatidylserine on the extracellular surface and a change in charge on the surface.

Integral Membrane Proteins

Interactions of proteins to biological membranes are illustrated in Figure 12.24. **Integral membrane proteins** are embedded in the membrane with a defined orientation determined by their primary structure. Their **transmembrane segments** contain sequences rich in hydrophobic amino acids such as leucine, isoleucine, valine, and phenylalanine, which are in contact with the lipid milieu. Some have large globular domains in contact with the aqueous environment on one or both sides of the membrane, and some, particularly those in the plasma membrane, are glycoproteins.

Depending on the specific protein, the amino and carboxyl termini can be on opposite sides or both on one side of the membrane. In the former case, the carboxyl terminus

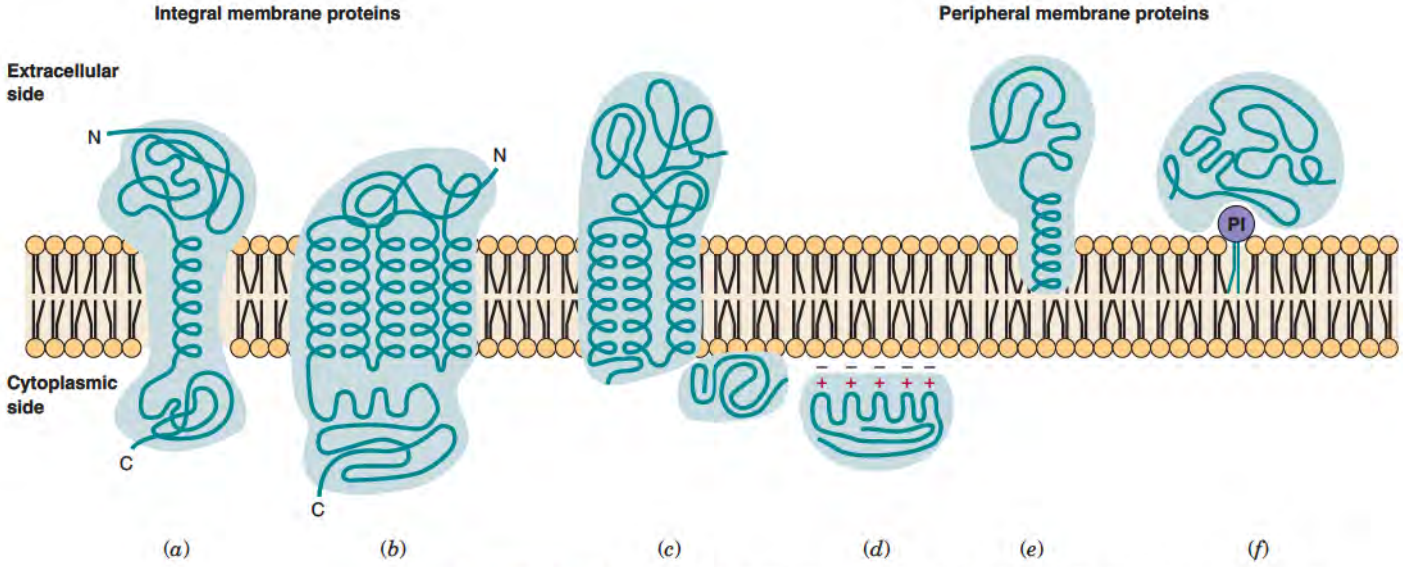

Figure 12.24 Interactions of membrane proteins with the lipid bilayer. Diagram illustrates the multiple types of binding of proteins in or to the lipid bilayer. (*a*) A single transmembrane segment. (*b*) Multiple transmembrane segments. (*c*) Bound to an integral protein. (*d*) Bound electrostatically to the lipid bilayer. (*e*) Attached by a short terminal hydrophobic sequence of amino acids. (*f*) Non-covalent binding to a phosphatidylinositol (PI) in the membrane.

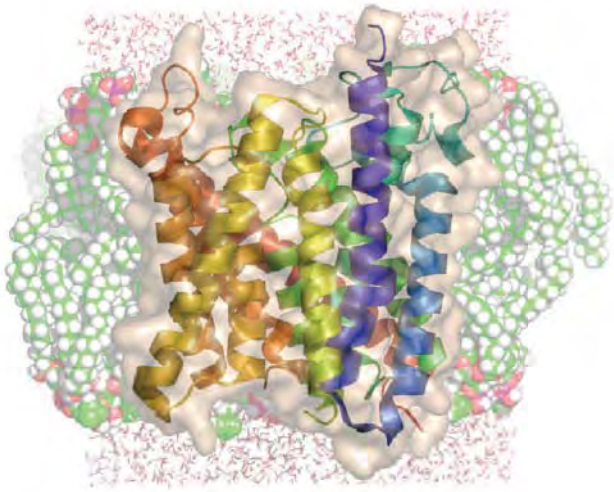

Figure 12.25 Integral membrane protein. The illustration shows one subunit of the trimeric ammonium transporter protein AmtB from *E. coli* embedded in a lipid bilayer membrane. Note the lipid–protein interaction, and the aqueous periplasmic (top) and intracellular (bottom) compartments on both sides of the membrane. Figure very generously supplied by Professor Fritz K. Winkler and Dr. Peter Hasler, Paul Scherrer Institute, Switzerland.

is often found on the cytoplasmic face. Many proteins of the plasma and endoplasmic reticulum membranes have a fourfold abundance of positively charged lysine and arginine residues on the cytoplasmic surface compared to the extracellular or luminal surface. Transverse (flip-flop) movement of integral proteins is prevented by their bulkiness and thermodynamic restrictions.

The transmembrane segments of most integral membrane proteins are α-helical but β-barrel motifs are also found. Some proteins contain a single transmembrane α-helical segment, as illustrated in Figure 12.24*a*. An example is **glycophorin**, with 131 residues, present in the plasma membrane of human erythrocytes; the transmembrane sequence consists of amino acid residues 73–91. The amino-terminus is exterior to the cell and contains various oligosaccharides including the ABO and MN blood group determinants; glycophorin contains 60% by weight carbohydrate. The **integrins** also have a single transmembrane segment; this ubiquitous family of proteins links the cytoplasm to the extracellular matrix (p. 367) and mediates transmembrane signaling in both directions.

Other integral proteins have multiple transmembrane sequences that loop back and forth across the lipid bilayer (Figure 12.24*b* and *c*). Figure 12.25 illustrates such a protein; note the interaction of the lipid with the protein and the aqueous compartments on both sides of the membrane. The number of putative transmembrane segments is determined by plotting the degree of hydrophobicity of each amino acid residue in the protein (p. 86). Those sequences with a high proportion of hydrophobic amino acids suggest a transmembrane segment. The hydropathy plot for aquaporin, an integral membrane protein, is presented in Figure 12.26; the plot indicates the presence of six

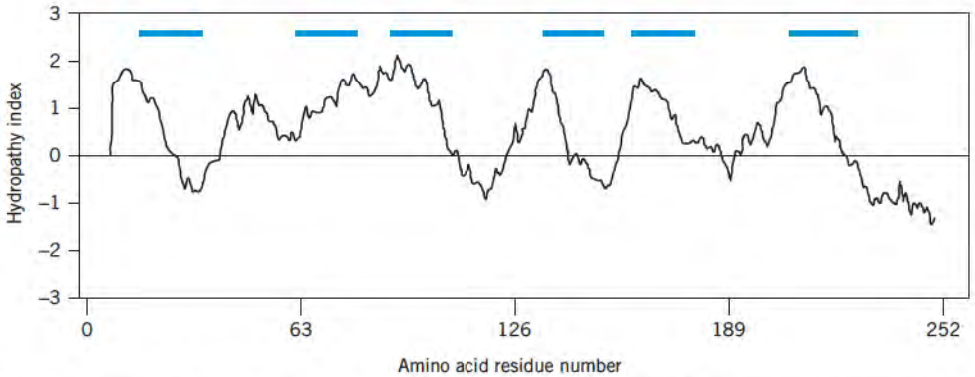

Figure 12.26 Hydropathy plot of aquaporin1 from human erythrocytes. Hydropathy index for an amino acid is a value indicating their hydrophobic and hydrophilic tendency. The more positive the value, the more hydrophobic the amino acid; a positive value is a good predictor of whether the amino acid will be in contact with an aqueous environment. Segments of the protein containing a high proportion of hydrophobic amino acids are considered to be putative transmembrane segments.

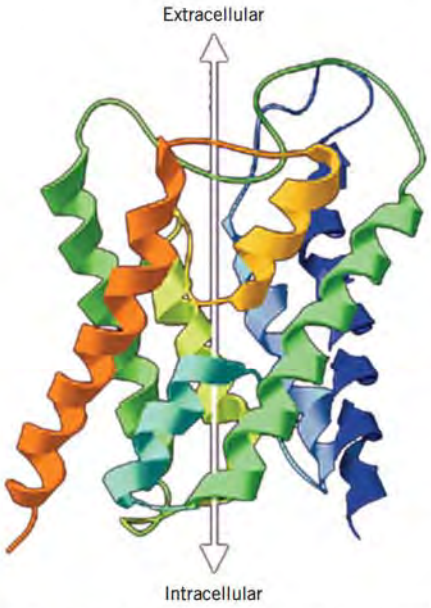

Figure 12.27 Multiple α-helical transmembrane segments. Ribbon model of human red cell AQP1 monomer. Multiple α-helical transmembrane segments form a tubular structure. The amino-terminus is blue and the carboxy-terminus is red. Six membrane-spanning tilted helices surround two hemipores (loops with short helices—cyan and orange) that meet in the center of the bilayer. The white arrow illustrates the aqueous channel through the protein.
Figure reproduced with permission from Kozono, D., Yasui, M., King, L. S., and Agre, P. Aquaporin water channels: atomic structure and molecular dynamics meet clinical medicine. *J. Clin. Invest.* 109: 1395, 2002. Copyright (2002) *Amer. Soc. Clin. Invest.* via Copyright Clearance Center.

putative transmembrane sequences. Proteins with putative transmembrane sequences from 2 to 24 have been identified on the basis of amino acid analysis of the protein or by gene analysis. Multiple α helical transmembrane segments of an integral protein are often organized to form a tubular structure, which can serve as a passageway for movement of molecules through the membrane (Figure 12.27). The **anion channel** of human erythrocytes forms a tubular channel (p. 490) that mediates the exchange of Cl^- and HCO_3^- across the membrane. It has two major domains: a hydrophilic amino-terminus domain on the cytoplasmic side of the membrane with binding sites for **ankyrin**, a protein that anchors the cytoskeleton and other cytoplasmic proteins, and a domain of 509 amino acids with 12 transmembrane sequences. With an even number of transmembrane segments, the carboxyl terminus is also on the cytoplasmic side. A common motif of integral proteins is oligomerization of the same monomers (homomeric complexes) and oligomerization of different monomers (heteromeric complexes).

Integral membrane proteins contain specific domains for ligand binding, for catalytic or transport activity, and for attachment of carbohydrate. The presence of bound lipids and specific sites for water molecules suggest a high degree of structural and functional variability. They are not rigid structures, and their shape in the membrane can be altered by interaction with other proteins and small molecules. The modulating effects of lipids on a protein may reflect a change in ordering and fluidity of the membrane as well as a direct influence on the activity of the protein. Many integral proteins bind specific lipids by non-covalent interactions between the charged head groups as well as the hydrophobic tail. Examples of the influence of lipids on protein activity are the requirement of D-β-hydroxybutyrate dehydrogenase (p. 698) for phosphatidylcholine for activity, and the stabilization of respiratory chain complexes by cardiolipin (p. 460). Maximum activity of diacylglycerol kinase occurs with phosphatidylcholine with C_{18} chains, and cholesterol has been implicated in the activity of various membrane ion pumps and acetylcholine receptors.

Peripheral Membrane Proteins: Lipid Anchors

Peripheral membrane proteins are on the surface of membranes and can be easily removed without disrupting the lipid bilayer. Many have a transient association with the membrane, with cyclic attachment and reattachment. This controls their activity. Many are involved in intracellular signal transduction (p. 509).

Their different methods of attachment are illustrated in Figure 12.24*c–f* (p. 468). Some bind to integral membrane proteins, such as ankyrin binding to the anion channel in erythrocytes (Figure 12.24*c*). Negatively charged phospholipids of membranes interact with positively charged regions of proteins and produce electrostatic binding (Figure 12.24*d*); in some cases Ca^{2+} mediates the binding. Several peripheral proteins have short sequences of hydrophobic amino acids at one end that serve as a membrane anchor (Figure 12.24*e*). Other peripheral membrane proteins have a specific conserved domain that binds non-covalently to the inositol 3-phosphate head group of phosphatidylinositol fixed in the membrane (Figure 12.24 *f*). Some proteins have several different forms of attachment.

A number of peripheral proteins have covalently linked lipid that is inserted into the lipid membrane, thus anchoring the protein to the membrane. The various types of lipid anchors are presented in Table 12.3 and Figure 12.28. One such anchor involves phosphatidylinositol (see Figure 12.8, p. 460), attached to a **glycan** consisting of ethanolamine, phosphate, mannose, mannose, mannose, and glucosamine (p. 659). The glycan is covalently bound to the carboxyl terminus of a protein by ethanolamine (Figure 12.28*a*), and the glucosamine is linked covalently to phosphatidylinositol. The fatty acyl groups of phosphatidylinositol are inserted into the lipid membrane. This form of attachment is referred to as a **glycosylphosphatidylinositol (GPI)** anchor; the fatty acyl groups appear to be specific for different proteins. Release and reattachment of the protein to the anchor is controlled, allowing regulation of the activity of the protein. A specific phosphatidylinositol-specific phospholipase C catalyzes the hydrolysis of the phosphate–inositol bond leading to release of the protein The GPI anchor also controls the localization of the protein on the membrane. Over 50 proteins including enzymes, antigens, and cell adhesion proteins are so attached (Table 12.3). The GPI anchor has been conserved through evolution.

TABLE 12.3 • Types of Lipid Anchors

Type of Anchor	*Lipid Involved in Attachment*	*Attachment*	*Representative Proteins*
Phosphatidyl inositol (GPI)	Phosphatidylinositol	Glycan (ethanolamine, phosphate, mannose, mannose, mannose, and glucosamine)	Acetylcholine esterase Alkaline phosphodiesterase Carbonic anhydrase Cell–cell adhesion molecules Cell surface hydrolases Lipoprotein lipase Scrapie prion protein Surface antigens
Myristoyl	Myristic acid (C_{14})	Amide linkage at N-terminal glycine	β-Adrenergic receptor c-CAMP protein kinase Insulin receptor α-Subunit of G protein
Thioester and hydroxy ester	Myristic acid (C_{14}) Palmitic acid (C_{16}) Stearic acid (C_{18}) Oleic acid (C_{18})	—SH or —OH of Cysteine Serine Threonine	G-protein-coupled receptors Transferrin receptor
Thioether-linked	Isoprenoid lipid Farnesyl (C_{15}) Geranylgeranyl (C_{20}) Dolichol	Cysteine	Many GTP-binding proteins Nuclear lamins Protein kinases Protein phosphatases

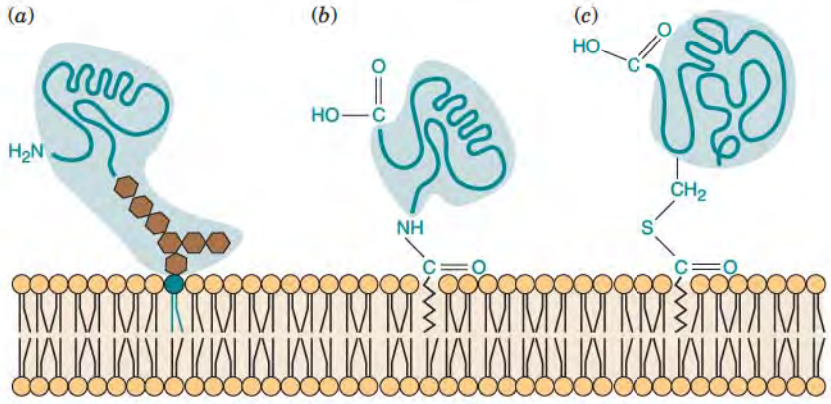

Figure 12.28 Types of lipid anchors for attachment of membrane proteins. (*a*) Glycosylphosphatidylinositol (GPI) anchor. (*b*) Myristoyl anchor. (*c*) Thioester anchor.

Thio-ester-linked acyl anchors (Table 12.3) involve myristic acid (C_{14}), palmitic acid (C_{16}), stearic acid (C_{18}), and oleic acid (C_{18}) covalently linked to a cysteine. The acyl groups serve as membrane anchors (Figure 12.28*c*) and acylation affects the protein in many ways including function, subcellular localization, stability, and interaction with other proteins. The acyl group is often found close to a myristic acid in amide linkage to an N-terminal glycine or a prenylated cysteine at the C-terminus. The function of the acylated protein is controlled by a dynamic cycling of acylation and deacylation. These acylated proteins serve as signaling molecules and are involved in vesicular transport and the neuronal synapse.

Another form of lipid attachment of a peripheral protein involves a thioether linkage between the protein and the isoprenoid lipids farnesyl (C_{15}) or geranylgeranyl (C_{20}) (Figure 12.29). Attachments are referred to as **CAAX prenylated proteins** because the isoprenoid is attached to a cysteine residue in the sequence Cys-Aliphatic-Aliphatic-Any residue close to the carboxyl terminus. The X apparently directs which isoprenoid is linked; glutamine, methionine, or serine is required for attachment of farnesyl, and leucine for geranylgeranyl. CAAX prenylated proteins are usually attached on the cytoplasmic surface.

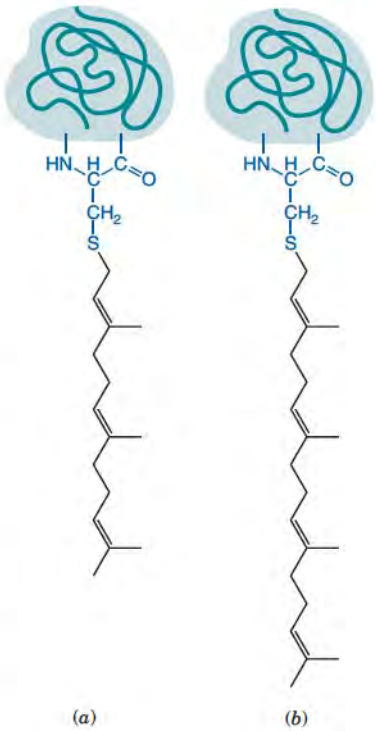

Figure 12.29 Isoprenoid thioether anchor for attachment of membrane proteins. (*a*) Farnesyl anchor. (*b*) Geranylgeranyl anchor.

Lipids and Proteins Diffuse in Membrane Leaflets

Interactions among different lipids and between lipids and proteins are very complex and dynamic. There is fluidity in the lipid portion of membranes, and individual lipids and proteins move rapidly across the surface of membranes. With artificial lipid membranes, the degree of fluidity is dependent on the temperature. At low temperatures, lipids are in a gel-crystalline state, restricting their mobility; as temperature increases a phase transition occurs, with an increase in fluidity (Figure 12.30). In biological membranes there is a mixture of liquid-ordered and liquid-disordered phases presumably depending on the lipid and protein composition, rather than a transition gel-crystalline to liquid-crystalline state. In fact, interactions between lipids and proteins lead to variations in the ordered–disordered states throughout the membrane and to differences in fluidity in different areas.

Membranes with glycerophospholipids containing short-chain and unsaturated fatty acyl groups have greater fluidity. *Cis*-double bonds in unsaturated fatty acids of phospholipids lead to kinks in the hydrocarbon chain; this prevents tight packing of the chains and creates pockets in the hydrophobic regions. Cholesterol with its flat, stiff ring structure reduces the coiling of the fatty acid chain and decreases fluidity. The clinical significance of high blood cholesterol on the fluidity of cell membranes is described in Clin. Corr.12.2.

CLINICAL CORRELATION 12.2

Abnormalities of Cell Membrane Fluidity in Disease

Membrane fluidity can control the activity of membrane-bound enzymes and functions such as phagocytosis, and cell growth and death. A major factor in the fluidity of the plasma membrane in higher organisms and mammals is the presence of cholesterol. With increasing cholesterol content, the lipid bilayers become less fluid on their outer surface but more fluid in the hydrophobic core. Erythrocyte membranes of individuals with spur cell anemia have increased cholesterol content, a spiny shape, and the cells are destroyed prematurely in the spleen. This condition occurs in severe liver disease such as alcoholic cirrhosis. Cholesterol content is increased 25%–65%, and the fluidity of the membrane is decreased. Erythrocyte membranes require a high degree of fluidity to pass through the capillaries. Increased plasma membrane cholesterol in other cells leads to an increase in intracellular membrane cholesterol, which also affects their fluidity. The intoxicating effect of ethanol on the nervous system is probably due to modification of membrane fluidity, altering membrane receptors and ion channels. Individuals with abetalipoproteinemia have an increase in sphingomyelin content and a decrease in phosphatidylcholine in cellular membranes, with a decrease in membrane fluidity.

Changes in membrane fluidity have been suggested as a factor in lecithin:cholesterol acyltransferase deficiency, hypertension, and Alzheimer disease. As techniques for measurement and evaluation of cellular membrane fluidity improve, some of the pathological manifestations in disease may be explained based on changes in membrane structure and function.

Cooper, R. A. Abnormalities of cell membrane fluidity in the pathogenesis of disease. *N. Engl. J. Med.* 297: 371, 1977; Muller, W. E., Kirsch, C., and Eckert, G. P. Membrane-disordering effects of beta-amyloid peptides. *Biochem. Soc. Trans.* 29: 617, 2001; and Tsudo, K., and Nishio, I. Membrane fluidity and hypertension. *Amer. J. Hypertension* 16: 259, 2003.

Ca^{2+} ion decreases fluidity of membranes because of its interaction with negatively charged head groups of the phospholipids, reducing repulsion between polar groups and increasing packing of lipid molecules. This causes aggregation of lipids into clusters and reduces fluidity. The asymmetric distribution of phospho- and sphingolipids leads to a difference in fluidity of the two leaflets. The hydrocarbon chains of the lipids are flexible, producing a greater degree of fluidity in the hydrophobic core than closer to the surface, where there are more constraints from stiffer portions of the hydrocarbon chains.

The composition of fatty acyl chains of phospholipids and of cholesterol in membranes is altered by diet, changes in cellular Ca^{2+}, free radicals, and lipid peroxidation, leading to a change in membrane fluidity. Anesthetics increase membrane fluidity *in vitro* and may act *in vivo* through their effect on membrane fluidity of specific cells. Anesthesia is induced by structurally unrelated compounds with common lipid solubility. Changes in fluidity of membranes in hypercholesteremia, hypertension, diabetes mellitus, obesity, alcoholism, schizophrenia, and Alzheimer disease have been reported.

Microdomains of Lipid–Protein Complexes Are Present in Membranes

There is a heterogeneous rather than homogeneous distribution of lipids and proteins in membranes. **Microdomains** containing specific lipids and proteins are present. These domains, referred to as **lipid rafts**, are organized bilayer structures with a different distribution of lipids than the surrounding membrane. Thus, biological membranes are actually a fluid mosaic of different microdomains (Figure 12.31). In plasma membranes they constitute a significant percentage of the total area. The function of lipid rafts is to segregate and concentrate specific proteins to facilitate their activity. Smaller rafts assemble and disassemble constantly and diffuse freely in the membrane. Plasma membranes and membranes destined to interact with the plasma membrane, such as the *trans* side of the Golgi complex, contain an abundance of these microenvironments but they may also occur in other cellular membranes. Membrane rafts are defined as small (10–200 nm), heterogeneous, dynamic microenvironments enriched with cholesterol and sphingolipids. The lipids in all rafts, however, are not necessarily in the same physical/chemical state. The higher concentration of cholesterol makes them less fluid than the surrounding lipid environment. Cholesterol is important in the assembly of the lipid rafts in the Golgi complex and in maintaining their integrity and function. The domains may play a role in cholesterol transport.

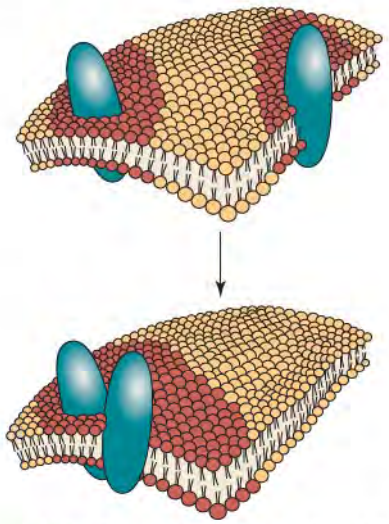

Figure 12.31 Schematic representation of lipid rafts of membrane. The diagram indicates the movement of lipid rafts with merging of rafts and association of two proteins.

The outer leaflets of rafts have a higher concentration of ceramides and glycosphingolipids (p. 460), which usually contain longer chain fatty acids. Their accumulation in the outer leaflet leads to areas of increased membrane thickness. The inner leaflet contains phospholipids with more highly saturated acyl chains than in the nonraft areas, which allows close packing of the chains. Thus, lipids in the rafts are more ordered and tightly packed than the surrounding bilayer. In addition, electrostatic interactions of polar head groups, hydrophobic interactions of cholesterol with selected phospholipids or glycolipids, and protein–lipid interactions constrain movement of lipids. Through protein–protein and protein–lipid interaction smaller rafts cluster to form larger, ordered subdomains in the membrane. Some of these are located in specific regions of the plasma membrane.

Some membrane proteins are associated mainly with rafts, some move in and out, and others are present only in the nonraft portions of the membrane.

Glycosylphosphatidylinositol (GPI)-anchored proteins (p. 470) partition into lipid rafts and CAAX prenylated anchored proteins (p. 471) are in rafts on the inner leaflet. In some cells the raft and the sequestered protein are attached to the cytoskeleton of the cell. Certain proteins involved in cell signaling are maintained in the inactive state in individual rafts; activation occurs when several rafts cluster together, forming a larger raft and bringing together the inactive proteins (Figure 12.31). Other proteins have a weak affinity for rafts in the unliganded state but after binding to a ligand undergo a conformational change or oligomerize increasing their affinity for a specific raft. Some peripheral membrane proteins are palmitoylated leading to association with a raft; they dissociate on depalmitoylation.

Plasma membranes of cells from some tissues contain **Caveolae**, small flasklike invaginations whose lipid composition is similar to the lipid rafts; they have a high content of

cholesterol and glycosphingolipids. Caveolae contain the cholesterol-binding proteins **caveolin-1, -2,** or **-3** that may be responsible for stabilizing the structure.

Lipid rafts are involved in many cellular processes, including membrane sorting and trafficking, and cell polarization. Growth factor and G protein receptor signaling also involve membrane rafts. The roles of lipid rafts in the pathogenesis of conditions such as Alzheimer, Parkinson, cardiovascular diseases, systemic lupus erythematosus, and HIV have been reported. Bacteria, prions (Clin Corr. 3.6, p. 114), viruses, and parasites utilize lipid rafts of cells for their infectivity.

Dynamic Environment of Membranes

Biological membranes (see Figure 12.22, p. 467) are in a state of constant change, with movement of proteins and lipids laterally, with association and dissociation of proteins in the membrane, with proteins and lipids moving into and out, and with modification (e.g., acylation and phosphorylation) of proteins. Even the thickness of the lipid bilayer varies due to the changing composition of lipids and proteins. Microenvironments are constantly being formed and dispersed. A membrane is a very crowded environment considering the estimated number of enzymes, receptors, channels, and transporters present. Mammalian plasma membrane components interact with the cytoskeleton of the cytoplasm, extracellular components, and other cells. Neither words nor illustrations can capture the complexity and dynamic state of biological membranes or their extensive role in so many different biological processes.

12.5 • MEMBRANE RECEPTORS

Biological cells have a large number of specific protein **receptors** that bind other molecules or react to specific stimuli to initiate a cellular response. Receptor proteins are either bound to plasma or intracellular membranes, or are present as soluble proteins in the cytoplasm or nucleus. The molecules binding to a receptor, referred to as **ligands**, are a communication link, or **signal**. Signal molecules can be generated in one compartment of a cell to stimulate a change in an activity present in another part of the same cell, or the signal may be generated by one cell to alter the activity of a different cell. Intercellular signal molecules, that is, ligands generated by one cell to change the activity of another cell, react either with receptors on the plasma membrane or with intracellular receptors. Ligands such as charged molecules, peptides, and proteins cannot transverse the membrane because of their charge or size and react with plasma membrane receptors on the extracellular face of the membrane. Molecules that can diffuse through the plasma membrane, such as steroids, bind to intracellular soluble receptors. Intracellular signals can either bind to soluble receptors or ones on the cytoplasmic side of the membrane. There are a variety of initial responses to the ligand receptor interaction including activation of an enzyme, release of an intermediate molecule that is recognized by a subsequent intermediate in a signal pathway, or opening of a channel in the membrane to permit the flux of ions. The major signal transduction pathways are presented in Chapter 13 (p. 503), and tissue responses to signal molecules will be described in presentations of individual cellular processes.

Signaling between cells allows individual cells to respond to the requirements of the whole organism; representative responses to ligand receptor binding are listed in Table 12.4. There are hundreds of different plasma membrane receptors; Table 12.5 lists three major classes. The largest and most diverse group of membrane receptors is the G protein-coupled receptors (p. 522) that occur in both prokaryotic and eukaryotic cells.

TABLE 12.5 • Classification of Plasma Membrane Receptors

Classification of Receptor	*Examples of Receptor*
G-Protein coupled	Glucagon Acetylcholine
Catalytic: tyrosine kinase	Insulin Erythropoietin
Ion transport	γ-Aminobutyric acid Glutamate

Membrane receptors are classified on the basis of homology of structure of the protein and mechanism; representative receptors with their ligands/activity are listed in Table 12.6. Receptors have a high degree of specificity for ligands and some receptors respond to stimuli such as light and temperature (Table 12.7). There are also plasma membrane receptors, such as the Toll-like receptors (TLR) that induce a response when bacteria or viruses bind; binding stimulates a host defense against the invading pathogens. Transport of proteins destined for secretion between endoplasmic reticulum and Golgi involve membrane receptors that recognize specific cargo-encoded sorting signals on the proteins.

TABLE 12.6 • Representative Plasma Membrane Receptors

Receptor	*Number of Receptors*	*Representative Ligand or Activity*
Cytokine type 1 receptors	43	Leptin
Cytokine type 2 receptors	11	Interferon

TNF/NGF	33	Tumor necrosis factor precursor

*TM, transmembran; Source: Human Plasma Membrane Receptors, www.receptome.org.

Binding of a **signal molecule** to its receptor is an equilibrium process (p. 512). This is similar to the binding of substrate to an enzyme, but in most cases of receptor binding there is no chemical modification of the bound ligand. As the concentration of free ligand in the aqueous phase increases or decreases, the ligand associates or dissociates from the receptor; dissociation ends the signaling process. Most receptors have very high affinities for their ligands, and some receptors react with ligands of dissimilar structure. Receptors are excellent targets for action of pharmaceuticals.

It has been estimated that about 5% of proteins coded in the human genome are plasma membrane receptors. The high degree of tissue specificity of action of signal molecules is because cells in different tissues express different receptors. As an example, insulin, a signal molecule, alters the metabolism of glucose in muscle and liver but not in most other tissues. Cellular response to a ligand is modulated by the number of receptor molecules in the plasma membrane. An increase in number of receptors, termed **upregulation** of receptor, the greater the cellular response; a decrease, or **downregulation**, leads to a decrease in response. Incorporation into and removal from the membrane of receptors is a controlled process.

Membrane receptors that span the membrane can have a single transmembrane or multiple transmembrane amino acid domains. The G protein-coupled receptors that occur in bacteria and eukaryotic cells (p. 522) have seven discrete transmembrane domains (7TM receptors). The human 7TM receptors are classified into six families on the basis of the sequence similarities of their transmembrane domains. Some receptors require formation of homomeric or heteromeric oligomers for activity. Binding of a ligand alters the tertiary or quaternary structure, leading to initiation of the cellular response. In one class of receptors a surface receptor binds to a ligand and then binds to second receptor (signal receptor) that initiates the cellular reaction. In this case, the ligand binding receptor is referred to as a **coreceptor**.

12.6 • TRANSLOCATION OF MOLECULES THROUGH MEMBRANES

Some Molecules Diffuse through Cell Membranes

Diffusion of a chemical species through a membrane involves (1) leaving the aqueous environment on one side and entering the membrane, (2) traversing the lipid milieu of the

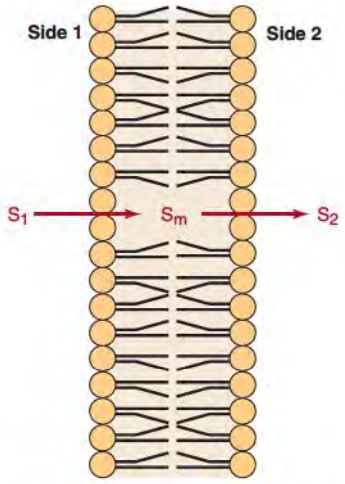

Figure 12.32 Diffusion of a solute molecule through a membrane. S_1 and S_2 are solute on each side of membrane, and S_m is solute in membrane.

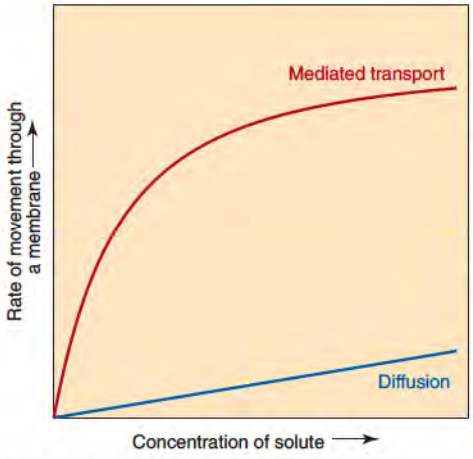

Figure 12.33 Kinetics of movement of a solute molecule through a membrane. Initial rate of diffusion is directly proportional to the concentration of solute. In mediated transport, rate will reach a V_{max} when carrier is saturated.

membrane, and (3) leaving the membrane and entering the aqueous phase on the opposite side (Figure 12.32). The flow can only be down the concentration gradient of the substance. Thermodynamic and kinetic constraints control the concentration equilibrium on two sides of a membrane and the rate at which it attains equilibrium. The rate of diffusion of a chemical species in a membrane is directly proportional to its solubility and diffusion coefficient in lipids; the latter is a function of the size and shape of the substance. Movement of solutes by diffusion is from a higher to a lower concentration, and the rate is described by Fick's first law of diffusion (Eq. 12.1).

$$J = -D\left(\frac{\delta c}{\delta x}\right) \tag{12.1}$$

where J = net amount of substance moved per time, D = the diffusion coefficient, and $\delta c/\delta x$ = chemical gradient of substance. As the concentration of solute on one side of the membrane is increased, there is an increasing *initial rate* of diffusion as illustrated in Figure 12.33. Net movement of molecules from one side to another will continue until the concentration in each is at chemical equilibrium. Continued exchange of solute molecules from one side to another occurs after equilibrium is attained but there is no net accumulation on either side as this would recreate a concentration gradient.

Gases, such as O_2, N_2, CO_2, NO, CO, and H_2S, and lipophilic molecules diffuse through the hydrophobic regions of a membrane. Water diffuses under osmotic forces, but in most cells the rate does not meet the needs for rapid equilibration of the aqueous phases on each side of the plasma membrane; a family of proteins, the aquaporins, facilitates transmembrane movement of water (p. 579). The shell of water surrounding many solutes must be stripped away before the solute enters the lipid milieu. Inorganic ions and charged organic molecules do not diffuse at a significant rate because of their attraction to water and the exclusion of charged species by the hydrophobic environment of membranes. Uncharged organic molecules, such as sugars, are essentially excluded, as are peptides, proteins, and nucleic acids because of their size and charge. If diffusion does occur, the rate is too slow to accommodate cellular needs.

Protein-Based Mechanisms for Translocation

Several hundred protein-mediated systems, each with a different set of proteins, have evolved to facilitate movement of water, ions, nutrients, metabolic waste products, and macromolecules across different cellular membranes. The proteins involved in each system from different organisms and even between organs in a species are very similar but not identical. A functional classification system of the membrane transport proteins, recommended by the **International Union of Biochemistry and Molecular Biology (IUBMB)** (Table 12.8), divides them into classes, subclasses, families, and subfamilies on the basis of mechanism of transport and their properties. Many of the proteins are present only in prokaryotes; many others in both prokaryotes and eukaryotes, including mammals. There is a structural homology of the proteins in many of the subfamilies. The following discussion will focus on transport systems in mammalian cells and specifically on the classes designated **pore/channel** (1.A., 1.B, and 1.C) and **transporter** (2.A and 3.A) (Table 12.8). A variety of other terms for describing transport systems appear in the scientific literature, but the current recommended nomenclature will be used here.

Pores and channels involve the presence of an aqueous pore in the protein structure through which molecules diffuse; movement is controlled by a gating mechanism. Transporter proteins are similar to enzymes, binding the solute on one side of the membrane, then changing conformation, and moving the substrate to the environment on the opposite side of the membrane. This occurs within the membrane portion of transport protein. Most pores/channels and transporters have a high degree of solute specificity. The rate of substrate translocation by channels is higher than by specific transporters; for channels the rate is about 10^7 ions/s, which is the rate of diffusion of a substance in water, whereas with transporters it is about 10^2–10^3 molecules/s.

A variety of substances, termed **substrates**, are transported, including inorganic anions and cations, water, metabolic intermediates, organic molecules, drugs, and macromolecules. In eukaryotic cells, substances translocated are unchanged during the process. Some bacteria have a class of transporters termed group translocation where the substrate is chemically

modified during transport (A Closer Look 12.2). Some substrates are transported by two different mechanisms in different cells and in some cases in the same cell. Subfamilies of membrane transport proteins have many isoforms, all with the same function. As an example, the kidney nephron has at least seven different isoforms of aquaporins, all responsible for translocation of water. In addition, many transporters are controlled by intra- or extracellular signal molecules and are also referred to as receptors for the specific ligand (Section 12.5; p. 474).

A CLOSER LOOK 12.2

Group Translocation and the γ-Glutamyl Cycle

Some bacteria have a mechanism for uptake of sugars, termed **group translocation**, where the sugar to be transported is chemically modified during translocation. The sugar is phosphorylated after binding to but before release from the transporter. The phosphorylated sugar is released into the cytoplasm and not the original unphosphorylated sugar. No group-translocation system has been found in mammalian cells. The γ-glutamyl cycle (p. 790), an important system for amino acid uptake by some mammalian cells, involves the modification of an amino acid by γ-glutamyl tranferase on the external surface of the cell membrane. The modified amino acid is then transported to the cytoplasm by an amino acid transporter. This cycle is not classified as group translocation because separate proteins catalyze the chemical modification and the transport.

12.7 • MEMBRANE CHANNELS AND PORES

Membrane **channels** and **pores** are ubiquitous in living organisms, being present in all types of organisms, from bacteria to higher eukaryotes. Channels and pores permit diffusion in aqueous channels created by the transporter proteins. They do not sequester molecules or ions in transit, and their specificity is based on the size and charge of the substance. Diffusion in channels and pores is (1) down the concentration gradient of the substance crossing the membrane, (2) active without utilization of metabolic energy for the actual movement of the substance, (3) regulated by specific mechanisms that open or shut the passageway, and (4) inhibited by various compounds. Pores consist of a number of different proteins and, in comparison to channels, have a very complex structure. A major difference between channels and pores is the specificity in what the system will permit to be translocated. Pores have relatively large openings, permitting a variety of small and large molecules to tranverse the membrane, whereas channels have a high degree of solute specificity.

Structures of Membrane Channels

Channel proteins have one of two major structures: α-type channels and β-barrel channels. **α-Type channels** are homo- or hetero-oligomeric proteins, in some cases with several dissimilar subunits, and can have 2 to 22 transmembrane **α-helical segments** (see Figure 12.27, p. 470). A common physical characteristic of channels is a structure formed by

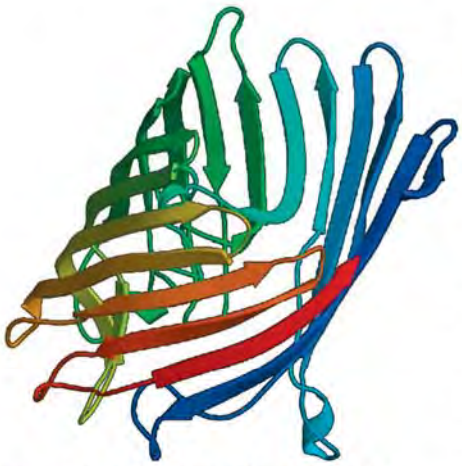

Figure 12.34 Structure of Ompf porin in a tetragonal crystal form. The transmembrane segments of the porin are β-helices.
PDB ID: 10PF. Cowan, S. W., Garavito, R. M., Jansonius, J. N., Jenkins, J. A. et al. The structure of Ompf porin in a tetragonal crystal form. *Structure* 3: 1041, 1995.

amphipathic α-helices from different transmembrane segments within a single polypeptide chain or of different protein subunits to create a central aqueous channel. In addition to the domains containing the actual pore, channel proteins contain domains for ligand binding or for sensing physical changes, such as changes in the membrane potential, which control the opening and closing of the channel. α-Type channels in mammals function as cellular sensors, responding to temperature changes, touch, pain, osmolarity, pheromones, taste, and other stimuli.

β-Barrel channels have a transmembrane sequence consisting of **β-strands** that form a β-barrel structure (p. 93) with a water filled channel from 0.6 to 3 nm in diameter (Figure 12.34). They are present in the outer membranes of mitochondria (porins), some bacteria, and plastids. Several bacterial porins consist of 16-stranded antiparallel β-barrel structures with hydrogen bonding between nearest neighbors along the chain. Polypeptide loops line the inner barrel wall limiting channel width and restricting size of molecules diffusing through. This subclass of channels has a wide range of substrate selectivity from inorganic ions to proteins. Porins can either be nonselective or exhibit some degree of selectivity, and some allow passage of any molecule smaller than a specific cutoff size.

Control and Selectivity of Membrane Channels

The two most studied classes of channels are those that respond to a change in the transmembrane potential, referred to as **voltage-gated channels**, and those responding to binding of a ligand, the **ligand-regulated channels.** Voltage-gated channels have a specific sensor domain in the protein that detects membrane potential changes and transfers the energy to the channel domain to control its gate. As examples, depolarization of the plasma membrane leads to opening of Na^+ channels. The mitochondrial outer membrane contains a voltage-dependent anion channel consisting of β-sheets, which permits the passage of substances of up to 10 kDa and has a role in apoptosis (p. 1010). Ligand-regulated channels respond to the binding of specific extracellular or intracellular chemical ligands (also referred to as **agonists)** and, depending on the channel, leads to either an opening or closing of the channel. Some have several ligand-binding domains, which permit cooperativity in binding. Opening and shutting is achieved in different ways including (1) with α-helical transmembrane segments that line the pore moving as a rigid body by tilting, rotating, or bending and (2) an attached terminal end that swings into the channel and physically plugs it.

Binding of acetylcholine to the **nicotinic-acetylcholine receptor** opens the channel, allowing flow of Na^+ into the cell. This is important in neuronal electrical signal transmission (p. 942). Other channels are controlled by binding neurotransmitters (p. 514), cAMP (p. 530), inositol 1,4,5-trisphosphate, diacylglycerol (p. 534), and G proteins (p. 522). Opening of most channels is very fast, permitting bursts of ion flow of 10^7 ions per second through the membrane. This rate is necessary because many of these channels are involved in nerve conduction and muscle contraction. The surface of a nerve terminal can contain several hundred different channels, including voltage-dependent channels for Ca^{2+} and K^+, Ca^{2+}-gated K^+ channels, Cl^- channels, ligand-gated channels, and stretch-activated channels. Some channels are controlled not only by ligand binding but also by phosphorylation-dephosphorylation. A number of pharmacological agents are used therapeutically to modulate channels; those that inhibit are referred to as **antagonists**.

Different classes of channels are very selective with respect to the inorganic ion, small organic molecule (e.g., urea), or protein allowed to move through the channel. The **Na^+ channel** of plasma membranes of eukaryotic cells permits movement of Na^+ at a rate more than 10 times greater than that for K^+, and some K^+ channels are 100–1,000 times more permeable to K^+ than Na^+. Other channels are less specific. Some members of the family of aquaporins are selective only for water while others permit translocation of both water and small, neutral organic molecules (p. 479). There are also differences from tissue to tissue in channels transporting the same solute. Over 15 different K^+ specific voltage-dependent channels have been reported in humans. One method of selectivity involves rings of positively charged residues in the channel, which exclude cations and facilitate flow of anions; negatively charged residues facilitate flux of cations.

TABLE 12.9 • Site of Expression of Selected Aquaporins in Humans

Tissue	*Location of Expression*	*Aquaporin*	*Function*
Blood cells	Erythrocytes	AQP1	Osmotic protection

Representative Membrane Channels and Pores

Aquaporins and Aquaglyceroporins

It is essential for all cells to control the distribution of water across the plasma and internal membranes because osmotic pressure changes can cause expansion or contraction of enclosed compartments. Nonfacilitated diffusion of water across biological membranes occurs, but it is too slow to account for the required rates of water movement. Over 200 different channel proteins in plants, bacteria, insects, and vertebrates permit the translocation of water and other small molecules and as a group are referred to as **aquaporins (AQP)**. Twelve mammalian aquaporins have been identified, which are divided by amino acid sequence homology and functional characteristics into channels that are selective only for water (aquaporins) and those that permit translocation of water and small solutes (**aquaglyceroporins**). The aquaporins permit movement of H_2O but not hydronium ions (H_3O^+), thereby maintaining the pH gradient across the cell membrane. Humans have at least 10 aquaporins and aquaglyceroporins (AQP0 to AQP9); sites of expression of selected aquaporins in humans are presented in Table 12.9. Some tissues have several different isoforms with different functions; the kidney has at least seven isoforms located at distinct sites along the nephron and collecting duct. Clin. Corr. 12.3 describes the distribution of aquaporins in kidneys and examples of pathophysiological changes. Plant aquaporins contribute to water uptake by rootlets, transpiration, and seed desiccation.

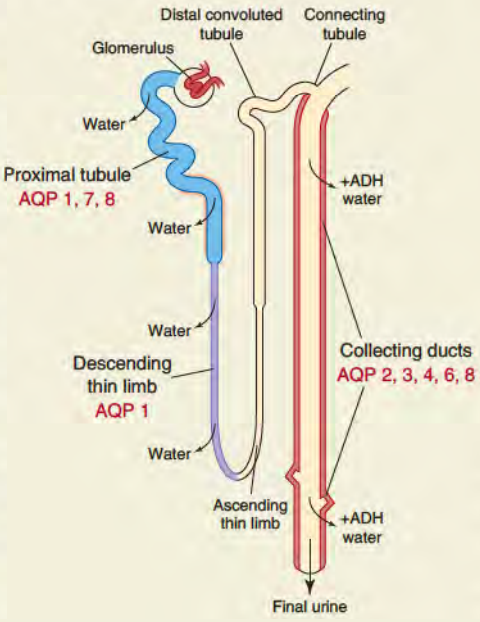
Aquaporins are small, hydrophobic, intrinsic membrane proteins with several highly conserved amino acid sequences. They assemble in membranes as homotetramers (Figure 12.35). Each monomer, consisting of six transmembrane α-helical domains, contains a distinct water pore. AQP1 of the human erythrocyte contains a highly conserved sequence motif consisting of an asparagine–proline–alanine in two separate loops. The loops fold into the lipid bilayer in an hourglass fashion forming an aqueous channel. The selectivity is due to a constriction of the channel to about 2.8 Å, which limits the size of molecules that can pass through. The aqueous pathway of AQP1 (Figure 12.36, p. 481) is lined with conserved hydrophobic residues and a few hydrophilic residues that attract H_2O but not charged molecules such as H_3O^+. Water molecules apparently flow through the channel in single file.

CLINICAL CORRELATION 12.3

The Mammalian Kidney and Aquaporins

The primary role of the kidney is to regulate the pH of blood, eliminate toxic products of metabolism, and regulate water balance of the body. Each kidney contains about one million nephrons, the multicellular functional units of the tissue. Each nephron has several distinct regions (see diagram), each with very specific functions in the processing of the blood filtrate, which occurs in the glomerulus. A large quantity of blood is filtered (about 150 L/day) and the water must be reabsorbed in the nephron and collecting ducts except for about 1.5 L that is excreted as urine. Aquaporins are responsible for the recovery of water from the filtrate as it flows through the lumen of the nephron. As indicated in the diagram, at least seven different isoforms of aquaporins, located at different sites along the nephron and collecting ducts, are responsible for water reabsorption.

There are a number of renal disorders where the reabsorption of water is abnormal and where the expression and function of the aquaporins has been investigated. Several animal models of these conditions have been invaluable in determining the cause of some of these conditions. Low levels of AQP2 and polyuria (excessive excretion of urine) are found in acquired nephrogenic diabetes insipidus (NDI), acquired hypokalemia (low blood K^+), and hypercalcemia (increased blood Ca^{2+}). In many cases, NDI is caused by the inability of the kidney to respond to vasopressin (p. 892); it is considered that this leads to a decreased expression and /or incorporation of AQP2 in the membrane. In other cases of NDI, there is a defect in the aquaporin gene; in some cases, this defect leads to an inability of the monomers to form normal tetramer structures. Levels of AQP1, AQP2, and AQP3 in animal models are reduced in tissue ischemia. In some conditions, such as congestive heart failure, liver cirrhosis, and pregnancy, there is an increase in the amount of AQP2 in the kidney, leading to an expansion of the extracellular fluid volume. Humans lacking AQP1 activity of the kidney apparently do not have any measurable problems under normal but may under stress conditions (dehydration). It is expected that additional clinical conditions will be attributed to changes in the other aquaporins.



Localization of aquaporins in each segment of the nephron and collecting duct of the kidney.

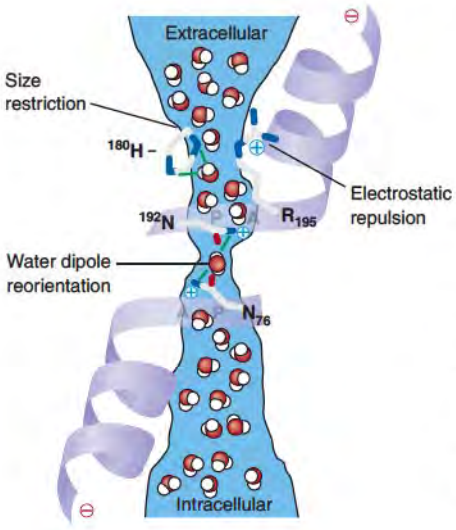

Figure 12.36 Water channel within an AQP1 subunit. The shape of the aqueous pore (blue) is derived from calculations based on the structure of bovine AQP1. Three features of the channel specify selectivity for water: (*a*) Size restriction. Eight Å above the midpoint of the channel, the pore narrows to a diameter of 2.8 Å (approximately the diameter of a water molecule). (*b*) Electrostatic repulsion. A conserved residue (R, Arg-195) at the narrowest constriction of the pore imposes a barrier to cations, including protonated water (H_3O^+). (*c*) Water dipole reorientation. Two partial helices meet at the midpoint of the channel, providing positively charged dipoles that reorient a water molecule as it traverses this point. Disrupting hydrogen bonding in the single-file chain water molecules prevents the formation of a proton conductance.

In addition to water, AQP1 permits translocation of CO_2, AQP3 of glycerol, and AQP9 of glycerol, urea, polyols, purines, pyrimidines, nucleosides, and monocarboxylates. AQP1 is reversibly inhibited by $HgCl_2$. AQP2 in kidneys of humans is under hormonal control and at least three others may be controlled by pH.

TABLE 12.10 • Subunit Composition of Voltage-Gated Cation Channels

Cation Channel	*Subunits*
Na^+	α, β_1, and β_2
K^+	4α, β
Ca^{2+}	α_1, $\alpha_2\delta$, and β

Na^+, Ca^{2+}, K^+, and Cl^- Voltage-Gated Ion Channels

The individual **voltage-gated ion channels (VIC)** for Na^+, Ca^{2+}, and K^+ are controlled by the transmembrane electrical potential. They open and close remarkably fast (milliseconds), and in mammalian cells are responsible for the generation of conducted electrical signals in neurons and other excitable cells. These ion channels are members of a large superfamily found in bacteria, archaea, viruses, and eukaryotes. In humans, there are six types of Ca^{2+} channels and at least 10 types of K^+ channels responding to different stimuli.

Each ion channel consists of specific glycoprotein subunits as homo- or hetero-oligomeric structures (Table 12.10). The large α-subunits (about 260 kDa) contain the ion-conducting channel. They have four homologous domains each with six transmembrane segments, connected by both intracellular and extracellular loops, for a total of 24 transmembrane segments (Figure 12.37). Accessory subunits (β, γ, or δ) do not share a common structure; some have several transmembrane segments and others are peripheral proteins located entirely intra- or extracellularly. They are usually involved in regulation of the channel; β-subunits may interact with cytoskeletal and extracellular matrix proteins. A model of the Na^+ channel is

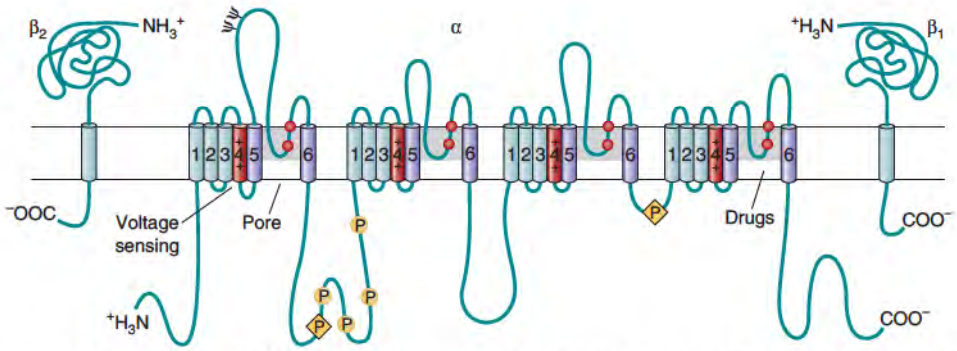

Figure 12.37 Subunit structure of the voltage-gated Na^+ channel. The primary structures of the subunits of the voltage-gated Na^+ channel are illustrated as a transmembrane folding diagram. Cylinders represent probable α-helical segments. The red cylinders represent the voltage sensor and the blue cylinders the segments in the pore (see Figure 12.38). Bold lines represent the polypeptide chains of each subunit, with length approximately proportional to the number of amino acid residues in the brain Na^+ channel subtypes. The extracellular domains of the β_1- and β_2-subunits are shown as globular structures. Protein phosphorylation sites are indicated.

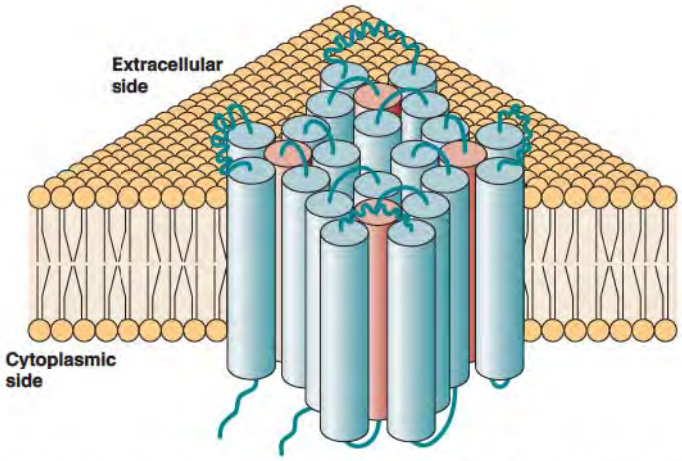

Figure 12.38 Model of the Na^+ channel. The single peptide consists of four repeating units with each unit folding into six transmembrane helices. The red transmembrane segments represent the voltage sensor. Redrawn from Noda, M., et al. *Nature* 320: 188, 1986.

presented in Figure 12.38. One transmembrane segment has a positively charged residue at every third position and may be the voltage-sensor domain; mechanical shift of this segment may lead to a conformational change in the protein, resulting in the opening of the channel. Two very different mechanisms have been suggested, but neither proven, for how the channel and the voltage-sensor domains are coupled to initiate the opening of the channel. The membrane protein responsible for the translocation of protons contains domains for sensing membrane voltage changes, but a channel domain has not been described.

Voltage-gated ion channels can exist in one of three conformational and functional states: closed (resting), open (active), and closed (inactive). In response to membrane depolarization, there is a transition from the closed to an open state. Transition between resting and inactive states occurs on binding of ligands or by protein phosphorylation.

In contrast to the cation channels, not much is known about the structure of the voltage-gated Cl^- channels (p. 943); they apparently have 12 transmembrane helical segments. Cl^- channels regulate cell volume, stabilize membrane potential, are involved in signal transduction, and regulate transepithelial transport. The cystic fibrosis transmembrane regulator is a Cl^- channel.

The voltage-gated ion channels have a distinctive expression pattern in different tissues. In humans, there are a considerable number of inherited ion channel diseases, termed channelopathies, caused by mutations in the anion and cation channels (see Clin. Corr. 3.8, p. 971). Clin. Corr. 3.12, p. 978, describes changes in cation voltage-gated channels in myotonic muscle disorders.

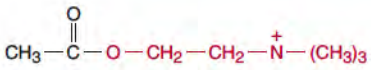

Figure 12.39 Structure of acetylcholine.

Nicotinic-Acetylcholine Channel (nAChR)

The **nicotinic-acetylcholine channel**, also referred to as the **acetylcholine receptor**, is an example of a ligand-regulated channel, in which binding of acetylcholine (Figure 12.39) opens the channel. The dual name is used to differentiate this receptor from other acetylcholine receptors that function in a different manner. The channel is expressed at the nerve–muscle synapse (p. 948) and is a member of a superfamily of transmitter-gated ion channels, which includes the serotonin, γ-aminobutyric-acid, and glycine receptors (p. 942). Acetylcholine diffuses to the skeletal muscle membrane where it interacts with the acetylcholine receptor, opening the channel and allowing positively charged ions and small nonelectrolytes but not negatively charged ions to flow through the channel. The channel complex consists of a pentameric complex of two α- and one each of β-, γ-, and δ-subunits (Figure 12.40). Each α-subunit is glycosylated, and two other subunits contain covalently bound lipid. Each subunit has an extracellular N- and C-terminus, four membrane-spanning domains (M1, M2, M3, and M4), with a long cytoplasmic loop between M3 and M4 that contains consensus sites for phosphorylation by protein kinases. Five juxtaposed M2 domains (one from each protein subunit) form the ion-conducting pore. The M2 domains of cation-selective receptor channels, such as the nicotinic-acetylcholine receptor,

Acetylcholine receptor channel structure in the resting, open, and desensitized states probed with the substituted-cysteine accessibility method. *Proc. Nat.l Acad, Sci.USA* 98: 1241, 2001. (*b*) Reproduced with permission from Miyazawa, A., Fujiyoshi, Y., and Unwin, N. Structure and gating mechanism of the acetylcholine receptor pore. *Nature* 423: 949, 2003. Copyright (2003) *Nature.*

are enriched in negatively charged amino acids at the intracellular "mouth" of the pore. This region acts to attract cations like Na^+ and repel anions like Cl^-. Binding of the neurotransmitter to extracellular sites on the complex induces very small, subtle rearrangements of the M2 domains. This near-instantaneous rearrangement removes the energetic barriers to ionic flow through the water-lined pore. Phosphorylation of the α-subunit is also required for activity. Closure of the channel occurs within a millisecond due to rapid hydrolysis of acetylcholine and dissociation of the products, acetate and choline, from the protein.

Several deadly neurotoxins, including ***d*-tubocurarine**, the active ingredient of **curare**, and several toxins from snakes, including **α-bungarotoxin**, **erabutoxin**, and **cobratoxin**, inhibit the nicotinic-acetylcholine receptor. **Succinylcholine**, a muscle relaxant, opens the channel leading to depolarization of the membrane; succinyl choline is used in surgical procedures because its activity is reversible due to the rapid hydrolysis of the compound after cessation of administration.

Gap Junctions and Nuclear Pores

Gap junctions and nuclear pores are relatively large multimeric protein channels. **Gap junctions** found in mammalian plasma membranes consist of transmembrane protein channels, referred to as **connexons**. Connexons in one cell dock end-to-end with connexons in the membrane of a neighboring cell, creating a connecting channel (Figure 12.41). Connexons consist of homo- or hetero-hexameric proteins of **connexins (gap junction proteins)**. Twelve subunits, six in each cell forming a hexameric structure in each membrane. Over 15 isoforms of connexin subunit are known; each has four putative α-helical transmembrane sequences. The molecular organization of a recombinant gap junction is presented in Figure 12.42. The diameter of the opening ranges from 1.2 to 2 nm. The aqueous channel mediates electrical coupling, and exchange between cells of ions and metabolites but not macromolecules. Gap junctions composed of different connexins may exhibit differing specificities for solutes. The channels are normally open. Closure occurs with increases in cytoplasmic Ca^{2+}, a change in metabolism, a drop in transmembrane potential, or acidification of the cytoplasm. Control may also involve specific growth factors and phosphorylation of the connexins. When the channel is open the subunits appear to be slightly tilted but when closed they appear to be more perpendicular in the membrane, suggesting that subunits slide over each other.

Nuclear pore complexes are dynamic macromolecular assemblies that span the two membranes of the nuclear envelope. They create a channel for passage of proteins, RNA, and small molecules in both directions. The pores have a flexible diameter of about 9 to 20 nm and are 45 nm in length. The nuclear pore complex is composed of 50 to 100 proteins, called nucleoporins. Small molecules diffuse passively in both directions through the channel but macromolecules do not. Proteins, RNA, and ribonucleoprotein particles are carried in both directions by specific carrier proteins. Nuclear receptors, **karyopherins**, and cytosolic factors are involved in nuclear import and export of proteins. Karyopherin β mediates export of macromolecules bound to nucleoporins and a GTPase protein, **Ran**. Proteins destined for the nucleus from the cytoplasm contain short amino acid sequences, termed **nuclear localization sequences**, which target them for import. Transport through the nuclear pore complex occurs by facilitated diffusion of the soluble carrier proteins and carrier-macromolecule complexes. The activity is regulated.

The least understood of the pores is one involved in the mitochondrial permeability transition. This opening occurs in the inner membrane in response to oxidative stress,

loss of adenine nucleotides, and increases in mitosolic Ca^{2+}. The structure has not been conclusively defined. Opening of the pore can lead to loss of mitochondrial matrix components and cytochrome c, and initiation of apoptosis (p. 1010). This pore may have an important role in tissue perfusion/reperfusion injury following tissue ischemia such as occurs in a stroke.

12.8 • MEMBRANE TRANSPORT PROTEINS

Membrane transport proteins facilitate movement of ions and molecules through a membrane by binding and physically moving them to access the environment on the opposite side of the membrane. It should be noted that physically moving the substrate does not require the protein to actually move the substrate across the entire width of a membrane. As will be discussed (p. 485), a small distance can move the substrate between two different environments in the protein. For most substances the rate of mediated transport is significantly greater than that of simple diffusion through a lipid membrane.

If S_1 is the solute on side 1 and S_2 on side 2, then the transporter promotes the establishment of equilibrium as follows:

$$[S_1] \rightleftharpoons [S_2]$$

Brackets represent the concentration of solute. If the transporter T is included, the reaction becomes

$$[S_1] + T \rightleftharpoons [S\text{–}T] \rightleftharpoons [S_2] + T$$

If no energy from another source is expended, the concentration on both sides of the membrane will be equal at equilibrium, but if there is an expenditure of energy, a concentration gradient can be established. As with an enzyme-catalyzed reaction, the transporter increases the rate but does not determine the final equilibrium. The transporter protein is unchanged at the end of the reaction. Its activity can be evaluated in the same kinetic terms as an enzyme-catalyzed reaction, because it has specificity for the substance to be transported, defined kinetics, catalyzes a vectorial transport, and is affected by both competitive and noncompetitive inhibitors. The transporter demonstrates saturation kinetics (Figure 12.33, p. 476), whereas simple diffusion does not. Constants such as V_{max} and K_m are determined for transporters. Theoretically a transporter can facilitate movement of a solute in both directions across the membrane but in most situations there is a unidirectional movement because of a large $\Delta G^{o'}$ for the reaction.

Most transporters have a high degree of structural and stereospecificity for substrate. In mediated transport of D-glucose in erythrocytes, the K_m for D-galactose is 10 times larger and for L-glucose 1000 times larger than for D-glucose, demonstrating a much lower affinity for D-galactose and L-glucose. The transporter has essentially no activity with D-fructose or disaccharides. Structural analogs of the substrate for a transporter inhibit competitively and reagents that react with specific groups on proteins are noncompetitive inhibitors.

Four Steps in the Transport of Solute Molecules

There are four steps of mediated transport (Figure 12.43): (1) recognition by transporter of appropriate solute from amongst a variety of solutes in the aqueous environment, (2) translocation of solute, (3) release of solute by transporter, and (4) recovery of transporter to its original condition.

The first step, **recognition** of a specific substrate by the transporter, is the same as recognition of a substrate by an enzyme (p. 387). Specific binding sites on the protein recognize the correct structure of the solute. The second step, **translocation**, requires a conformational change in the transporter after binding of the substrate (Figure 12.44), which moves the substrate a short distance, perhaps only 2 or 3 Å to the environment of the opposite side of the membrane. It is not necessary for the transporter to move the molecule the entire distance across the membrane (Figure 12.45). The conformational change of the protein is sufficient to change the environment. Step 3, **release** of

$$\begin{aligned} &\text{Recognition:} && S_1 + T_1 \rightleftharpoons S\text{–}T_1 \\ &\text{Transport:} && S\text{–}T_1 \rightleftharpoons S\text{–}T_2 \\ &\text{Release:} && S\text{–}T_2 \rightleftharpoons T_2 + S_2 \\ &\text{Recovery:} && T_2 \rightleftharpoons T_1 \end{aligned}$$

Figure 12.43 Steps involved in mediated transport across a biological membrane. S_1 and S_2 are solutes on side 1 and 2 of the membrane, respectively; T_1 and T_2 are binding sites on the transporter on sides 1 and 2, respectively.

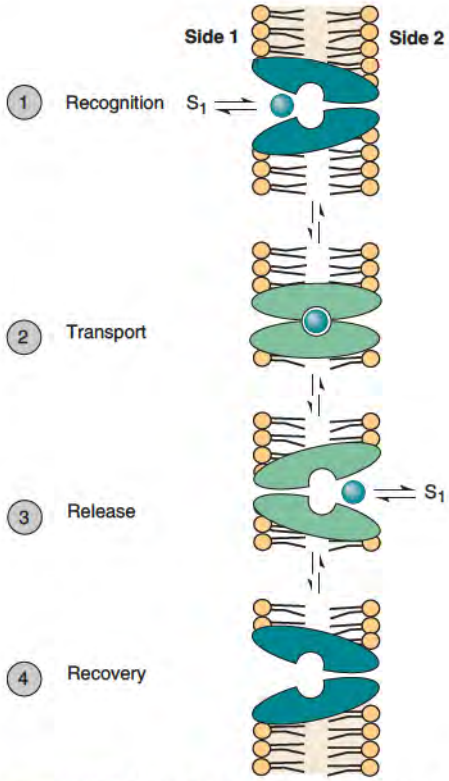

Figure 12.44 Model for a mediated transport system in a biological membrane. Model is based on the concept of specific sites for binding of substrate and a conformational change in the transporter to move bound solute a short distance but into the environment of the other side of the membrane. Once moved, solute is released from the transporter.

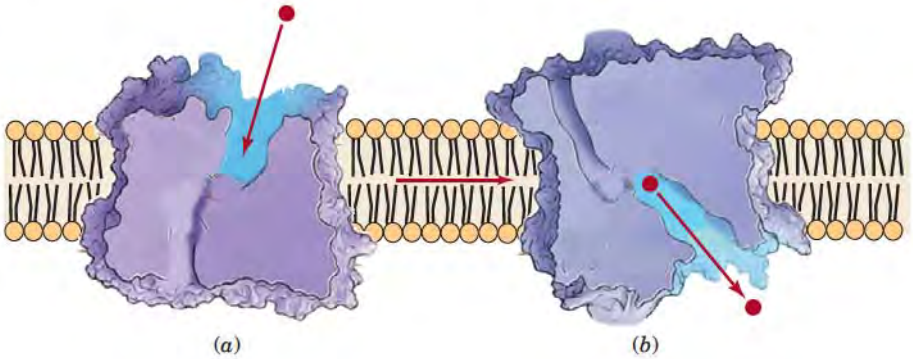

Figure 12.45 Transport of a substrate through a membrane. After binding of substrate on one side of the membrane, a conformational change in the protein occurs moving the substrate to an environment on the opposite side.
Model of protein redrawn from Arkin, I. T., et al. Mechanism of Na^+/H^+ antiporting. *Science* 317: 799, 2007.

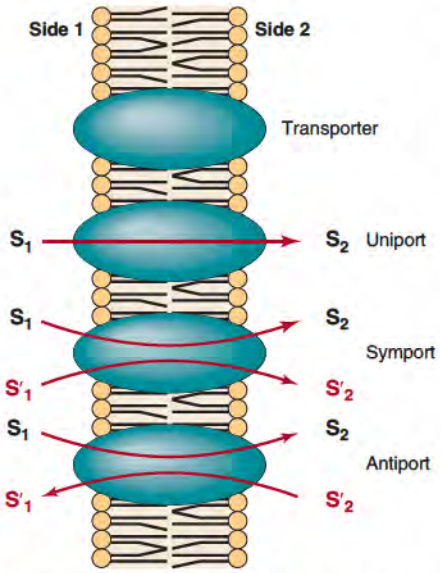

Figure 12.46 Uniport, symport, and antiport mechanisms for translocation of substances. S and S' represent different molecules.

substrate, depends on the affinity of the transporter for the substrate. Without a change in affinity (K_{eq}) for substrate, the substrate will be released in the new environment if the concentration of substrate is lower in the new environment than in the initial environment because of a shift in the equilibrium between bound and free substrate. For a transporter that moves a substrate against a concentration gradient, release of the substrate at the higher concentration requires the transporter to change so that it has a lower affinity (higher K_m) for the substrate. A conformational change of transporter can lead to a decrease in affinity. Finally in **recovery**, step 4, the transporter returns to its original conformation on release of substrate.

This discussion centered on movement of a single substrate by a transporter (**uniport** mechanism). There are systems that move two substrates simultaneously in one direction (**symport**) and two substrates simultaneously in opposite directions (**antiport**) (Figure 12.46). When a charged substance is translocated and no ion of the opposite charge is moved or two molecules with different charges are translocated by an antiport mechanism, a charge separation occurs across the membrane. This mechanism is termed **electrogenic transport** and leads to development of a membrane potential. If an oppositely charged ion is moved to balance the charge or two molecules of the same charge are moved in opposite directions across the membrane, the mechanism is termed **neutral** or **electrically silent transport**.

Energetics of Membrane Transport Systems

Eq. 12.2 gives the change in free energy when an uncharged molecule moves from concentration C1 to concentration C2 on the other side of a membrane.

$$\Delta G' = 2.3RT\log\left(\frac{C_2}{C_1}\right) \tag{12.2}$$

When $\Delta G'$ is negative—that is, there is release of free energy—movement of solute occurs without the need for a driving force. When $\Delta G'$ is positive, as would be the case if C_2 is larger than C_1, then there needs to be input of energy to drive the transport. For a charged molecule (e.g., Na^+) both the electrical potential and concentrations of solute are involved in calculating the change in free energy as indicated in Eq. 12.3

$$\Delta G' = 2.3RT\log\left(\frac{C_2}{C_1}\right) + Z\mathcal{F}\Delta\Psi \tag{12.3}$$

where $\Delta G'$ is electrochemical potential, Z is charge of the transported species, $\mathcal{F}$ is Faraday constant (96.49 kJ/V/mol, 23.06 kcal/V/mol), and $\Delta\Psi$ is electrical potential difference in volts across the membrane. The magnitude and sign of both Z and $\Delta\Psi$ influence $\Delta G'$. When $\Delta G'$ is negative movement of solute occurs spontaneously; this is often referred to as passive transport. When $\Delta G'$ is positive, input of energy from some source is required and the process is called active transport.

Transport in mammalian cells requiring energy input is driven by either hydrolysis of nucleoside triphosphate (e.g., ATP → ADP+ phosphate) or utilization of the electrochemical gradient of Na^+ (**sodium motive force, SMF**) or H^+ (**proton motive force, PMF**). Prokaryotes also have transporters driven by decarboxylation and methyl transfer reactions, and plants have light-absorption-driven transporters. The SMF is generated at the expense of ATP hydrolysis and the PMF by oxidation–reduction reactions (p. 572). Inhibition of ATP synthesis or collapse of the PMF will dissipate the Na^+ and/or H^+ gradient leading to a cessation of transport.

In the simplest transport mechanism, that is, the transport of a single solute by a uniport mechanism, molecules are transported down their chemical gradient if they have no charge or down an electrochemical gradient if charged; this is often referred to as **protein-mediated diffusion** or **facilitated diffusion.** These transporters cannot create a concentration gradient of the substance across the membrane. In a symport (two molecules being moved simultaneously in the same direction) or antiport (two molecules being moved simultaneously in opposite directions), movement down a concentration gradient of one of the solutes can drive the translocation of the other molecule. These have been referred to as **secondary active transporters**, to distinguish them from primary active transporters, which utilize energy derived from cellular metabolism directly. The large Na^+ concentration gradient across the plasma membrane (high extracellular and low intracellular concentration; Figure 1.9, p. 14) is used to translocate sugars and amino acids by a symport mechanism into cells.

Some transporters maintain very large concentration gradients, such as the plasma membrane transporter that maintains the Na^+ and K^+ gradient (p. 491). Another striking example is an active transporter in parietal cells of gastric glands, which is responsible for secretion of HCl into the lumen of the stomach (p. 1042). The pH of plasma is about 7.4 (4×10^{-8} M H^+), and the luminal pH of the stomach can reach a pH of 0.8 (0.15 M H^+). H^+ is transported against a concentration gradient of greater than 1×10^6. Assuming there is no electrical component, the energy for H^+ secretion under these conditions is calculated from Eq. 12.1 and is 38 kJ mol/L (9.1 kcal mol/L) of HCl.

Mammalian Membrane Transporters

The two major protein classes of transporters in mammalian cells (see Table 12.8, p. 477) are

- **electrochemical-potential-driven transporters**, which move their substrate across a membrane by utilizing the concentration gradient of the substrate or another solute, and
- **primary active transporters**, which require the input of metabolic energy to move the substrate.

Mammalian cells have a wide variety of transporters and in many instances use different subfamilies of transporters to translocate the same substrate depending on the specific requirements of the cell or tissue. Transport systems are present in plasma as well as intracellular membranes, including mitochondria, lysosomes, peroxisomes, and endosomes. The number of active transporters present in a membrane at a given time establishes the maximum rate of uptake by a cell or organelle. Thus, in many cases, the synthesis of the protein transporter and incorporation into a membrane controls the concentration of a particular substrate in a cell or cellular compartment. All of these translocation systems are regulated, permitting moment-by-moment control of transport. Many genetic diseases are attributable to defects in the various transport systems (Clin Corr. 12.4).

12.9 • ELECTROCHEMICAL-POTENTIAL-DRIVEN TRANSPORTERS

Electrochemical-potential-driven transporters utilize

1. a uniport mechanism where a single solute is transported either by mediated diffusion or in a membrane-potential-dependent manner if the solute is charged;

CLINICAL CORRELATION 12.4

Diseases due to Loss of Membrane Transport Systems

A number of pathological conditions are due to an alteration in a transport system for specific cellular components. Individuals with a decrease in glucose uptake from the intestinal tract lack the specific sodium-coupled glucose–galactose transporter. Fructose malabsorption syndromes are caused by an alteration in the activity of the transport system for fructose. In Hartnup disease there is a decrease in the transport of neutral amino acids in the epithelial cells of the intestine and renal tubules.

In cystinuria, renal reabsorption of cystine and the basic amino acids lysine, arginine, and ornithine is abnormal, resulting in formation of renal cystine stones. In hypophosphatemic, vitamin D–resistant rickets, renal absorption of phosphate is abnormal. Recently there have been reports about genetic-based diseases involving the substrate transporters for dopamine and creatine, and the mitochondrial aspartate glutamate transporter. The various ATP-requiring active transporters have been implicated in a number of pathophysiological conditions.
