3. a symport mechanism where two or more species are transported together in the same direction in a coupled process not utilizing any form of energy other than the electrochemical-potential gradient of one substrate; the gradient of one solute drives the movement of the other solute

Hundreds of such transporters have been reported, many exclusively in bacteria, with specificity for inorganic ions, sugars, amino acids, and other metabolic intermediates. Table 12.11 illustrates the variety of solutes transported in eukaryotic cells by this mechanism. Many of the transporters have 2 to 24 putative α-helical transmembrane sequences. Electrochemical-potential-driven transporters demonstrate saturation kinetics, specificity of substrate moving across the membrane, and specificity for inhibitors.

Representative Electrochemical-Potential-Driven Transporters

Glucose is Translocated by a Passive Uniport Mechanism

A family of **glucose transporters** (**GLUT**) facilitates transport of D-glucose across the plasma membranes of mammalian cells by a uniport mechanism. The genes for the GLUT

TABLE 12.11 • Representative Substrates for Membrane Transport Proteins in Eukaryotes

Inorganic cations	H^+, K^+, Na^+, NH_4^+, Ca^{2+}, Co^{2+}, Cu^{2+}, Fe^{2+}, Mg^{2+}, Zn^{2+}
Inorganic anions	Cl^-, HCO_3^-, SO_4^{2-}, iodide, phosphate, arsenite
Sugars	Fructose, glucose, hexoses, lactose, maltose, myo-inositol
Organic acids	Acetate, bile acids, bilirubin, citrate, glucose 6-phosphate, α-ketoglutarate, lactate, malate, oxalacetate, prostaglandins
Amino acids	Acidic, basic, neutral, branched chain
Peptides/proteins	Some
Nucleosides/nucleotides	ATP, ADP, all others
Vitamins/cofactors	Ascorbate, biotin, folate, lipoate, thiamin
Drugs	Multiple drugs

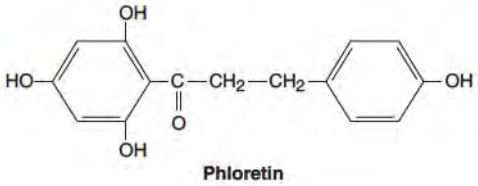
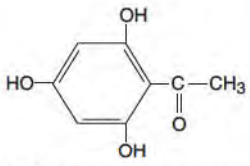
TABLE 12.12 • Major Isoforms of Glucose Transporter

Isoform	*Tissue*	*Cellular Localization*	*Comments*
GLUTI	Muscle Heart Blood-brain barrier Glia cells Placenta	Plasma membrane	Activity in muscle increased by insulin, hypoxia, and diet
GLUT2	Liver Pancreas Intestine Kidney	Plasma membrane	
GLUT3	Brain Kidney Placenta	Plasma membrane	
GLUT4	Muscle Adipose Heart Blastocysts	Plasma membrane	Activity in muscle and adipose tissue stimulated by insulin, and in muscle by hypoxia and diet
GLUT5	Muscle Spermatozoa	Sarcolemmal vesicles	Fructose as substrate



Phloretin



2,4,6-Trihydroxyacetophenone

Figure 12.47 Inhibitors of passive transport of D-glucose in erythrocytes.

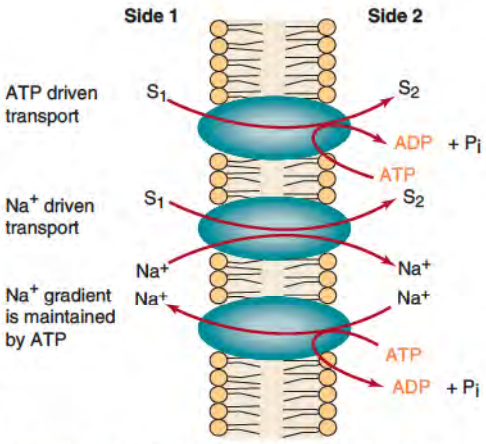


Figure 12.48 Involvement of metabolic energy (ATP) in active mediated transport systems. Chemical energy released on hydrolysis of ATP to ADP and inorganic phosphate is used to drive transport of various substances, including Na^+. The transmembrane concentration gradient of Na^+ is used for active transport of substances by symport and antiport (not shown) mechanisms.

family are expressed in a tissue specific manner. The glucose transporters, designated as GLUT1, GLUT2, and so on (Table 12.12), all have 12 transmembrane segments, with a significant amino acid similarity. Most are in the plasma membrane where direction of movement of glucose is usually out to in. Depending on the concentration gradient, however, erythrocyte **GLUT1** facilitates transport in both directions demonstrating the reversibility of the system. The three high-affinity transporters (GLUT1, **GLUT3**, and **GLUT4**) function *in vivo* at rates close to maximal velocity because their K_ms are below the normal blood glucose concentration. D-Galactose, D-mannose, D-arabinose, and several other D-sugars as well as glycerol are translocated by some isoforms. **GLUT5** of sarcolemmal membranes of skeletal muscle transports fructose preferentially. GLUT1 is important for supplying erythrocytes and brain cells with glucose. The rate of glucose uptake by the low-affinity GLUT2 increases in parallel with the rise in blood glucose concentration and has a major role in intestinal absorption of sugars (p. 1049). In liver cells, **GLUT2** catalyzes both glucose influx and efflux, having responsibility for glucose export (p. 596); in pancreatic β-cells, GLUT2 it is involved in sensing blood glucose levels. GLUT4 is an insulin-responsive transporter (p. 595) in adipose tissue, heart muscle, and skeletal muscle. Activity of some glucose transporters in muscle is stimulated by exercise and hypoxia apparently because there is a need for increased glucose utilization by the tissue. Several sugar analogs as well as phloretin and 2,4,6-trihydroxyacetophenone (Figure 12.47) are competitive inhibitors.

Glucose and Amino Acids Are Translocated with Na+ by a Symport Mechanism

The Na^+ electrochemical gradient (**sodium motive force**, **SMF**) across the plasma membrane (p. 14) is an energy source for symport movement of Na^+ with sugars, amino acids, ions, and other small molecules. There are over 400 expressed transporters in this family of proteins. As described previously (p. 487), the SMF is generated by transport of Na^+ coupled to hydrolysis of ATP (Figure 12.48); inhibition of ATP synthesis will lead to dissipation of the Na^+ gradient and cessation of transport.

The general mechanism of the **sodium/glucose cotransporter** (**SGLT**) is presented in Figure 12.49. The diagram represents transport of D-glucose driven by the movement of Na^+. In the process two Na^+ move into the cell down the Na^+ electrochemical gradient by passive facilitated transport, and glucose is carried along against its concentration gradient.

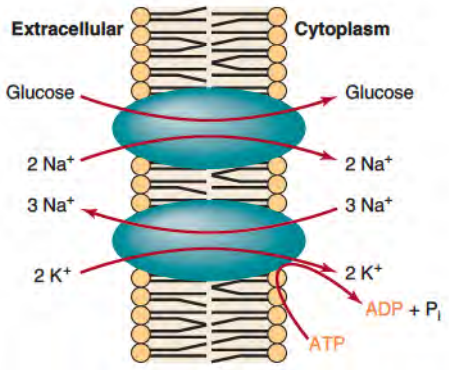

Figure 12.49 Na^+-dependent transport of glucose across the plasma membrane by a symport mechanism transport.

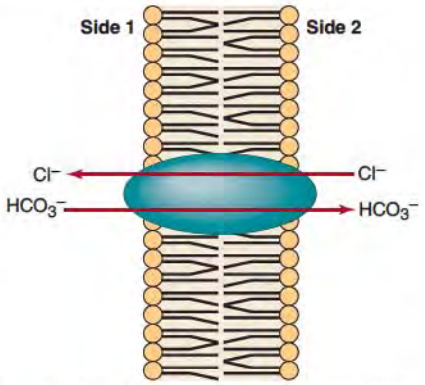

Figure 12.50 Anion antiport mechanism for movement of Cl^- and HCO_3^- across the erythrocyte plasma membrane.

The Na^+ gradient dissipates in the process but the Na^+/K^+-exchanging ATPase continuously reestablishes it (p. 491). Thus, metabolic energy in the form of ATP is indirectly involved in transport because it is required to maintain the Na^+ gradient. Inhibition of the Na^+/K^+-exchanging ATPase leads to a decrease in the Na^+ gradient, thus preventing glucose uptake by this mechanism.

Over 37 members of the SGLT gene family have been identified in animal cells, yeast, and bacteria; four are expressed in humans. Some isoforms are expressed in proximal renal tubules and small intestinal epithelium (p. 1042). All SGLTs have a common core structure of 13 transmembrane helices, but different isoforms have additional transmembrane segments, including human SGLT1 which has 14. SGLTs can catalyze a uniport movement of Na^+ and water in the absence of glucose. Na^+ binds in an extracellular cavity of the transporter, inducing a conformational alteration that increases the affinity of the transporter for glucose. The binding of glucose, forming a ternary complex, induces another structural change that exposes Na^+ and substrate to a cavity in the protein contiguous with the intracellular environment on the other side of the membrane. Na^+ dissociates from the transporter because of the low intracellular Na^+ concentration leading to a return of the transporter to its original conformation, which has a decreased affinity of glucose. Thus glucose is released. The empty transporter is reorientated in the membrane allowing the cycle to begin again.

Amino acids are translocated across intestinal epithelial cells by **Na^+/amino acid transporters** by a symport mechanism; at least seven transporters have been identified for different classes of amino acids (p. 78). The Na^+ gradient across the plasma membrane is also utilized to drive the transport of other ions, including a symport mechanism for uptake of Cl^- and an antiport mechanism for excretion of Ca^{2+}.

Cl^- and HCO_3^+ Are Transported by an Antiport Mechanism

An anion transporter in erythrocytes and kidneys mediates the electroneutral antiport movement of Cl^- and HCO_3^- (Figure 12.50). The transporter is referred to as the **Na^+ independent Cl^-–HCO_3^- exchanger** or **anion exchange protein**, and in erythrocytes as band 3, the latter because of its position in SDS polyacrylamide gel electrophoresis of erythrocyte membrane proteins. The direction of ion flow depends on the concentration gradients of the ions across the membrane. The transporter is important in adjusting the erythrocyte HCO_3^- concentration in arterial and venous blood. The kidney transporter is a truncated form of the erythrocyte protein and is responsible for base (HCO_3^-) efflux to balance ATP driven H^+ efflux.

Na^+/H^+ Exchanger Regulates Cytoplasmic pH

The nine mammalian isoforms of the **Na^+/H^+ transporter** are members of a large family of proteins in bacteria, archaea, yeast, plants, and animals. They vary in size from 541 to 894 residues and have 10–12 predicted transmembrane α-helical segments. A major physiological function is to extrude H^+ generated during metabolism, thus regulating cytoplasmic pH and preventing intracellular acidification. In the kidney, isoform-3 serves to recover Na^+ from the nephron lumen. Isoform-1 in heart muscle is activated by decreased pH and by phosphorylation. This isoform may have a significant role in the pathogenesis of a myocardial infarct and tissue hypertrophy.

Mitochondria Have a Number of Electrochemical-Potential-Driven Transporters

The inner mitochondrial membrane contains transporters for exchange of anions between cytoplasm and mitochondrial matrix, including (1) an antiporter for exchange of ADP and ATP, (2) a symporter for transport of phosphate and H^+, (3) a dicarboxylate transporter, and (4) an antiporter for glutamate-aspartate (see p. 578 for a detailed discussion). These transporters are important in energy conservation and metabolism. In the absence of an input of energy, these transporters can mediate a passive exchange of metabolites down their concentration gradient to achieve a thermodynamic equilibrium. In some cases, the transporter mediates the antiport movement of an equal number of electrical charges on the substrates with the mitochondrial membrane potential influencing the equilibrium.

12.10 • PRIMARY ACTIVE TRANSPORTERS

Primary active transporters in mammalian cells include transport systems where

1. the free energy of hydrolysis of a pyrophosphate bond (p. 543) is utilized to drive the movement of substrate against their chemical or electrochemical gradient; and
2. the transport protein may be transiently phosphorylated during the transport process, but the substrate is not phosphorylated or modified.

This family of transporters catalyzes the translocation of a solute against its concentration gradient, leading to creation of a chemical or electrochemical gradient. Like all transporters, they are characterized by saturation kinetics, specificity for one or a few related substrates, and an ability to be inhibited. They are found in all living organisms. Mammalian cells utilize ATP or another nucleoside triphosphate as the energy source. Transporters utilizing ATP are also referred to as **ATPases**, indicating their enzyme activity in hydrolyzing ATP during translocation. Decarboxylation, methyl transfer, oxidoreduction, and light absorption serve to drive transport in other organisms.

Three subfamilies of primary active transporters catalyze the translocation of inorganic cations (Na^+, K^+, Ca^{2+}, or H^+) and are classified as P-, V-, or F-type transporters. **P-type transporters** are phosphorylated and dephosphorylated during transport; there are over 300 members of this subfamily. **V-type transporters** (V for vacuole) are proton pumps, responsible for acidification of the interior of lysosomes, endosomes, Golgi vesicles, and secretory vesicles. **F-type transporters**, present in mitochondria, chloroplasts, and bacteria, translocate protons at the expense of ATP hydrolysis, but synthesize ATP when functioning in the reverse direction, that is, when protons are transported down their concentration gradient (p. 572).

The ATP-binding cassette (ABC) transporters are a very large and unique superfamily of ATP dependent primary active transporters, required for transport of a variety of inorganic and organic molecules.

Representative Primary Active Transporters

Antiport Translocation of Na^+ and K^+ is by Primary Active Transport

The external or plasma membrane of cells from all forms of life contain a P-type Na^+/K^+ antiporter, which utilizes the energy from hydrolysis of ATP to ADP+ phosphate to drive translocation. The transporter is termed the **Na^+/K^+-exchanging ATPase**, but it is frequently referred to as **Na^+/K^+-ATPase** or **Na^+ pump**. This superfamily of multi-subunit proteins found in bacteria, archaea, and eukaryotes have a large subunit that catalyzes both the ATPase activity and ion translocation. Members of the superfamily have been described in bacteria for uptake and/or efflux for K^+, Mg^{2+}, Ca^{2+}, Ag^+, Zn^{2+}, Co^{2+}, Pb^{2+}, Ni^{2+}, Cd^{2+}, and Cu^{2+}.

The plasma membranes of all mammalian cells catalyze the reaction

$$ATP \xrightarrow[Mg^{2+}]{Na^+ + K^+} ADP + Pi \qquad (12.4)$$

with an absolute requirement for Na^+ and K^+ ions, and for Mg^{2+}, a cofactor for ATP-requiring reactions. The transporter is responsible for maintaining the high K^+ and low Na^+ concentrations in the cytoplasm of mammalian cells (p. 14). Excitable tissues, such as muscle and nerve, and cells actively involved in movement of Na^+ ion, such as those in the salivary gland and kidney cortex, have high activities of the Na^+/K^+-exchanging ATPase. It has been estimated that this transporter uses about 60%–70 % of the ATP synthesized by nerve and muscle cells and about 35% of ATP generated in a resting individual.

The transporter consists of an α-subunit (110 kDa) and a β-subunit (55 kDa); there is some question whether the actual transporter may be a tetramer with two α- and two β-subunits. The α-subunit has 10 transmembrane α-helical segments (Figure 12.51), contains both the ATPase and translocation activity, and is phosphorylated and dephosphorylated on a specific aspartic acid residue to form a β-aspartyl phosphate during ion translocation. The cation and ATP-binding sites are on different domains of the α-subunit. The β-subunit

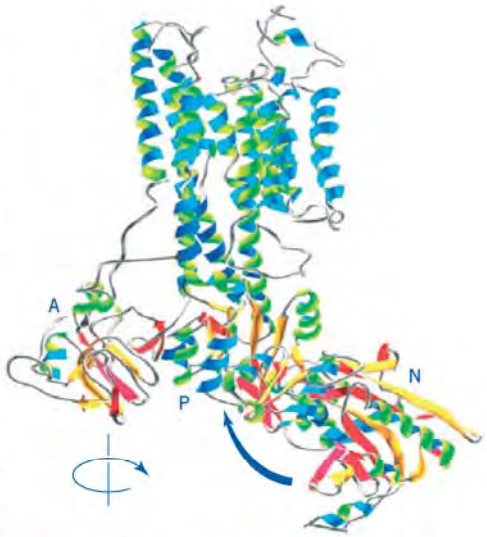

Figure 12.51 Structure of the α-subunit of Na^+/K^+-exchanging ATPase. Model of the sheep Na^+/K^+-exchanging ATPase α-subunit. The predicted domains are the nucleotide binding (*N*) and the phosphorylation domain (*P*). α-Helices are shown in shades of blue and green, β-sheets are shown in shades of red and yellow, and coils are shown in gray.

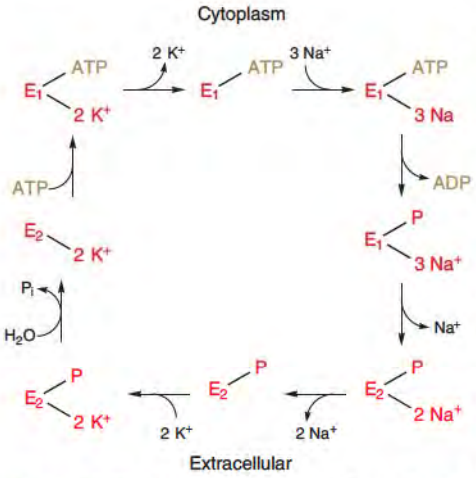

Figure 12.52 Proposed sequence of reactions and intermediates in hydrolysis of ATP by the Na^+/K^+-exchanging ATPase. E_1 and E_2 are different conformations of the enzyme. Phosphorylation of the enzyme requires Na^+ and Mg^{2+} and dephosphorylation involves K^+.

is heavily glycosylated, facilitates insertion of the α-subunit into the membrane after synthesis, and stabilizes the complex; it may also function actively in the transport activity. The transporter from the kidney contains a γ-subunit, which may influence kinetic parameters of the activity. Phosphorylation of the α subunit requires Na^+ binding and Mg^{2+} but not K^+, whereas dephosphorylation requires K^+ binding but not Na^+ or Mg^{2+} (Figure 12.52). The protein complex has two distinguishable conformations and is classified as an **E1-E2-type transporter**, to indicate the change in conformation.

Movement of Na^+ and K^+ is an electrogenic antiport process, with three Na^+ ions moving out and two K^+ ions into the cell for each ATP molecule hydrolyzed. This leads to an increase in external positive charge and is part of the mechanism for maintaining the transmembrane potential in cells. ATP hydrolysis by the transporter occurs only if Na^+ and K^+ are translocated. A model for movement of Na^+ and K^+ is presented in Figure 12.53. The protein goes through conformational changes during which the Na^+ and K^+ move short distances within the protein. This conformational transition decreases the affinity of the binding site for the cations, resulting in the release of the cation into a milieu where the concentration is higher than that from which it was transported.

Various isoforms of the transporter are regulated by different mechanisms including substrate concentration, the cytoskeleton, circulating inhibitors, and a variety of hormones. The activity has a requirement for phospholipids; the transporter has binding sites for about 30 lipid molecules and levels of docosahexaenoic acid (long-chain polyunsaturated fatty acid) in brain correlate with the ATPase activity. **Cardiotonic steroids**, such as **digitalis**, are inhibitors of the Na^+/K^+-exchanging ATPase and increase the force of contraction of heart muscle by altering the excitability of the tissue. **Ouabain** (Figure 12.54) is one of the most active inhibitors of Na^+/K^+-exchanging ATPase; it binds on the small subunit on the external surface of the membrane.

Ca^{2+} Translocation Is Catalyzed by a Primary Active Transporter

Calcium is an important intracellular messenger that regulates many cellular processes from carbohydrate metabolism to muscle contraction. Cytosolic Ca^{2+} is about 0.10 μM, over 10,000 times less than that of extracellular Ca^{2+}. Ca^{2+} in the cytosol increases rapidly by release of Ca^{2+} from the endoplasmic or sarcoplasmic reticulum or transient opening of Ca^{2+} channels in the plasma membrane permitting flow of Ca^{2+} down the large concentration gradient (p. 481). To reestablish low cytosolic levels, Ca^{2+} is actively transported by two different **Ca^{2+}-transporting ATPases (Ca^{2+}-ATPase)**, one transporting Ca^{2+} back into the lumen of the endoplasmic or sarcoplasmic reticulum, and the other out of the cell across the plasma membrane. The Ca^{2+}-ATPases are P-type transporters, phosphorylated by ATP on an aspartyl residue; they exist in two conformational states, thus are E1-E2-type transporters.

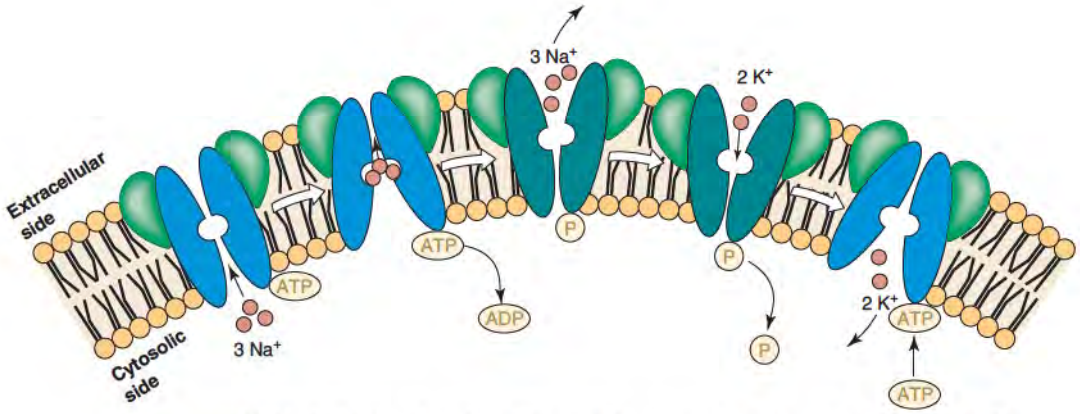

Figure 12.53 Model for translocation of Na^+ and K^+ across plasma membrane by the Na^+/K^+-exchanging ATPase. (1) Transporter in conformation 1 binds Na^+. (2) Transporter in conformation 2 translocates and releases Na^+. (3) Transporter in conformation 2 binds K^+. (4) Transporter in conformation 1 translocates and releases K^+.

The Ca^{2+}-ATPase of muscle sarcoplasmic reticulum (SERCA) is involved in the contraction–relaxation cycles of muscle, representing 80% of the integral membrane protein of the sarcoplasmic reticulum and occupying one-third of the surface area (p. 975). It consists of a single polypeptide chain with ten transmembrane helices (Figure 12.55). Two Ca^{2+}s are translocated from the cytosol to the lumen against a large concentration gradient (10^4), in an antiport exchange for 2 H^+ per ATP hydrolyzed. In the E1 state (Figure 12.56), the binding sites have a high affinity for Ca^{2+} and are accessible from the cytosol, whereas in the E2 state, the Ca^{2+}-binding sites have low affinity and are open to the lumen. The Ca^{2+}-free form shows large conformational differences from the Ca^{2+}-bound form (Figure 12.56). The two Ca^{2+}s are bound side by side, surrounded by four transmembrane helices. It has been proposed that the sarcoplasmic reticulum Ca^{2+}-ATPase may also play a role in **thermogenesis** by binding Ca^{2+}, followed by hydrolysis of ATP, but releasing the Ca^{2+} back into the cytosol without translocation of the cation. The energy of the ATP hydrolysis is released as heat. A small peptide, **sarcolipin**, increases heat production.

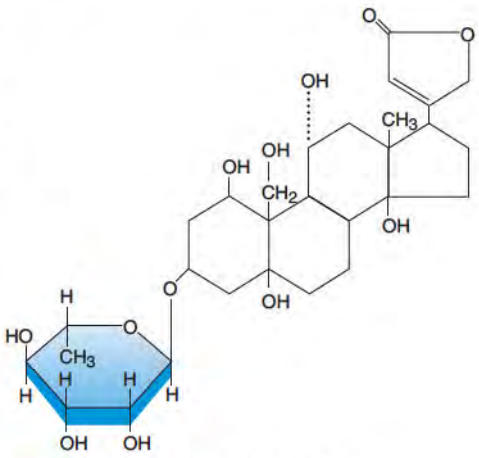

Figure 12.54 Structure of ouabain, a cardiotonic steroid, a potent inhibitor of the Na^+/K^+-exchanging ATPase.

Calmodulin Controls the Ca^{2+}-Transporting ATPase of Plasma Membranes

The Ca^{2+}-transporting ATPase of plasma membranes (PMCA) resembles that of the sarcoplasmic reticulum. Thirty isoforms of PMCA are known. In contrast to the SERCA, it transports only one Ca^{2+} per ATP hydrolysed. In eukaryotic cells, the transporter is regulated by cytoplasmic Ca^{2+} levels through **calmodulin,** a Ca^{2+}–binding protein (Figure 12.57). As cytosolic Ca^{2+} levels increase, Ca^{2+} binds to calmodulin, which has a dissociation constant of ~ 1 μM for Ca^{2+}. The Ca^{2+}–calmodulin complex binds to the Ca^{2+}

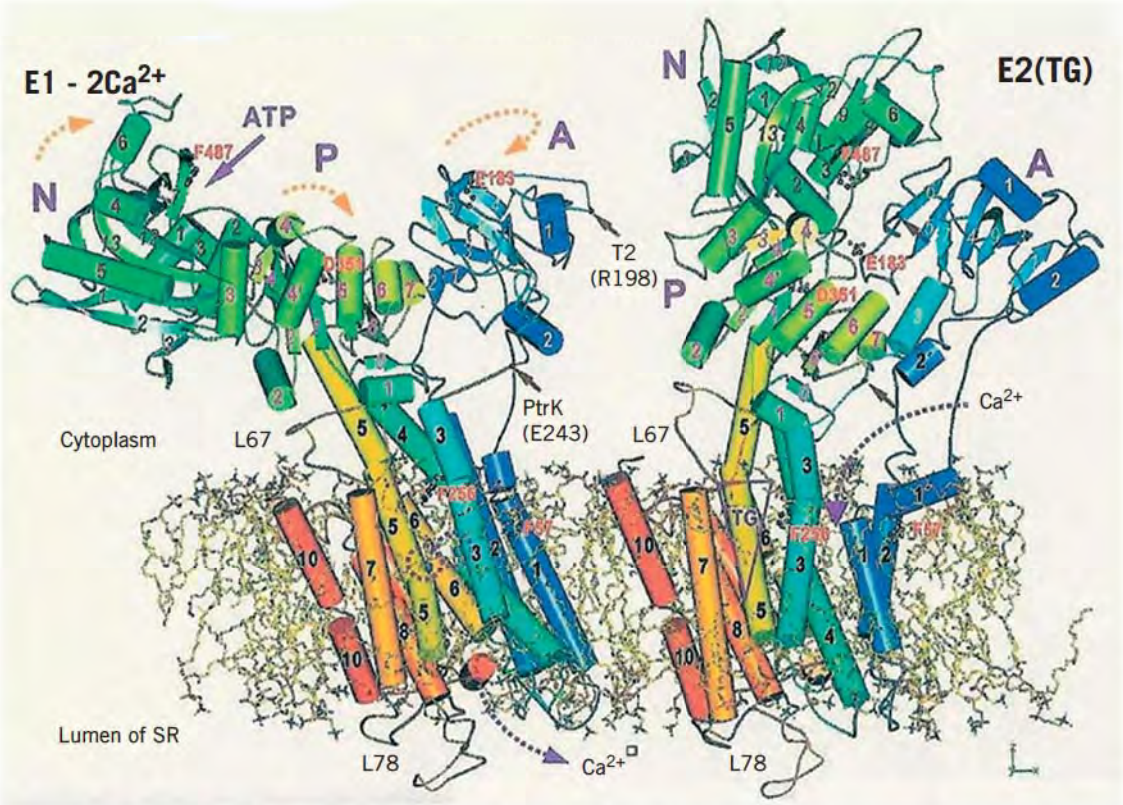

Figure 12.55 Structure of Ca^{2+}-transporting ATPase. Conformational changes of the Ca^{2+}-transporting ATPase of the sarcoplasmic reticulum. Points of entry and exit of Ca^{2+} are shown by the purple arrow. Figure on the left is with bound Ca^{2+}, and on the right without Ca^{2+}.

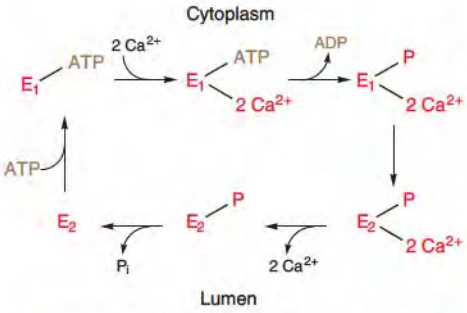

Figure 12.56 Proposed sequence of reactions and intermediates in translocating Ca^{2+} by Ca^{2+}-transporting ATPase. E_1 and E_2 are different conformations of enzyme.

transporter, lowering the K_m for Ca^{2+} from about 20 to 0.5 μM and increasing Ca^{2+} transport. Increased activity reduces cytosolic Ca^{2+} to its normal resting level (~ 0.10 μM) at which concentration the Ca^{2+}–calmodulin complex dissociates and the rate of Ca^{2+} transport returns to its basal value.

Other cellular processes are also regulated by the Ca^{2+}–calmodulin complex. Calmodulin is one of several Ca^{2+}-binding proteins, including **parvalbumin** and **troponin C**, which have very similar structures. Calmodulin (17 kDa) has the shape of a dumbbell with two globular ends connected by a seven-turn α-helix; it contains four Ca^{2+}–binding sites, two of high affinity on one end and two of low affinity on the other. Binding of Ca^{2+} to the lower-affinity binding sites causes a conformational change which reveals a hydrophobic region that interacts with a protein it controls. Each Ca^{2+}–binding site consists of a helix–loop–helix secondary structure (Figure 12.57) with Ca^{2+} bound in the loop connecting the helices. The motif is called the EF hand, on the basis of studies with parvalbumin where the Ca^{2+} binds between helices E and F of the protein.

The two families of Ca^{2+} transporters share some properties; for example, the high affinity for Ca^{2+}, the membrane topography, and the organization of the catalytic domain. They are different in structural and functional characteristics, however, principally in their regulation.

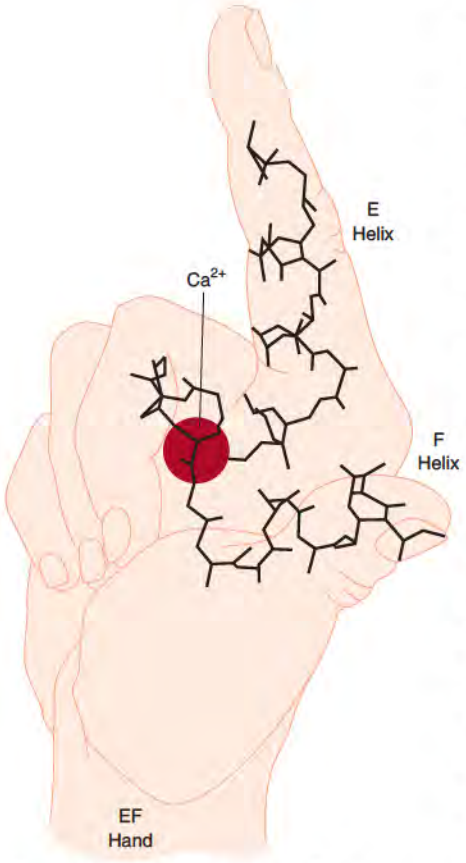

Figure 12.57 Binding site for Ca^{2+} in calmodulin. Calmodulin contains four Ca^{2+}-binding sites, each with a helix–loop–helix motif. Ca^{2+} ion is bound in the loop that connects two helices. This motif occurs in various Ca^{2+}-binding proteins and is referred to as the EF hand.

ATP-Binding Cassette (ABC) Transporters

Membranes from prokaryotes to eukaryotes have transporters that belong to the superfamily of **ATP-binding cassette (ABC) transporters** that catalyze an ATP-dependent vectorial movement of diverse substances. There are dozens of subfamilies within the superfamily and over 1000 genes, mostly from bacteria, for ABC transporters have been cloned; the human genome contains at least 49 genes. ABC transporters are present in both the plasma and intracellular membranes of mammalian cells, catalyzing either influx or efflux of various lipids (phospholipids, long-chain fatty acyl CoA, bile salts, and cholesterol), peptides, a variety of toxic organic molecules, and chemotherapeutic agents. The ABC transporters in bacteria are very versatile, transporting ions, heavy metals, sugars, drugs, amino acids, peptides, and proteins. These transporters have a modular structure, with a six-transmembrane-segment domain, and a cytosolic ATP-binding domain (or cassette). The ATP-binding domains in the superfamily share extensive sequence homology. Most subfamilies have a tandem repeat of two transmembrane domains and two ATP-binding domains (Figure 12.58). Individual ABC transporters function mechanistically as either channels or transporters. ATP binding induces a conformational change in the transmembrane domains, but ATP hydrolysis does not lead to phosphorylation of the transporter. The mechanism of coupling the energy of ATP hydrolysis with movement of substrate is still not defined.

One subfamily of ABC transporters in humans is coded by the **multidrug resistance (Mdr) family** of genes. The gene products are glycoproteins, termed **P-glycoproteins**, some of which are responsible for extrusion from cells of a variety of xenobiotics. Overexpression of Mdr genes by tumor cells leads to increased resistance to a variety of drugs because chemotherapeutic agents are rapidly transported out of cells with the increased numbers of transporters. Therefore, the drug does not attain effective therapeutic concentrations. Other **multidrug resistance associated proteins (MRP)** are responsible for the efflux from cells of compounds conjugated to glutathione, glucuronate, and sulfate. P-glycoprotein transporters are responsible for efflux of lipids such as phosphatidylcholine, cholesterol, and of bile acids across the canalicular plasma membrane of hepatocytes. One member has the important physiological role of transporting bilirubin glucuronides from the liver into the bile (p. 800). Another ABC transporter is the **sulfonylurea receptor** linked to a K^+-channel, which functions in the regulation of glucose-induced insulin secretion.

The **c**ystic **f**ibrosis **t**ransmembrane conductance **r**egulator (CFTR) is an ABC transporter but mechanistically is both a conductance regulator and a Cl^- channel. The channel mediates transepithelial salt and liquid movement in the apical plasma membrane of epithelial cells. CFTR consists of five domains, two domains each of six transmembrane helices, two ATP-binding domains, and a regulatory globular domain (Figure 12.59). Phosphorylation

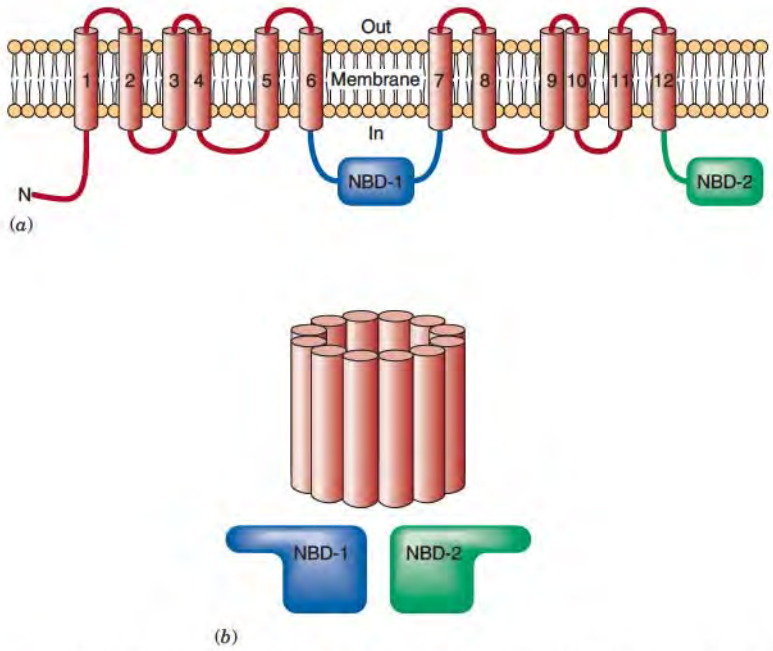

Figure 12.58 Model of a P-glycoprotein, an ATP-binding cassette (ABC) transporter. NBD-1 and NBD-2 are nucleotide-binding domains.

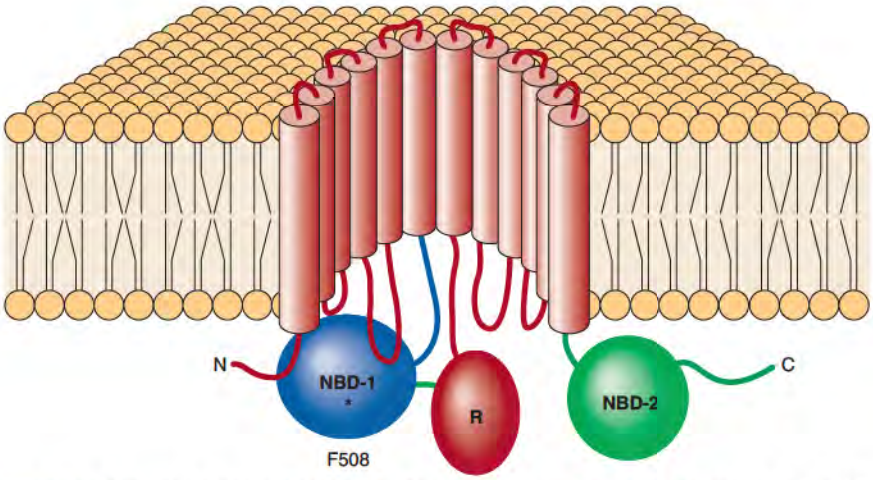

Figure 12.59 Schematic diagram of the cystic fibrosis transmembrane conductance regulator (CFTR), a member of the ABC transporter family. NBD-1 and NBD-2 are ATP-binding subunits and R is a regulatory subunit. F508 is the site of deletion of phenylalanine which occurs in about 70% of patients with cystic fibrosis.
Redrawn based on a figure in Ko, Y. H., and Pedersen, P. L. Frontiers in research on cystic fibrosis: Understanding its molecular and chemical basis and relationship to the pathogenesis of the disease. *Bioenerg. Biomemb.* 29: 417, 1997.

of the regulatory domain regulates channel activity whereas ATP hydrolysis controls gating of the channel. A dysfunction of CFTR causes the genetic disease cystic fibrosis. A deletion of phenylalanine residue F508 in the ATP-binding loop NBD-1 (nucleotide-binding domain-1) is present in about 70% of the cases of cystic fibrosis. This deletion prevents the proper folding of NBD-1 (Clin. Corr. 12.5, and Clin. Corr. 6.7, p. 231).

Other genetic diseases attributed to defects in specific ABC transport proteins include adrenoleukodystrophy, Stargardt macular dystrophy, a hereditary degenerative disease of the macula lutea leading to rapid loss of visual acuity, and Dubin–Johnson syndrome (Clin. Corr. 12.6).

CLINICAL CORRELATION 12.5

Cystic Fibrosis and the Cl^- Channel

Cystic fibrosis (CF), an autosomal recessive disease, is the commonest, serious, inherited disease of Caucasians, occurring with a frequency of 1 in 2000 live births. It is a multiorgan disease, with pulmonary obstruction as a principal manifestation; thick mucous secretions obstruct the small airways allowing recurrent bacterial infections. Exocrine pancreatic dysfunction occurs early and leads to steatorrhea (fatty stool); see page 1032 for a discussion of the role of the pancreas in fat digestion and absorption. CF patients have reduced Cl^- permeability that impairs fluid and electrolyte secretion, leading to luminal dehydration. Diagnosis of CF is confirmed by a significant increase of Cl^- content of sweat of affected in comparison to normal individuals.

The gene responsible for CF was identified in 1989 and over 800 mutations leading to CF have been found. The most common mutation affects about 70% of the patients and is a deletion of a single phenylalanine at position 508 on the protein, but missense, nonsense, frameshift, and splice-junction mutations (p. 197) have been reported. Many mutations lead to a change in protein folding. The CF gene product is the **c**ystic **f**ibrosis **t**ransmembrane conductance **r**egulator (**CFTR**). CFTR is a cAMP-dependent Cl^- channel, which may regulate other ion channels; it is expressed in epithelial tissues. Phosphorylation of a cytoplasmic regulatory domain by protein kinase A activates the channel. CFTR is a polypeptide of 1480 amino acids with structural homology to the superfamily of ATP-binding cassette (ABC) transporters. The gene has been cloned, and a major effort is under way to treat the disease by gene therapy, using both viral and nonviral vectors including liposomes (see Clin. Corr. 12.1).

12.11 • PORE-FORMING TOXINS AND IONOPHORES

Bacteria and a few mammalian tissues synthesize **pore-forming toxins**. They belong to a large family (58 members) of peptides and proteins synthesized on ribosomes. They are secreted from cells and form transmembrane pores in membranes of another cell. The created pores allow the flow of electrolytes and small molecules through the membrane, thus initiating a toxic effect. **Defensin**, a pore-forming toxin synthesized by epithelial and hematopoietic cells, has broad-spectrum antibiotic activity.

An interesting group of small molecular weight compounds (up to several thousand Daltons), synthesized and excreted by bacteria and fungi, facilitates the translocation of inorganic ions across membranes. These molecules, referred to as **ionophores**, have antibacterial activity because they disrupt the ionic balance of a cell. They are also valuable experimental tools in studies of ion translocation in biological membranes and for manipulation of the ionic compositions of cells.

Ionophores are classified as nonribosomally synthesized channels (p. 477); there are two major subgroups: mobile transporters that bind an ion and readily diffuse in a membrane, and channel formers. Some major ionophores are listed in Table 12.13.

Each mobile transporter has an ion specificity. **Valinomycin** (Figure 12.60) has an affinity for K^+ 1000 times greater than for Na^+, and **A23187** (Figure 12.61) has an affin-

TABLE 12.13 • Major Ionophores

Compound	*Major Cations Transported*	*Action*
Valinomycin	K^+ or Rb^+	Uniport, electrogenic
Nonactin	NH_4^+, K^+	Uniport, electrogenic
A23187	Ca^{2+}/2 H^+	Antiport, electroneutral
Nigericin	K^+/H^+	Antiport, electroneutral
Monensin	Na^+/H^+	Antiport, electroneutral

Alamethicin	K^+, Rb^+	Forms channels

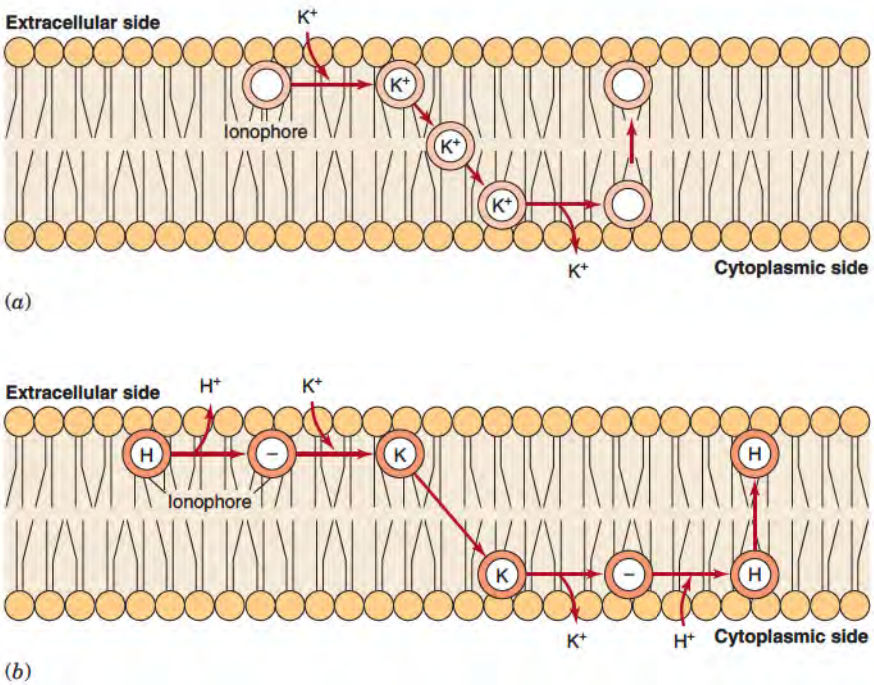

Figure 12.62 Mechanism for ionophoretic activities of valinomycin and nigericin. (*a*) Transport by valinomycin. (*b*) Transport by nigericin. I represents ionophore. The valinomycin-K^+ complex is positively charged and translocation of K^+ is electrogenic leading to creation of a charge separation across membrane. Nigericin translocates K^+ in exchange for a H^+ across membrane and the mechanism is electrically neutral.
Diagram adopted from Pressman, B. C, *Annu. Rev. Biochem.* 45: 501, 1976.

ity for Ca^{2+} 10 times greater than Mg^{2+}. Several of the mobile transporters have a cyclic structure and the ion coordinates to oxygen atoms in the core of the structure; the periphery of the molecule consists of hydrophobic groups. When an ion is chelated by the ionophore, its water shell is stripped away and the ion encompassed by the hydrophobic shell. The ionophore–ion complex freely diffuses across the membrane. Since interaction of ion and ionophore is an equilibrium reaction, a steady-state concentration of the ion develops on both sides of the membrane. Valinomycin transports K^+ by an electrogenic uniport mechanism that creates an electrochemical gradient across a membrane as it transports a positively charged K^+ (Figure 12.62*a*). **Nigericin** is an electrically neutral antiporter; its carboxyl group when dissociated binds a positive ion, such as K^+, leading to a neutral complex that moves across a membrane. It transports a proton back on diffusion through the membrane, leading to an exchange of K^+ for H^+ (Figure 12.62*b*).

Gramicidin A is a 15-residue peptide with alternating D- and L-amino acids. In membranes it forms a β-helix and dimerizes, forming a long (25 Å) and narrow (5 Å) diameter) transmembrane channel (Figure 12.63). Polar residues line the channel and hydrophobic

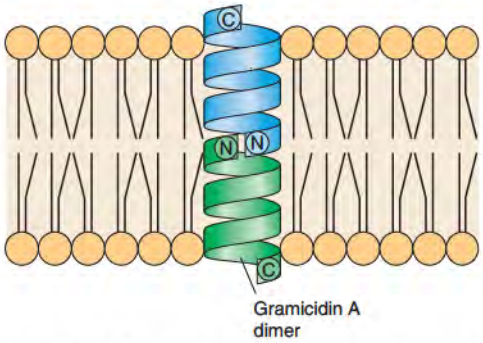

Figure 12.63 Action of gramicidin A Two molecules of gramicidin A form a dimer by hydrogen binding at the amino ends of the peptides creating a channel in a membrane.

CLINICAL CORRELATION 12.6

Diseases Involving the Superfamily of ABC Transporters

ATP binding cassette (ABC) transporters are a superfamily of proteins with a number of subfamilies that all contain a conserved ATP-binding domain and diverse transmembrane domains. The members of the superfamily catalyze the ATP-dependent transport of a wide variety of substances and are present in many different tissues. A number are found in mutant form in various diseases. The following lists selected ABC transporters, their substrates, and related diseases:

Transporter	*Substrate*	*Disease*
ABCA1	Phospholipid	Tangier disease
ABCG5	Plant sterols	Sitosterolemia
ABCR	Phosphatidyl-ethanolamine	Juvenile macular degeneration
		Retinitis pigmentosa
ABC7	Iron?	Sideroblastic anemia with ataxia
BSEP	Bile salts	Progressive familial intrahepatic cholestasis
MRP1	Xenobiotics	Multidrug resistance
MRP2	Bilirubin glucuronides	Dubin–Johnson syndrome
PGY3	Long-chain phosphatidyl-choline	Cholestasis of pregnancy
TAP1	Peptide transporter	Ankylosing spondylitis
		Insulin-dependent diabetes mellitus
		Celiac disease

Note that genetic diseases involving the ABC transporters involve a variety of pathophysiological conditions, involving a number of different tissues, and various biochemical systems.

For a detailed list of the ABC transporters and their diseases, see http://nutrigene.4t.com/humanabc.htm.

groups are on the periphery of the channel interacting with the lipid membrane. The structure permits the passage of water and univalent cations but not anions. Association and dissociation of the monomers control the rate of ion flux.

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. All of the following are ways in which peripheral proteins bind to membranes except
   - **A.** binding to an integral protein.
   - **B.** electrostatic binding between phospholipids and positive groups on the protein.
   - **C.** by a short hydrophobic group at one end of the protein.
   - **D.** attached by the charged carboxyl group at the carboxyl terminus of the protein.
   - **E.** binding non-covalently to membrane phosphatidylinositol.

2. Characteristics of a mediated transport system include
   - **A.** nonspecific binding of solute to transporter.
   - **B.** release of the transporter from the membrane following transport.
   - **C.** a rate of transport directly proportional to the concentration of solute.
   - **D.** release of the solute only if the concentration on the new side is lower than that on the original side.
   - **E.** a mechanism for translocating the solute from one side of the membrane to the other.

3. The translocation of Ca^{2+} across a membrane involves all of the following except
   - **A.** active transport by Ca^{2+}-transporting ATPases.
   - **B.** maintaining $[Ca^{2+}]$ very much higher in the cell than in extracellular fluid.
   - **C.** phosphorylation of the transporter.
   - **D.** regulation by the binding of a Ca^{2+}-calmodulin complex to the transporter in eukaryotes.
   - **E.** different transporters for transport into the lumen or out across the plasma membrane

4. Cell membranes typically
   - **A.** are about 90% phospholipid.
   - **B.** have both integral and peripheral proteins.
   - **C.** contain cholesteryl esters.
   - **D.** contain free carbohydrate such as glucose.
   - **E.** contain large amounts of triacylglycerols.

5. All of the following are correct about an ionophore except it
   - **A.** requires the input of metabolic energy for mediated transport of an ion.
   - **B.** may diffuse back and forth across a membrane.
   - **C.** may form a channel across a membrane through which an ion may diffuse.
   - **D.** may catalyze electrogenic-mediated transport of an ion.
   - **E.** will have specificity for the ion it moves.

6. Cells control the distribution of water across membranes by aquaporins and aquaglyceroporins because nonfacilitated diffusion is too slow. Aquaporins (AQP)
   - **A.** permit translocation of water and small solutes.
   - **B.** reduce the pH gradient because they transport H_3O^+.
   - **C.** are peripheral proteins of the membrane.
   - **D.** form channels through which water flows.
   - **E.** have no specific controls to open the channel.

Questions 7 and 8: Two problems encountered with oral or intravenous administration of drugs are the lack of tissue specificity in the action of the drug and rapid metabolism, and therefore limited period of effectiveness, of some drugs. One attempt to circumvent these problems is the use of liposomes to encapsulate the drugs. Some drugs have a longer period of effectiveness when administered this way. Liposomes can be prepared with specific proteins to bind specific cellular membrane receptors. Liposomes are also useful as a research tool to study the properties of biological membranes since they have a similar structure and properties. Much of our understanding of biological membranes has been obtained using liposomes.

7. Plasma membrane receptors
   - **A.** usually have as ligands molecules like steroids.
   - **B.** are always coupled to G-proteins.
   - **C.** are fixed in number for a given cell.
   - **D.** often span the membrane with one or more transmembrane domains.
   - **E.** when bound to their ligand, always result in the release of a small molecule (second messenger) into the cell.

8. Which of the following statements concerning membranes is correct?
   - **A.** Microdomains, called lipid rafts, are fixed in position in membranes.
   - **B.** Lipid composition of the two layers of the membrane equilibrate.
   - **C.** As demonstrated with liposomes, the membrane is most fluid at the surfaces.
   - **D.** An increase in the cholesterol content of a membrane increases membrane fluidity.
   - **E.** Lipid transporters catalyze unidirectional movement of specific lipids from one layer to the other.

Questions 9 and 10: Cystic fibrosis is a relatively common (1 in 2000 live births) genetic disease of Caucasians. Although it affects many organs, pulmonary obstruction is a major problem. CF patients have reduced Cl^- permeability and the disease can be diagnosed by elevated $[Cl^-]$ in sweat. Genetic mutations lead to defects in cystic fibrosis transmembrane conductance regulator (CFTR) protein which is a cAMP-dependent Cl^- channel. CFTR has structural homology to the superfamily of ATP-binding cassette (ABC) transporters.

9. Membrane channels
   - **A.** have a large aqueous area in the protein structure so are not very selective.
   - **B.** commonly contain amphipathic α-helices.
   - **C.** are opened or closed only as a result of a change in the transmembrane potential.
   - **D.** are the same as gap junctions.
   - **E.** allow substrates to flow only from outside to inside of the cell.

10. ATP-binding cassette (ABC) transporters
    - **A.** have both a membrane-spanning domain that recognizes the substrate and an ATP-binding domain.
    - **B.** all effect translocation by forming channels.
    - **C.** are found only in eukaryotes.
    - **D.** all have two functions: forming a channel and conductance regulation.
    - **E.** are all P-glycoproteins.

Questions 11 and 12: Alterations in membrane transport systems for specific components lead to a number of diseases. In Hartnup disease there is a decrease in transport of neutral amino acids by intestine and renal tubules. Individuals with a decreased glucose uptake from the intestinal tract lack a specific glucose–galactose transporter. In these diseases the transport systems are Na^+/(amino acid) or (glucose) co-transporters.

11. This type of transport system
- **A.** moves Na^+ and the amino acid or glucose in opposite directions across the membrane.
- **B.** uses the energy of the Na^+ gradient (SMF) to concentrate the other substance against its gradient.
- **C.** results in the hydrolysis of ATP during the transport.
- **D.** is the same as coded for by the multidrug resistance (Mdr) family of genes.
- **E.** is the only type of system used to transport glucose across membranes.

12. A different type of transport system that maintains the Na^+ and K^+ gradients across the plasma membrane of cells
- **A.** involves an enzyme that is an ATPase.
- **B.** is a symport system.
- **C.** moves Na^+ either into or out of the cell.
- **D.** is an electrically neutral system.
- **E.** in the membrane hydrolyzes ATP independently of the movement of Na^+ and K^+.

Problems

13. Draw a curve illustrating the rate of movement of a solute through a membrane as a function of the concentration of the solute for (a) O_2 and (b) uptake of glucose into the erythrocyte.

14. What kind of transporter is the acetylcholine receptor of skeletal muscle membrane, and how is it controlled?

Answers

1. D A single electrostatic charge probably would not be sufficient. A: An example is ankyrin binding to the anion channel in erythrocytes. B: The negative charge of the phospholipids is involved. C: This would insert into the lipid bilayer. E: A specific domain binds to the inositol 3-phosphate head group.

2. E This is essential to having the solute transported across the membrane. A: Specificity of binding is an integral part of the process. B: Recovery of the transporter to its original condition is one of the characteristics of mediated transport. C: Only at low concentrations of solute; transporters show saturation kinetics. D: Active transport, movement against a gradient, is also mediated transport.

3. B Extracellular Ca^{2+} is about 10,000 times higher than intracellular. A: This is a primary active transport. C: These are P-type transporters (phosphorylation is on an aspartate). D: This binding lowers the K_m for Ca^{2+} and increases Ca^{2+} transport. E: They are known as CERCA and PMCA.

4. B Some proteins are embedded in the membrane whereas others are at the surface. A: This is more than the total lipid. C: Cholesterol in membranes is unesterified. D: All carbohydrate in membranes is in the form of glycoproteins and glycolipids. E: This is a minor component.

5. A Ionophores transport by passive mediated mechanisms. B and C: These are the two major types of ionophores. D: Valinomycin transports K^+ by a uniport mechanism. There are also antiport systems that are electroneutral. E: Valinomycin has an affinity for K^+ 1000 times greater than for Na^+.

6. D They assemble as homotetramers with each monomer forming a specific pore. A: This is a description of aquaglyceroporins. B: They do not transport H_3O^+. C: They are integral proteins that span the membrane. E: Channels need controls.

7. D This is a common mechanism for anchoring the protein in the membrane. A: Steroids can diffuse through the plasma membrane and have intracellular receptors. B: This is just one of the three major classes of plasma membrane receptors. C: Receptors can be upregulated or downregulated to modify the cellular response to a ligand. E: There are a variety of initial responses of the receptor- ligand binding, including opening a channel.

8. E Asymmetry is maintained by ATP-dependent flippases and flippases. A: They diffuse freely and can cluster into larger domains. B: Moving a charged head group through the lipid core of the membrane is thermodynamically unfavorable. C: The area of greatest fluidity is the center of the membrane. D: Cholesterol is a rigid molecule which decreases fluidity.

9. B The helices typically form the channel with hydrophilic side chains lining the channel and hydrophobic ones facing the lipid core of the membrane. A: This describes a pore; channels are quite specific. C: Voltage gated channels, like that for Na^+, are controlled this way but others, like the nicotinic acetylcholine channel, are chemically regulated. D: Clusters of membrane channels work together to form a gap junction. E: Substances may move in either direction as dictated by the concentration gradient.

10. A These are the common features. B: They operate by a variety of mechanisms, including transporters and receptors. C: Both prokaryotes and eukaryotes have them. D: CFTR is unusual in having both of these functions. E: Some, such as those coded for by the Mdr gene family or the transporter for cholesterol out of cells are P-glycoproteins, but others are not.

11. B These are Na^+-dependent secondary active transporters. A: These are symports, moving both substances in the same direction. C: ATP is used to maintain the Na^+ gradient, not in the transport of the amino acid or glucose. D: Mdr are ABC transporters. E: Glucose can also be transported by a passive uniport system.

12. A The Na^+, K^+-transporter is the Na^+/K^+-exchanging ATPase. B, C, and D: It is an antiport, vectorial (Na^+ out), electrogenic ($3Na^+$, $2K^+$) system. E: ATP hydrolysis is not useless.

13. See Figure 12.32. (a) O_2 crosses membranes by simple diffusion; thus, rate increases with concentration as illustrated by the lower curve on the figure. (b) Uptake of glucose by erythrocytes is a passive mediated transport so should show saturation kinetics as illustrated by the upper curve in the figure.

14. This is also called the nicotinic-acetylcholine channel and is an example of an agonist regulated channel. Acetylcholine interacts with the acetylcholine receptor on the membrane causing a conformational change in the protein which opens the channel and allows cations (but not anions) to flow through. Hydrolysis of acetylcholine with release of the products closes the channel.

Key Concepts

- Communication between cells involves intercellular signaling via secreted molecules (hormones, neurotransmitters, and other mediators) and intracellular signaling cascades regulated by receptors that bind the secreted molecules. Receptors include: (1) cell surface proteins that bind hydrophilic or large secreted molecules, and (2) intracellular proteins that bind hydrophobic secreted molecules.
- Cell surface receptors initiate reactions that rapidly change the intracellular concentrations of small second-messenger molecules, such as cyclic nucleotides, Ca^{2+} ions, or lipid metabolites.
- Two major types of molecular switches control the transmission of intracellular signals: (1) the phosphorylation status of proteins; and (2) G proteins that when bound to GTP, switch between conformational states that turn on or off the activity of other proteins.
- Some protein kinases and phosphatases are intrinsic activities of cell surface receptor proteins that bind growth factors; others are separate proteins that are regulated by transient association with cell surface proteins or by binding small second messengers.
- Protein kinases and phosphatases regulate intracellular signaling by changing the phosphorylation status and function of: (1) enzymes, including other kinases and phosphatases; (2) ion channels and ion transporters; (3) transcription factors; and (4) structural proteins that regulate cell shape, size, and motility.
- G proteins are regulated by their interaction with other proteins that increase the rate of GTP/GDP exchange by the G proteins;

these include the G protein-coupled receptors (GPCR) that constitute the largest superfamily of cell surface receptors and include the sensory receptors involved in vision, smell, and taste.
- G proteins regulate the activity of other proteins including enzymes that synthesize second messengers, ion channels that control membrane potential or the flux of regulatory ions, and other protein kinases.
- Combinations of different intercellular and intracellular signaling reactions constitute signaling networks that allow cells in one organ or tissue to respond to changes in the function of cells in other organs or tissues; these signaling networks ensure homeostasis within the entire organism.
- Aberrant expression or function of signaling proteins, including secreted molecules, receptors, G proteins, and protein kinases, is the underlying cause of common human diseases including many cancers, heart failure, diabetes, and some behavioral disorders; about 50% of the most widely used therapeutic drugs target signaling proteins.

13.1 • SIGNAL TRANSDUCTION BETWEEN CELLS

Communication or signal transduction between cells and tissues consists of two phases. Intercellular signal transduction characterizes the passage of a signal from one cell to target cells via the extracellular environment. Intracellular signal transduction comprises the biochemical decoding of that signal on receipt by the target cells, a process that involves stepwise regulation of intracellular signaling proteins that ultimately results in altered function of proteins involved in metabolism, gene regulation, membrane transport, and cell motility (Figure 13.1). The combination of intercellular and intracellular signaling allows cells in one organ or tissue to respond to changes in the function of cells in other organs or tissues to ensure homeostasis within the entire organism.

13.2 • INTERCELLULAR SIGNAL TRANSDUCTION

Two Fundamental Modes of Intercellular Signal Transduction

Intercellular signaling describes the mechanisms by which one cell (the "sender" cell) sends a message to change the function of another cell (the "target" or recipient cell). Two cells can communicate (i.e., transmit information to each other) in several different ways (Figure 13.2). One requires that they be in direct physical contact; this mode is **juxtacrine** or **contact dependent**. A second and more common mode is contact independent and involves release of **secreted molecules** from the sender cells. The secreted molecules diffuse through extracellular space to the target cells where they interact with receptor proteins resulting in an activation of intracellular signaling and altered function. This latter mode permits intercellular communication

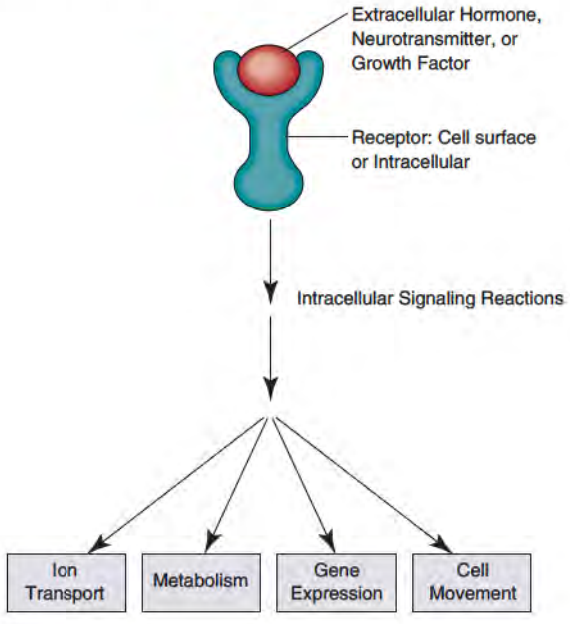

Figure 13.1 Basic elements of a signal transduction pathway at the cellular level.

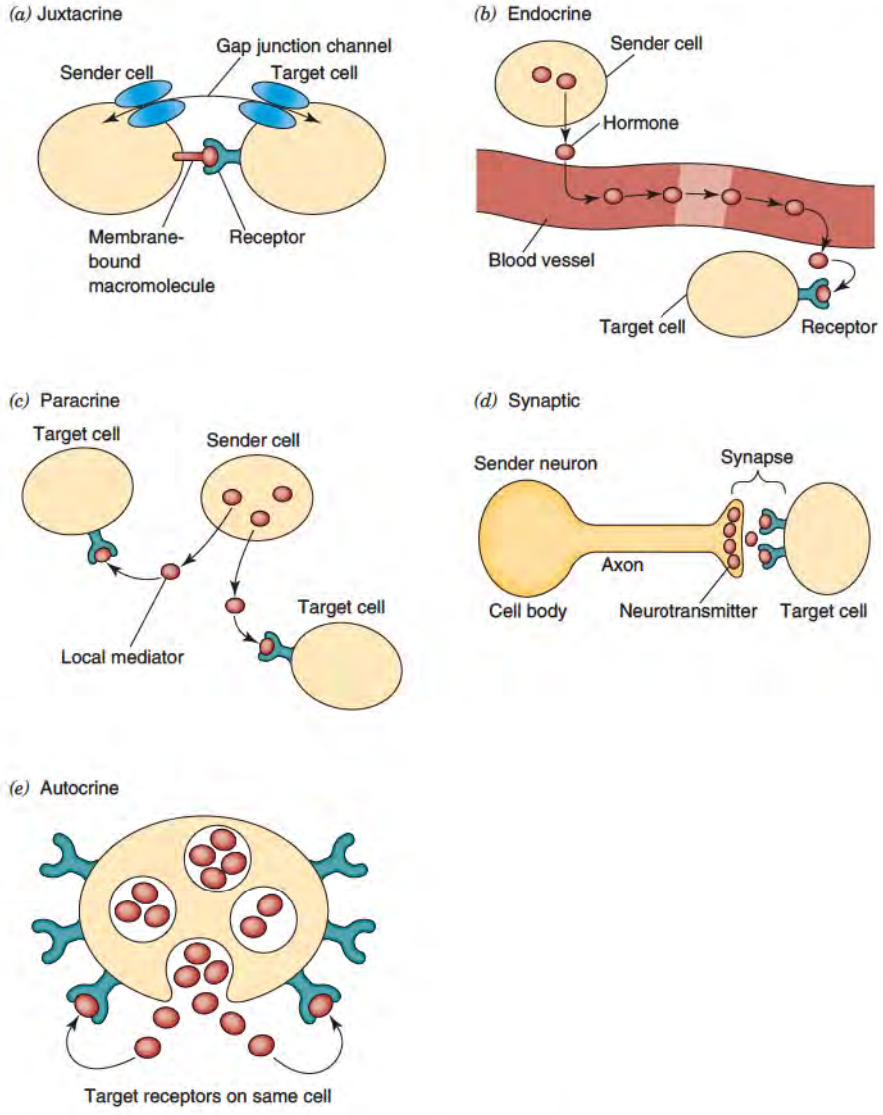

Figure 13.2 Five major modes of intercellular signal transduction.
Redrawn based on figures from Alberts, B., et al., *Essential Cell Biology,* 2d ed. New York: Garland Science, 2004; and Lodish, H., et al., *Molecular Cell Biology,* 4th ed. New York: Freeman, 2000.

between cells separated by large distances, for example, cells in different tissues or organs or between cells separated by short distances. Contact-independent signaling by secreted molecules includes four modes: **endocrine**, **paracrine**, **synaptic** or neuronal, and **autocrine**. These modes are distinguished by: (1) the actual distance between the sender and target cells; and (2) the biochemical nature of the secreted molecules.

Juxtacrine, or Contact-Dependent, Signaling

In juxtacrine signaling, cells communicate by either of two mechanisms. One is through gap junction channels that allow direct transfer of small ions, metabolites, and second messenger molecules between neighboring cells. The structure and function of these channels is described in detail on page 477 and in Figures 12.41, page 484, and 12.42, page 484. The second mechanism involves the interaction of a protein expressed on the surface of the sender cell with a receptor protein expressed on the surface of the target cell (Figure 13.2*a*). This interaction changes the conformation of the receptor protein and triggers a cascade of intracellular signaling events in the target cell that results in altered function of that cell. Important elements of juxtacrine signaling include a variety of proteins, such as integrins, involved in cell–cell adhesion and regulation of cell shape and motility.

Endocrine Signaling

This mode involves signaling between cells separated by short or long distances. Specialized sender cells in glandular tissues synthesize, package, and secrete molecules called hormones

(Figure 13.2*b*). By definition, hormones are molecules secreted into the blood for long-distance transport to the target cells in various tissues. This is a broadcast type of remote signaling because blood carries the hormone to most cell types in most tissues. Although most cells in the body will be exposed to the hormone, only those cells that express specific receptors for that hormone will be target cells. Two important aspects of endocrine signaling should be noted. First, because a hormone is being secreted into the total blood volume, it will be diluted many-fold by the time it reaches target cells in peripheral tissues. The concentration of hormones in blood and interstitial spaces is always low (picomolar to nanomolar concentrations, i. e., 10^{-12} to 10^{-9} M) even during maximal rates of secretion from the source gland. Given the low concentration of hormones, the target cell receptors must have a very high affinity and selectivity for a particular hormone. One consequence of this high affinity is that once the hormone is bound, it cannot easily dissociate from its receptor. Second, it takes a considerable amount of time to increase and or to decrease the concentration of a hormone in blood because of the large volume or capacity of the blood. Following secretion, hormone concentrations in the blood and interstitial fluid can remain elevated for many minutes or even for hours. This and the high affinity of hormone—receptor interactions have important consequences for the mechanisms by which target cells turn off their response to a hormone. It also ensures that intracellular signaling by the target cell will last for long periods.

Paracrine Signaling

In this mode, a sender cell does not secrete signaling molecules into the blood for long-distance transport, but only secretes such molecules into its immediate or local environment (Figure 13.2*c*). This greatly restricts the distances over which the molecules can travel (by passive diffusion) and thus limits responses only to target cells in the immediate vicinity of the sender cell. Given their localized action, the secreted molecules used for paracrine signaling are generically termed *local mediators*. Because, unlike secreted hormones, the secreted local mediators are not massively diluted, their concentration near target cells can be fairly high (nanomolar to micromolar range, i. e., 10^{-9} to 10^{-6} M). Thus, target cell receptors for local mediators usually have lower affinity for these secreted molecules. Lower affinity means that the local mediator can rapidly dissociate from the receptor when the local, extracellular concentration of the mediator is reduced. Moreover, because the mediator is secreted locally into a small extracellular volume, its concentration at the target cell will be only transiently elevated due to rapid diffusion and dilution into the larger tissue space. Thus, paracrine signaling is used for rapid and localized communication between cells.

Synaptic or Neuronal Signaling

This type of paracrine signaling is specific to nerve cells that send out specialized cellular extensions (axons) to the immediate vicinity of a target cell that is usually another neuron or a muscle cell (Figure 13.2*d*). The synapses between a neuron and its target cells constitute a restricted extracellular space into which the neuron secretes signaling molecules called neurotransmitters. Given this special synaptic geometry, neurotransmitters travel only very short distances to the target cell. Because of this short intercellular distance and the restricted synaptic volume, the local concentration of neurotransmitter reaching the target cell can be very high (micromolar to millimolar range, i. e., 10^{-6} to 10^{-3} M). Thus, receptors on the target cell can have relatively low affinity for the neurotransmitter. This low affinity ensures that neurotransmitters can rapidly dissociate from their receptors following decreases in their local concentration. This is essential for the very rapid (millisecond) termination of neurotransmission from the presynaptic neuron to its postsynaptic targets.

Autocrine Signaling

This type of paracrine signaling occurs when one cell type is both the sender cell and the target cell (Figure 13.2*e*). Autocrine signaling is often used by organisms during tissue growth, organ development, and immune and inflammatory responses. The general features of autocrine signaling are the same as for nonsynaptic paracrine signaling except that the sender cell provides both the secreted molecule (often a large polypeptide growth factor) and a receptor for that molecule. For example, early tissue development

often involves increased expression of a growth factor and the receptor for that growth by a particular progenitor or stem cell. The released growth factor induces autocrine activation of its target receptor to initiate replication of the original stem cell and its progeny cells.

Secreted Signaling Molecules

Many types of biological molecules, including proteins, glycoproteins, small peptides, amino acids, amines, lipids (fatty acids or steroids), nucleotides, nucleosides, and gases (e.g., nitric oxide), are used as secreted signaling molecules by various cells. The major differences between the signaling molecules are in their size and relative water solubility. Hormones used for endocrine signaling are amino acid products (large proteins, glycoproteins, polypeptides, or small peptides) or steroids. Neurotransmitters used for synaptic signaling are small, simple molecules such as amino acids (e.g., glutamate, glycine), substituted amines (e.g., epinephrine, acetylcholine, γ-amino-butyric acid [GABA]), nucleotides (e.g., ATP), or small peptides. Local mediators used for paracrine (nonsynaptic) and autocrine signaling are very diverse and include proteins, small peptides, simple organic molecules (e.g., histamine, ATP, and adenosine), or fatty acid derivatives (e.g., prostaglandins).

13.3 • RECEPTORS FOR SECRETED MOLECULES

Receptors for secreted molecules can be divided into two major classes: **intracellular receptors** and **cell surface receptors** (Figure 13.3). Hydrophobic molecules readily pass through the plasma membrane of target cells and bind to **intracellular receptor** proteins.

Intracellular receptors are specific for secreted steroid hormones, derivatives of vitamin D_3, retinoic acid, and thyroid hormone (Figure 13.3*a*). They compose a highly homologous group of structurally related proteins. Their structures and functions (see Figures 22.46,

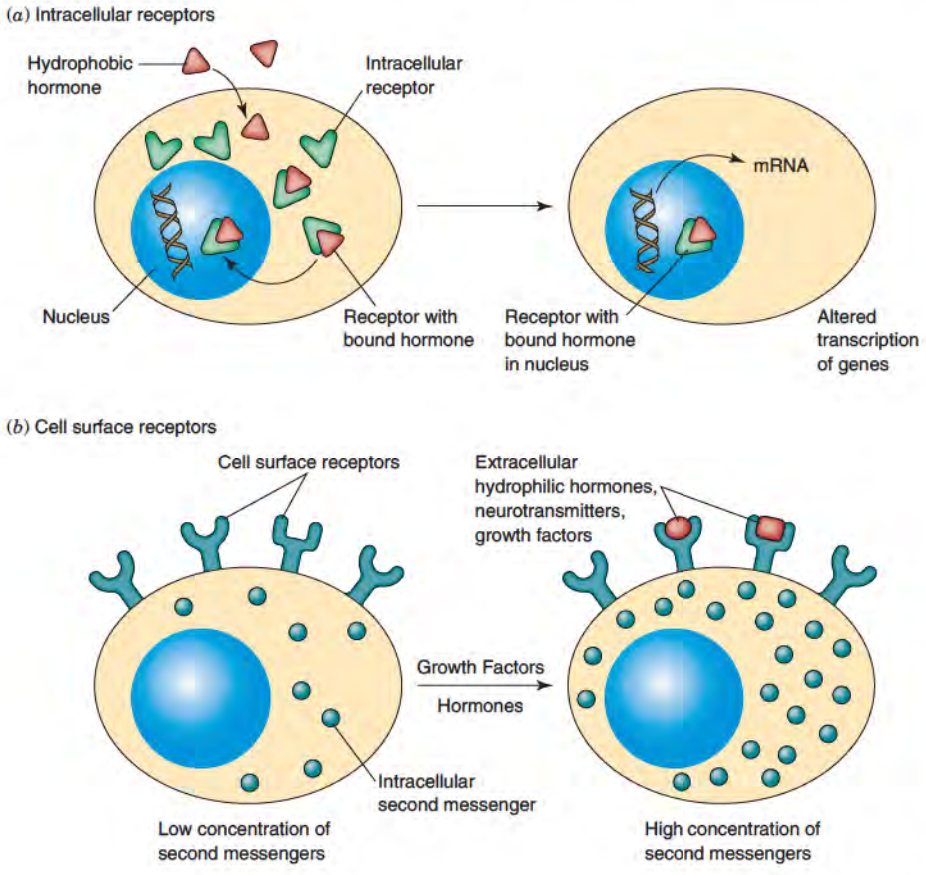

Figure 13.3 Basic properties of intracellular receptors versus cell surface receptors.

p. 927, and 22. 47, p. 929) are described in detail in Chapter 22. Some are cytosolic proteins that traffic to the nucleus only when bound to their cognate hormone; others enter the nucleus even in the absence of bound hormone. In all cases, the hormone-bound receptors function as dimeric complexes (homomers or heteromers) that bind to specific DNA sequences within the upstream regulatory elements of various genes to enhance or repress transcription and thus alter expression of proteins encoded by these genes. Because of their effects on gene expression, activation of intracellular receptors produces long-lasting changes (hours to days) in the function of target cells.

Cell surface receptors are recognition sites for the vast majority of signaling molecules that are either too big (protein or polypeptide hormones) or too hydrophilic to rapidly cross the target cell plasma membrane. Such signaling molecules interact with the target cell by binding to cell surface receptors that are integral membrane proteins (Figure 13.3*b*). Surface receptor proteins are coupled to a variety of intracellular biochemical reactions termed **signal transduction cascades** or **pathways**. The earliest signal transduction event triggered by binding of a signal molecule to such a receptor is a conformational change in the receptor that results in: (1) the generation of intracellular signaling molecules known as **second messengers** (the extracellular secreted molecule is the first messenger) or (2) a change in plasma membrane electrical potential or (3) activation of enzymatic cascades involving protein kinases, protein phosphatases, or proteases. Four major superfamilies of structurally and functionally related cell surface receptors that mediate the vast majority of intercellular communication pathways (Figure 13.4) are **(1) ligand-gated ion channel receptors**, **(2) enzyme-linked or catalytic receptors**, **(3) cytokine family receptors**, and **(4) G protein-coupled receptors** or **GPCR**.

13.4 • INTRACELLULAR SIGNAL TRANSDUCTION BY CELL SURFACE RECEPTORS

Ligands, Receptors, and Receptor–Ligand Interactions

A **ligand** is any molecule that binds to a receptor protein. An **agonist** is a ligand that on binding, activates signal transduction, whereas an **antagonist** is a ligand that prevents signal transduction when it binds to the receptor. A **physiological agonist** or **antagonist** is a naturally occurring molecule (like a hormone or neurotransmitter) that acts as a receptor ligand. A **pharmacological agonist** or **antagonist** is a synthetic molecule that acts as a receptor ligand. Many therapeutic drugs are agonists or antagonists of receptors.

Certain physiological agonists stimulate multiple types of receptors that are termed **receptor subtypes**. This means that the same extracellular signaling molecule may bind to different receptor proteins that are the products of different genes. For example, the neurotransmitter acetylcholine interacts with a ligand-gated ion channel receptor that causes contraction of skeletal muscle, or with a G protein-coupled receptor that causes relaxation of cardiac muscle (Figure 13.5). Each of the neurotransmitters, for example, acetylcholine, serotonin, and dopamine, recognizes a dozen or more receptor subtypes. Each receptor subtype can be differentially expressed in various tissues or/cells or can be coexpressed in the same tissue or cell. Moreover, receptor subtypes often activate opposing signal transduction responses. This greatly complicates the design and testing of synthetic agonists and antagonists and is a major reason why most drugs aimed at receptors have dangerous side effects when used improperly.

Relationships between Receptors, Effectors, and Second Messengers

The first step in signaling by cell surface receptors is the binding of the extracellular agonist to the receptor protein that changes the intrinsic energy and structural conformation of the receptor protein. In this conformation, the receptor interacts with **effector proteins** that are signaling proteins (enzymes or ion channels) distal to, but activated by, the agonist-bound receptor (Figure 13.4). In some cases, the receptor protein itself is also the effector. Activation of an effector leads to generation of **second messengers** or to changes in membrane potential. Some receptors interact directly with effector proteins whereas others require **coupling** or **transducing proteins** to interact with the effector. GTP-binding regulatory proteins (G proteins) are a very important class of such coupling proteins.

Enzyme effectors may be intrinsic components of a receptor protein (e.g., receptor tyrosine kinases) or distinct proteins (e.g., nonreceptor tyrosine kinases). They can be integral membrane proteins (e.g., adenylate cyclase) or cytosolic proteins (e.g., guanylate cyclase)

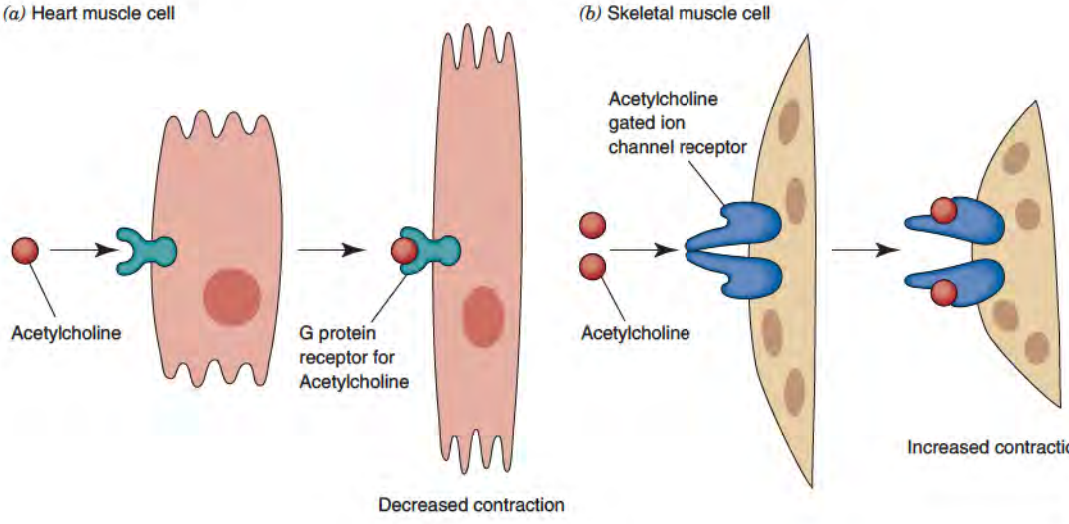

Figure 13.5 Basic characteristics of receptor subtypes as functionally distinct receptor proteins that bind a common extracellular signaling molecule.

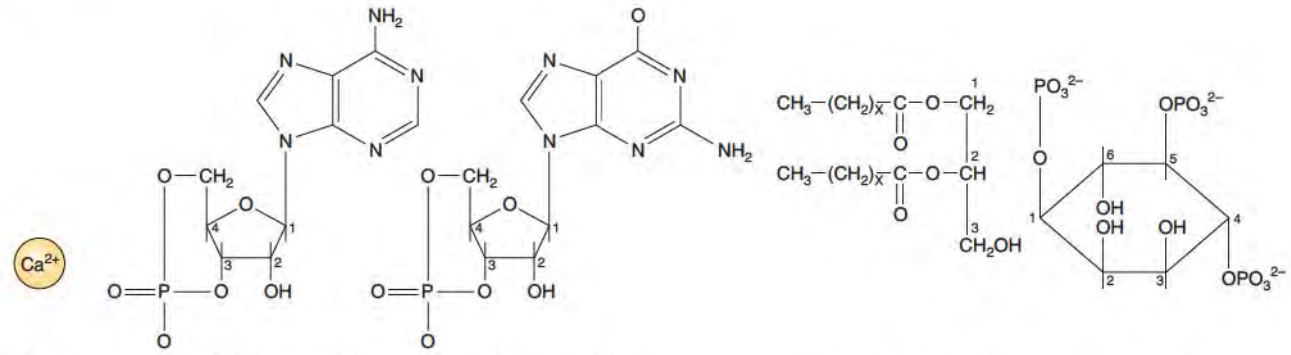

Figure 13.6 Structures of four second-messenger molecules.

and include nucleotide cyclases, phospholipases, protein kinases, and protein phosphatases. These will be discussed in later sections. Ion channel effectors are an intrinsic component of some receptors (ligand-gated ion channels) whereas others are indirectly regulated by receptors via G proteins or second messengers.

Second messengers are small intracellular molecules that transmit and amplify the initial signal from agonist-activated receptors (Figure 13.6). They can be inorganic ions or organic products of enzyme-catalyzed reactions.

Ions passing through receptor-regulated channels function as second messengers in two ways. If the ionic flux is sufficiently great, the cytosolic concentrations of certain regulatory ions can change appreciably; Ca^{2+} is the major intracellular regulatory ion. If the particular ionic flux is the predominant current across the plasma membrane, the membrane potential will be driven to the equilibrium potential for that ion. This will result in depolarization or hyperpolarization of the membrane.

Effector enzymes often catalyze the rapid production of **water-soluble second-messenger molecules**, for exmple, cyclic AMP (cAMP), cyclic GMP (cGMP), and inositol trisphosphate (IP_3) (Figure 13.6).

Other effector proteins, such as phospholipases or lipid kinases, catalyze rapid production of membrane-associated **lipid second messengers**, for example, diacylglycerol (DAG) or phosphatidylinositol 3,4,5-trisphosphate (PIP_3) (Figure 13.6).

Protein Phosphorylation in Signal Transduction

Most pathways of intracellular signal transduction involve changes in the phosphorylation status of certain proteins. Phosphorylation of proteins can change their secondary, tertiary, or quaternary structure and result in altered function. Such phosphorylation involves the regulated activity of a variety of **protein kinases** and **protein phosphatases** (Figure 13.7*a*). Protein kinases are classified on the basis of their selectivity for particular amino acids. Most protein

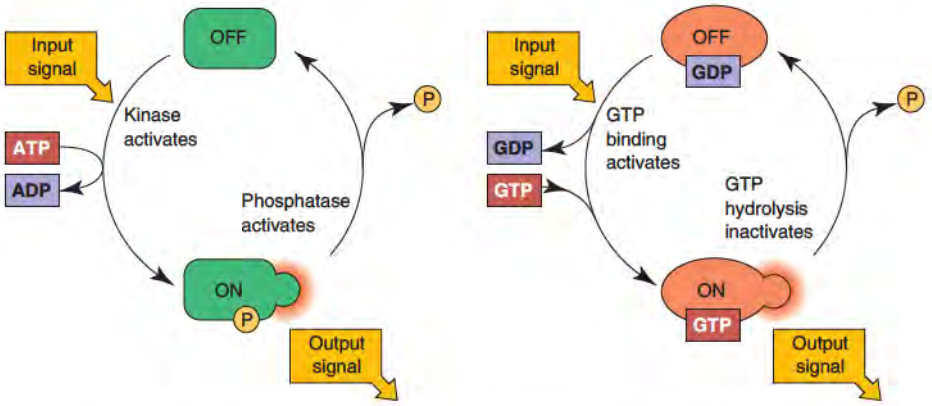

Figure 13.7 Protein phosphorylation versus guanine nucleotide binding as two major types of molecular switches for changing protein function during intracellular signaling.

kinases activated by second messengers phosphorylate specific proteins on serine or threonine residues. Many growth factors and cytokines will also stimulate kinases that phosphorylate proteins on tyrosine residues. These protein tyrosine kinases play important roles in regulation of cell growth and differentiation. Protein substrates for either serine/threonine kinases or tyrosine kinases are very diverse and include metabolic enzymes, ion channels, transcriptional factors, or other protein kinases. Protein phosphatases also exhibit selectivity for serine/threonine phosphate or tyrosine phosphate residues. The ability of some protein kinases to phosphorylate and activate target proteins, which are themselves protein kinases, underscores the involvement of **protein kinase cascades** in the regulation of complex cellular responses. These cascades are often critical elements in the **amplification** process that characterizes the intracellular signaling reactions initiated by binding of ligands to cell surface receptors.

Protein kinases can be regulated by receptors in several ways. Some tyrosine kinases are intrinsic components of the receptor protein structure (e.g., receptor tyrosine kinases) whereas others are cytosolic proteins that transiently associate with activated receptors (e.g., nonreceptor tyrosine kinases that bind to cytokine receptors). Most serine/threonine kinases are soluble proteins that are regulated by an increase in second-messenger concentration (e.g.. cAMP-dependent protein kinase). Likewise, there are multiple types of phosphatases, which reverse the signals generated by receptor- or second-messenger activated kinases.

GTP-Binding Regulatory Proteins in Signal Transduction

The G proteins that are functionally coupled to the G protein-coupled receptors belong to a larger family of proteins that bind and hydrolyze GTP as part of their specific cellular function (Figure 13.7*b*). These **GTPases** have an important **molecular switch** role, being involved in critical biological functions such as initiation, elongation, and termination of protein synthesis; microtubule assembly; regulation of enzyme activity; and membrane trafficking. Many of these "switch" GTP-binding proteins are monomeric proteins; this distinguishes them from the trimeric, receptor-coupled G proteins. All GTP-binding proteins (monomeric and trimeric molecules) have different conformations and activities depending on whether they have guanosine-5′-diphosphate (GDP) or GTP bound. The GDP-bound form interacts with another protein (a **guanine nucleotide exchange factor [GEF]**) that catalyzes the exchange of GDP for GTP. The GTP-bound form interacts with, and changes the activity of, downstream effector protein. The GTPase activity converts the GTP-bound form to a GDP-bound form, which has decreased ability to interact with effector proteins and must interact with a GEF in order to resume its active conformation. A major function of many cell-surface receptors is to trigger, directly or indirectly, the GDPGTP exchange reactions that result in G protein activation.

Other Components of Receptor-Mediated Signaling Complexes and Cascades

In addition to effector proteins, second messengers, trimeric G proteins, and protein kinases, a wide variety of intracellular proteins may be involved in the cell-surface receptor-mediated intracellular signaling pathways. By physically colocalizing multiple signaling proteins within a given signaling pathway, **scaffold** and **adaptor proteins** increase the fidelity and speed of a complex signaling cascade. Proteins termed **anchoring proteins** localize and concentrate soluble signaling proteins at particular subcellular locations. For example, a wide variety of A-Kinase Anchoring Proteins (AKAPs) localize cAMP-regulated protein kinases (protein kinase A [PKA]) at the plasma membrane, the cytoskeleton, or within the nucleus. The assembly of receptors, adaptor proteins, effector proteins, and other signaling components into signaling complexes often involves the specific interactions of particular domains within these proteins (Figure 13.8). **SH2** (**S**rc-**H**omology type **2**) **domains** and **PTB** (**p**hosphotyrosine **b**inding) **domains** recognize and bind to specific phosphorylated tyrosine residues on a variety of signaling proteins. **SH3** (**S**rc-**H**omology type **3**) **domains** bind to proline-rich domains that characterize certain signaling proteins. **PH** (**P**leckstrin **H**omology) **domains** specifically recognize and bind to certain inositol phospholipids that have important roles as either lipid second messengers or lipid substrates for phospholipase C.

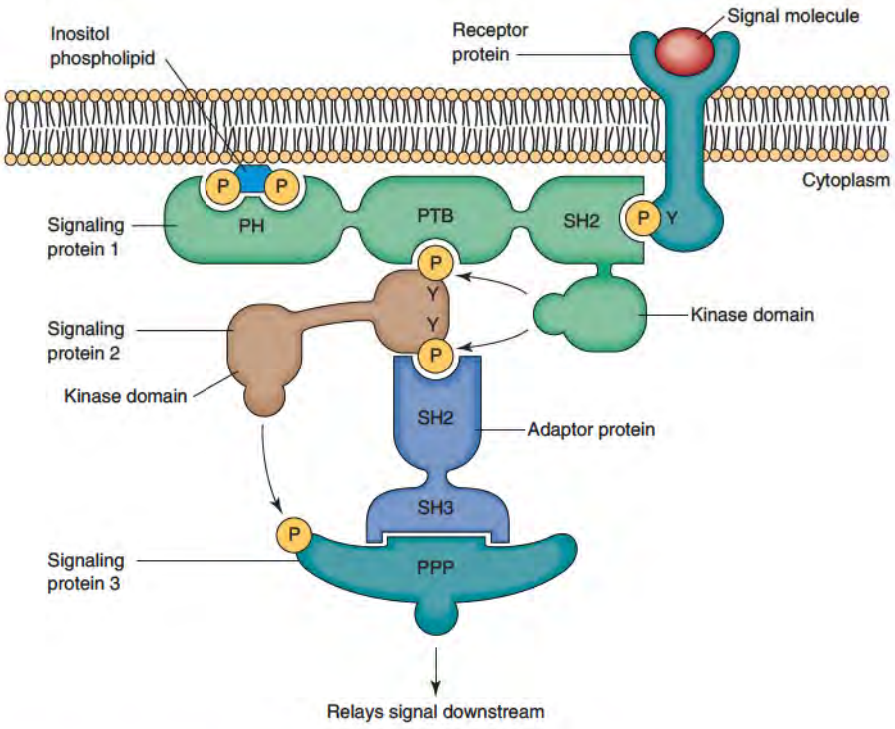

Figure 13.8 Roles of adapter proteins and protein–protein interaction domains in the assembly of intracellular signaling complexes. Redrawn based on figure from Alberts, B., et al., *Molecular Biology of the Cell*, 4th ed. New York: Garland Science, 2002.

Ligand–Receptor Interaction and Downstream Signaling Events

Binding of an **agonistic ligand** to a receptor is characterized by the receptor's binding **affinity** and **capacity**. Affinity describes the relationship between agonist concentration and formation of agonist–receptor complexes. Affinity is inversely related to the **dissociation constant (K_D)** (measured in ligand Molarity) that characterizes the agonist–receptor complex (Figure 13.9). The K_D is equal to the concentration of free agonist that permits binding of 50% of the total number of binding sites on the receptor (half-maximal occupancy). **Potency** is a term used to measure the relative affinity of an agonist for its receptor. An agonist with high potency binds even when present at very low concentrations (high affinity, low K_D). The capacity of the interaction refers to the absolute number of receptor sites. Because receptor proteins are usually expressed in relatively small amounts per cell, agonist–receptor binding curves show saturation. In addition to directly measuring the binding of an agonist to its receptor, one can indirectly measure the agonist–receptor interaction by assaying the various functional responses triggered by the agonist-bound receptor.

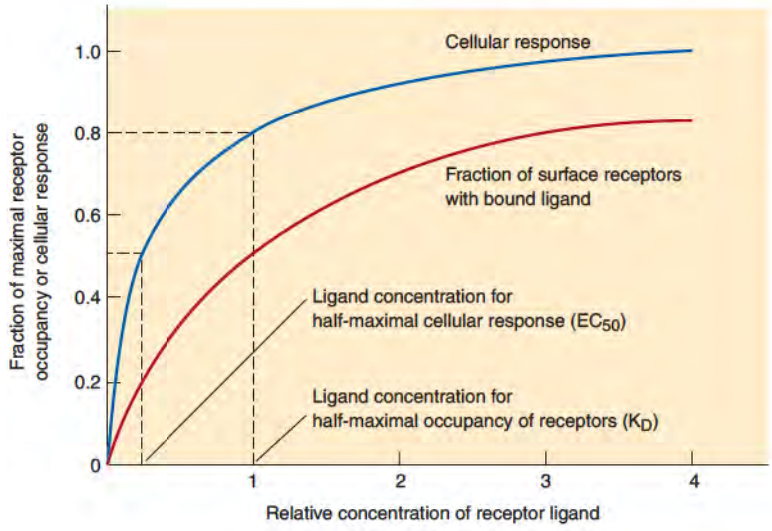

Figure 13.9 Relationship between K_d as a measure of ligand-receptor binding affinity, and EC_{50}, as a measure of functional response to the formation of ligand–receptor complexes.

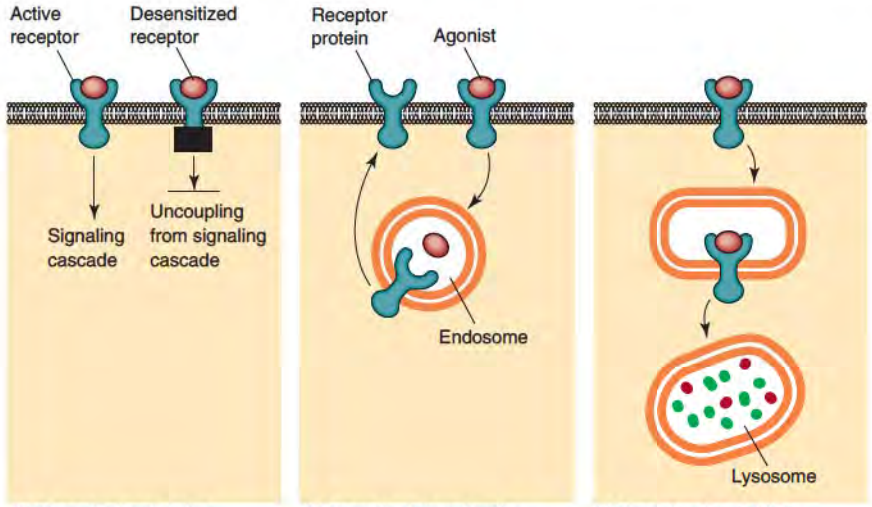

Figure 13.10 Major mechanisms for the termination of receptor-dependent signal transduction.

In general, the magnitude of these responses is proportional to the amount of agonist-bound receptor complex. The **dose–response curve** measures the relationship between agonist concentration and biological response.

The concentration of agonist that causes a half-maximal response is the half-maximal effective concentration or $\mathbf{EC_{50}}$. This is directly proportional to the K_D of the agonist–receptor complex (Figure 13.9). However, EC_{50} is usually much lower than the K_D; that is, the agonist concentration required for half-maximal activation of the cell's biological response is lower than the agonist concentration required for half-maximal occupancy of the cell's total number of receptors. This means that a cell usually expresses more receptors than it needs for effective biological responses. These extra, or spare, receptors permit the cell to respond to agonist even after the inactivation or degradation of receptors activated by previous agonist occupation. As described below, receptor inactivation or degradation plays an important role in terminating signal transduction by receptors.

Termination of Signal Transduction by Cell Surface Receptors

Cells express multiple mechanisms that permit them to terminate or attenuate their responses to various hormones, neurotransmitters, or local mediators. These mechanisms allow cells to return to their basal, prestimulus state and prevent overactivation or inappropriate activation of the functions controlled by a particular receptor (Figure 13.10). They include: (1) reducing agonist availability in the extracellular vicinity of a target cell, (2) internalizing and degrading the agonist-bound receptor complex, and (3) rapidly modifying the receptor (e.g., by phosphorylation) so that it becomes inactive or desensitized.

The simplest mechanism for terminating signal transduction is to reduce the extracellular concentration of the secreted agonist. The effectiveness and rapidity of this mechanism is determined by (1) the stability of the secreted agonist, (2) the size or capacity of the extracellular compartment into which the agonist is secreted, and (3) the proximity of sender cells to target cells. It is difficult to terminate endocrine signaling by reducing agonist availability rapidly because hormones are secreted into a large-capacity extracellular environment. In contrast, rapid reduction in agonist availability plays a significant role in terminating synaptic signaling; neurotransmitters are locally secreted into a very low-capacity space, the synaptic cleft, and diffuse away rapidly. Some cells also actively reduce the concentration of nearby agonist by reaccumulating the released agonist (e.g., synaptic reuptake of neurotransmitters like serotonin and dopamine) or by metabolizing the extracellular agonist. Extracellular metabolism can be catalyzed by specific enzymes (e.g., the acetylcholinesterases) present on the surface of target cells. Certain neurotoxins act as inhibitors of neurotransmitter breakdown.

Cells can also terminate signal transduction by regulating the functional availability of receptors, a process known as **adaptation** or **desensitization**. If repeatedly exposed to a particular agonist, a cell adapts its sensitivity to that agonist. Over time, a cell will become

less and less sensitive to a concentration of agonist that normally causes maximal activation. This desensitization results from several processes. First, many receptors are rapidly internalized when bound by their agonistic ligand. These receptor–ligand complexes are incorporated in endosomes and subsequent acidification of endosomes causes dissociation of the ligand–receptor complexes. Some endosomes containing ligand-free receptor are routed back to the plasma membrane where the receptors can be reincorporated into the surface membrane. Other endosomes are routed to lysosomes where both the ligand and receptor protein are degraded. Thus, over time, there will be fewer receptors on the surface membrane. Second, a much faster mechanism for desensitization involves structural modification of the receptor that results in functional inactivation. Such inactive receptors remain on the surface membrane and may even bind agonist. However, they cannot trigger the intracellular steps of signal transduction. In many cases, functional inactivation of a receptor is due to phosphorylation of the receptor protein itself. Thus, while the agonist-occupied receptor stimulates a cascade of signal transduction events involving activation of protein kinases, some of these protein kinases phosphorylate the receptor itself; this then inactivates that receptor. This is a classic type of negative feedback regulation. Depending on the receptor, this functional inactivation can be reversed rapidly or slowly.

13.5 • LIGAND-GATED ION CHANNEL RECEPTORS

Very rapid (milliseconds) signaling is required at nerve–nerve or nerve–muscle synapses. Thus, neurotransmitter receptors need to change cell responses via a minimum number of enzymatic steps because some biochemical reactions are relatively slow (seconds–minutes). Many (but not all) neurotransmitters bind to receptors that are **ligand-gated ion channels** (see Figure 13.4*a*, p. 507). The extracellular ligands for these receptors are invariably very small organic molecules like amino acids, substituted amines, or nucleotides. These are packaged in vesicles and released via rapid exocytosis at synapses. Because these ligands are so small, they diffuse rapidly (Figure 13.11). The ligands bind to their receptors with low affinity (micromolar to millimolar K_D). This permits rapid dissociation of the ligand–receptor complex on reduction of the extracellular concentration of the neurotransmitter.

The binding of neurotransmitter to extracellular ligand-binding sites of such receptors triggers a near-instantaneous change in receptor conformation that permits ions to permeate through the receptor protein complex. The flux of these ions rapidly changes the

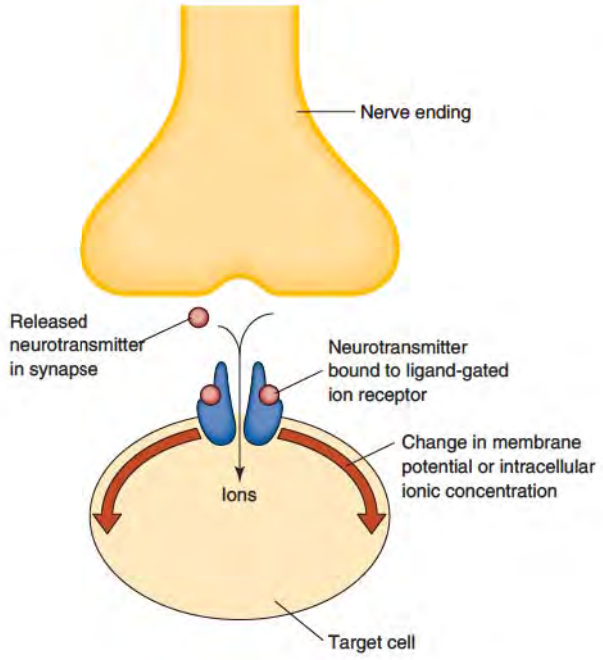

Figure 13.11 Neurotransmitter-gated ion channel receptors as major signal transduction elements at neuronal synapses.

cell's membrane potential. If a cation like Na^+ passes through the receptor channel, the cell becomes depolarized; if an anion like Cl^- is the permeating species, the cell becomes hyperpolarized (Figure 13.12). Cation-selective receptors are gated by the **excitatory neurotransmitters** (acetylcholine, glutamate, serotonin, and ATP) whereas anion-selective receptors are gated by the **inhibitory neurotransmitters**, (γ-amino butyric acid [GABA] and glycine). Activation of these neurotransmitter-gated ion channels changes the cell's plasma membrane potential and results in secondary regulation (activation or inhibition) of many types of voltage-gated channels, including voltage-gated channels for Ca^{2+}. Changes in the activity of these channels will alter the cytosolic concentration of Ca^{2+}, a key second messenger. In turn, increased cytosolic Ca^{2+} drives acute responses in target cells, such as exocytotic release of neurotransmitter-containing vesicles from neurons or contraction of muscle cells, or long-term responses, such as activation of Ca^{2+}-sensitive gene expression. Most of the neurotransmitters that activate ligand-gated ion channel receptors can also interact with other receptor subtypes that are G protein-coupled receptors. Thus, receptors for acetylcholine are either **nicotinic receptors** (because they also bind the drug nicotine) that are ligand-gated channels, or **muscarinic receptors** (because they also bind the drug muscarine) that are G protein coupled.

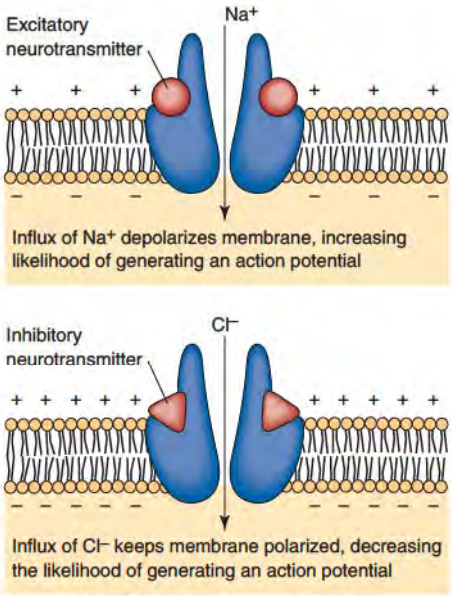

Figure 13.12 Excitatory versus inhibitory neurotransmitters as agonists for ligand-gated ion channel receptors.

Ion Channel Receptors

All ion channel receptors are oligomeric complexes of three to five protein subunits. Some are homomeric complexes that contain several copies of the same protein subunit (i.e., the product of the same gene). Others are heteromeric complexes of different protein subunits (i.e., each subunit is the product of a different gene). Each individual subunit is an integral membrane protein with multiple transmembrane domains. **Nicotinic acetylcholine receptors** provide a good example of the important structural features that characterize ligand-gated ion channel receptors. These are pentameric complex of subunits, each of which has an extracellular N-and C-terminus and four membrane-spanning domains (M1, M2, M3, and M4). The five juxtaposed M2 domains, one from each protein subunit, form the ion-conducting pore. Binding of the neurotransmitter to extracellular sites on the receptor complex causes very small and subtle rearrangements of how the M2 domains pack together. This near-instantaneous rearrangement removes the energetic barriers to ionic flow through the water-lined pore. In this state, the receptor is ligand bound and activated. However, the activated state of ligand-bound receptor channels persists for only a few seconds or minutes (it varies with different types of ligand-gated receptor channel) before a second rearrangement of the subunits occurs. That causes the channel to assume a nonconducting conformation even though the neurotransmitter remains bound (i.e., the receptor is ligand bound but inactive). This rapid inactivation is a non-covalent form of receptor desensitization (Figure 13.13). Reactivation of the receptor channel occurs only after the neurotransmitter dissociates from the extracellular binding sites. Thus, these receptors cycle between three major functional states (no ligand/inactive > ligand-bound/active > ligand-bound/inactive).

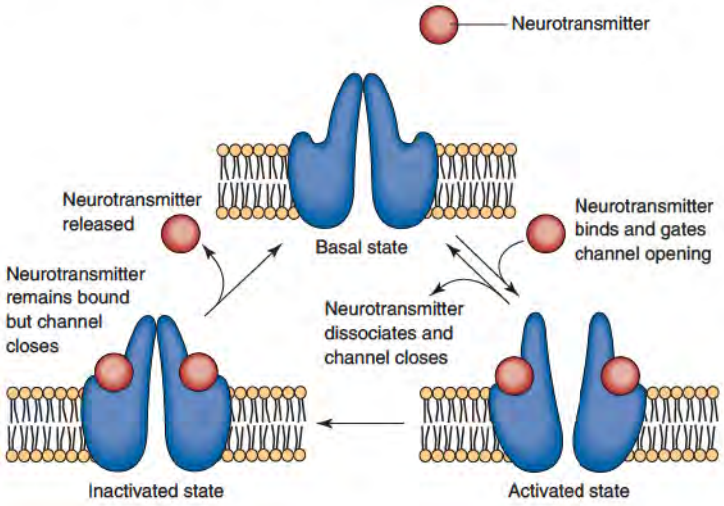

Figure 13.13 Conformational changes in ligand-gated ion channels during activation and inactivation of receptor function. Redrawn based on figure from Alberts, B., et al., *Molecular Biology of the Cell,* 4th ed. New York: Garland Science, 2002.

Termination of Signaling by Ion Channel Receptors

Several mechanisms exist for termination of signaling by ion channel receptors. First, the ligands for these receptors are secreted very transiently in very small, defined extracellular spaces (e.g., the synapse) permitting them to diffuse away from the receptor rapidly. Second, the extracellular concentration of the neurotransmitter is reduced by rapid breakdown by enzymes (like acetylcholinesterase) on the outer surface of the plasma membrane or by rapid re-uptake into the secreting neuron. Finally, the formation of the ligand-bound, inactive state ensures a very brief period of signal transduction by these neurotransmitter receptors.

Although rapid gating of ion fluxes is their direct function, these receptors also associate with a large number of other cellular proteins. Some of these associated proteins act as adapter proteins to co-localize efficiently these receptors with other downstream signaling proteins. They form concentrated **signaling complexes** at particular subcellular domains such as the plasma membrane at synaptic contacts. For example, the intracellular C-terminal tail of the glutamate-gated ion channel receptor associates with an **adapter protein** called PSD-95 at the **P**ost-**S**ynaptic **D**ensity under the synaptic contact site. This interaction is facilitated by a domain on PSD-95 called the PDZ domain. (PDZ is an acronym combining the first letters of three **p**roteins–**p**ostsynaptic **d**ensity protein [PSD95], **D**rosophila disc large tumor suppressor [DlgA], and **z**onula occludens-1 protein [Zo-1]–that were first found to share the domain). PSD-95 contains multiple PDZ domains (in addition to the specific PDZ site that binds to the glutamate-gated channels) that permit the co-localization of the receptor with various kinases, phosphatases, and cytoskeletal proteins.

Other proteins that associate with neurotransmitter-gated channels act as chaperones to ensure the localization and clustering of these receptors at the synaptic membrane. For example, nicotinic acetylcholine receptors are highly concentrated at the neuromuscular synapse via their physical interaction with the protein rapsyn, a 43 kDa membrane-associated protein that tightly associates with the intracellular domain of nicotinic receptors. When rapsyn is knocked out in mice, nicotinic receptors are not appropriately clustered at the neuromuscular junction, and this results in myasthenia or muscle weakness.

Other Ligands of Ion Channel Receptors

Receptors other than the neurotransmitter-gated ion channels utilize ion channels for intracellular signal transduction. Certain types of channels are activated by direct protein–protein interaction with subunits from activated trimeric G proteins, which in turn are activated when upstream G protein-coupled receptors are activated by agonistic ligands. Other types of ion channels are activated on binding with intracellular second-messenger ligands such as cAMP, cGMP, or Ca^{2+}. These second messengers accumulate on activation of many types of cell surface receptors, including G protein-coupled receptors, catalytic receptors for certain growth factors, and some cytokine receptors. Thus, these ligand-gated ion channels are indirectly regulated by cell surface receptors. Very important second-messenger-gated ion channels are the Ca^{2+} channels localized in the endoplasmic reticulum. Finally, the activity of yet other ion channels can be increased (or decreased) on phosphorylation by various second-messenger-regulated protein kinases. This is another example of indirect regulation of channel function by cell surface receptors.

13.6 • ENZYME-LINKED RECEPTORS

Physiological Roles and Extracellular Ligands

The receptors for many polypeptide growth factors and hormones are transmembrane proteins that have intrinsic catalytic activity (Figure 13.14). **Enzyme-linked** or **catalytic receptors** of this *superfamily* of proteins are distinguished by several major structural features. Their intracellular domains have protein kinase, protein phosphatase, protease, or nucleotide phosphodiesterase activities. These receptors primarily regulate long-term cell functions on a time scale of minutes to hours by initiating intracellular signaling cascades

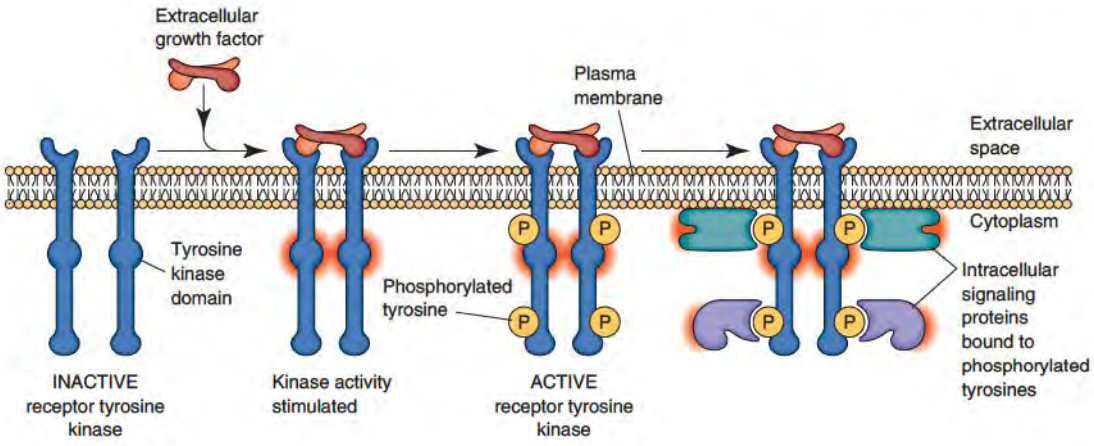

Figure 13.14 Conformational and functional changes in a receptor tyrosine kinase during activation by growth factor binding.
Redrawn based on figure from Alberts, B., et al., *Essential Cell Biology,* 2d ed. New York: Garland Science, 2004.

that culminate in activation or inhibition of gene expression. In turn, these changes in gene expression direct very fundamental pathways of integrated cellular response, such as **cell division**, **programmed cell death**, or **cell differentiation**. Their agonists are usually large, secreted proteins that function as paracrine/endocrine growth factors or differentiation factors. These ligands generally bind to their cognate receptors with very high affinity (picomolar K_D). However, the agonistic ligands for some types of catalytic receptors are macromolecules expressed on the extracellular surfaces of adjacent cells (juxtacrine signaling). The most common catalytic receptors have tyrosine kinase activity. These **receptor tyrosine kinases (RTK)** include the receptors for epidermal growth factor (EGF), platelet-derived growth factor (PDGF), insulin, and many other polypeptide **growth factors**. Some catalytic receptors have **serine/threonine kinase** activity. Finally, certain hormones involved in blood pressure regulation bind to receptors with **guanylate cyclase** activity (see Figure 22.33, p. 915).

Receptor Tyrosine Kinases (RTK)

Most RTKs are single subunit receptors but some (like the insulin receptor) exist as multimeric complexes (see Figure 22.29, p. 911). Each monomer has a single transmembrane (TM) spanning domain that comprises 25–28 amino acids. The NH_2-terminal ends of such receptors are extracellular and compose a very large domain for binding the growth factor or hormone. The COOH-termini are intracellular and contain the domains responsible for the catalytic activities of the receptors.

When a growth factor binds to the extracellular domain of an RTK, it triggers dimerization with adjacent RTK subunits (Figure 13.14); this leads to rapid activation of the cytoplasmic kinase domain. The first protein substrate for this activated tyrosine kinase is the receptor itself; the intracellular domain of the receptor becomes autophosphorylated on multiple tyrosine residues. The phosphorylated tyrosine residues then act as recognition or anchoring sites for other proteins that are substrates for the RTK. These protein substrates usually contain a SH2-type protein–protein interaction domain which recognizes the phosphorylated tyrosines on the receptor. This permits tight binding to the receptor and subsequent phosphorylation of tyrosines on the substrate proteins. Thus, activation of RTK results in accumulation of many types of tyrosine-phosphorylated proteins. These "downstream" substrates act as effectors for the RTK and include signaling proteins such as other protein kinases, regulators of small GTPases, and enzymes that modify phospholipid synthesis and breakdown. When phosphorylated on tyrosine residues, these effector proteins become active links in signaling cascades that ultimately result in changes in the location or functional activity of transcription factors or other proteins involved in cell division or differentiation.

Mutation of certain RTK genes results in expression of receptors that assume activated conformations in the absence of binding of growth factor (Figure 13.15). Mutated RTK genes can act as **oncogenes** (see p. 1016 and Table 24.2) that contribute to the initiation or progression of cancer (Clin. Corr. 13.1).

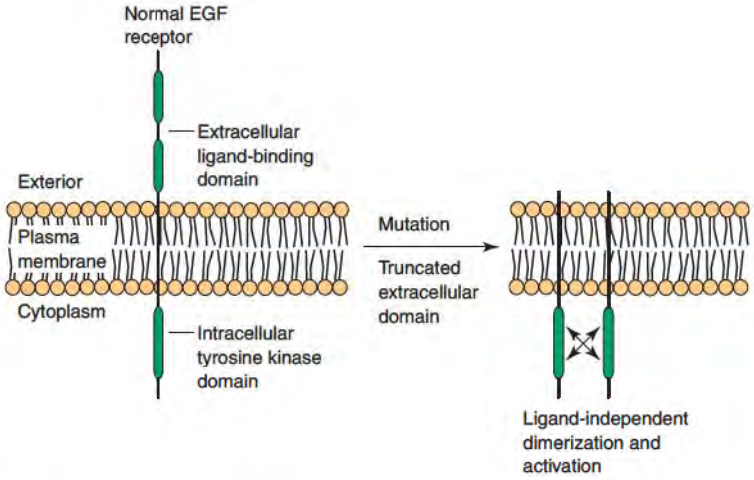

Figure 13.15 Mutated forms of receptor tyrosine kinases as the products of cancer-causing oncogenes.

Receptor dimerization also triggers an endocytic internalization of the growth factor–RTK complex. Acidification of these endosomes leads to dissociation of the growth factor from the receptor and degradation of the internalized growth factor by lysosomes. Although some of the internalized receptors are also degraded, most are rerouted back to the plasma membrane. This internalization of receptor–ligand complex, followed by dissociation of the ligand is the major mechanism for terminating signal transduction by these receptors.

Ras GTPase and MAP Kinase

Ras is a small GTPase or monomeric GTP-binding regulatory protein that is a critical regulator in cell proliferation. About 30% of all human tumors involve cells that express mutated **Ras oncogenes**. Proteins that directly bind to phosphotyrosine sites of an activated RTK include adapter molecules that recruit and stimulate Ras-activating proteins (Figure 13.16). The stimulated Ras-activating proteins act as GEFs to enhance the exchange of GTP for GDP on Ras itself; this results in accumulation of Ras molecules with an active,

CLINICAL CORRELATION 13.1

ErbB/HER Receptor Tyrosine Kinases as Targets for Cancer Chemotherapy

Receptors belonging to the ErbB/HER family are linked to many different types of human cancers. Overexpression of the human ErbB1 gene, which encodes the EGF receptor (HER1), is common in bladder, breast, kidney, prostrate, and non-small-cell lung cancers. A mutant ErbB1 gene produces a receptor that lacks the extracellular EGF-binding domain, and this is highly expressed in glioblastomas that account for 25% of the brain tumors in adult humans. Human ErbB3 and ErbB4 encode the HER3 and HER4 receptors that bind extracellular proteins of the NRG (neuregulin/heregulin/neu) family of growth and differentiation factors. ErbB3 is often overexpressed in breast, colon, prostate, and stomach cancers, whereas ErbB4 overexpression occurs in ovarian granulosa cell tumors. ErbB2 encodes the HER2 protein that does not bind any known extracellular growth factor. However, HER2 can form homodimers or heterodimers with growth-factor-bound HER1, HER3, or HER4 receptors. Because dimerization activates the intrinsic tyrosine kinase activity of this protein, even modest overexpression of HER2 can alter normal cell growth regulation. Significantly, ErbB2 gene expression is amplified by up to two orders of magnitude in 20%–30% of human subjects with invasive breast cancer. The aberrant expression of ErbB/HER genes in multiple human cancers has prompted the development of several drug therapies that target these receptors. One group consists of monoclonal antibodies that bind to functionally significant extracellular domains of different HER subtypes. Trastuzumab (Herceptin® from Genentech), an anti-HER2 antibody, has been used in the treatment of those breast cancers characterized by overexpression of ErbB2/HER2. Its mechanism of action involves recruitment of immune factors that kill the tumor cells and also suppression of constitutive HER2 dimerization. Cetuximab (IMC-C225 or Erbitux® from ImClone), an antibody against the EGF-binding domain of the ErbB1/HER1 protein, prevents ligand-induced activation of the receptor. It is being tested in patients who have either squamous cell cancers of the head and neck or non-small-cell cancers of the lung. A variety of small molecule drugs have been designed to target the intracellular tyrosine kinase domains of the ErbB/HER proteins. These drugs are competitive inhibitors of the ATP-binding sites of the kinases, particularly the ErbB1/HER1 subtype. They are being tested in patients suffering from non-small-cell lung cancers that fail to respond to other chemotherapies.

GTP-bound conformation. In turn, these active Ras proteins transiently bind to and stimulate a family of serine/threonine protein kinases that trigger the **m**itogen-**a**ctivated **p**rotein kinase cascade, or **MAP kinase cascade** (Figure 13.17). This amplification cascade involves the serial actions of three protein kinases; the initial Ras-activated kinase (or MAP kinase kinase kinase) activates an intermediary set of MAP kinase kinases, which activate the terminal **MAP kinase** effectors. Activated terminal MAP kinases phosphorylate multiple target proteins in both the cytosol and the nucleus, including transcription factors that regulate the expression of genes required for cell division, cell survival, or phenotypic differentiation.

Receptor Serine/Threonine Kinases

The growth regulatory factors **transforming growth factor-β (TGF-β)** and **bone morphogenetic proteins (BMP)** have receptors with intrinsic serine/threonine kinase activity. These growth factors have important signaling roles in tissue development at the fetal and neonatal stages and in the maintenance of a differentiated tissue phenotype in adult organisms. As in the case of receptor tyrosine kinases, mutations in TGF-β receptors and other serine/threonine kinase receptors contribute to the initiation or progression of certain cancers.

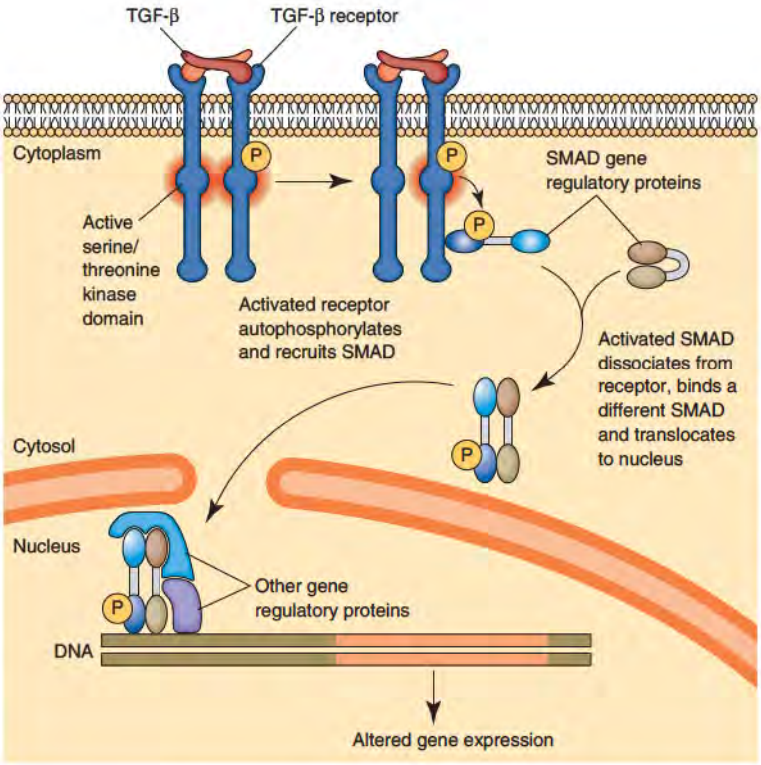

Figure 13.18 Intracellular signaling cascades triggered by a receptor serine/threonine kinase during activation by TGFβ (transforming growth factor β).
Redrawn based on figure from Alberts, B., et al., *Essential Cell Biology*, 2d ed. New York: Garland Science, 2004.

Similarly, these receptors compose plasma membrane proteins with an extracellular amino terminus, a single transmembrane-spanning region, and an intracellular carboxy terminus that contains the catalytic domain. They also form homodimeric complexes when their agonists bind to the tandem extracellular domains (Figure 13.18). The resulting conformational change results in one catalytic subunit phosphorylating its partner subunit on serine/threonine residues. This initial phosphorylation allows the partner subunit to recruit and to phosphorylate cytoplasmic proteins termed **SMADs** that comprise a family of gene regulatory factors. (SMAD proteins are homologs of a Drosophila protein "mothers against decapentaplegic," or MAD, and a C. elegans protein SMA; the name is a combination of the two). In their dephosphorylated state, SMADs adopt a folded conformation, which prevents their interaction with other SMADs and also maintains their localization as cytosolic proteins. However, phosphorylation by activated receptor kinases allows certain SMAD subtypes to unfold and to form dimeric complexes with other SMAD subtypes. This dimerization also exposes **nuclear localization sequences (NLS)** on the SMADs that result in translocation of the cytosolic complex into the nucleus where the SMAD dimers interact with other gene regulatory proteins to modulate the transcription of genes involved in organ development or tissue differentiation.

13.7 • CYTOKINE RECEPTORS

Cytokines represent another group of secreted polypeptides that act as autocrine/paracrine regulators of growth and differentiation. Many cytokines control the growth and differentiation of **hematopoietic** (blood-forming) cells including the various types of white blood cells, or leukocytes. For this reason, some cytokines are known as **interleukins** because they regulate information transfer among different types of leukocytes during various stages of immune or inflammatory responses (Clin. Corr. 13.2). Other cytokines are called **interferons** for their ability to interfere in the changes in function induced in cells and tissues infected with viral or bacterial **pathogens**. Like the growth factors that bind to catalytic receptors, cytokines bind to their cognate receptors with high affinity and trigger the rapid activation of protein kinase cascades and accumulation of phosphorylated signaling proteins that ultimately direct long-lasting changes in gene expression. However, the plasma membrane receptors for cytokines lack intrinsic tyrosine kinase or serine/threonine kinase activity (see Figure 13.4*c*, p. 508).

CLINICAL CORRELATION 13.2

Endogenous Antagonists of Interleukin-1 Receptors as Therapy for Inflammatory Diseases

Interleukin-1 (IL-1) is the composite designation for two related cytokines (IL-1α and IL-1β) that bind to the same multi-subunit IL-1 receptors (IL-1R). The broad expression of IL-1R underlies the central role of IL-1 in many immune, inflammatory, metabolic, and hematopoietic responses. These include fever, increased expression of leukocyte adhesion proteins on endothelial cells, induction of acute phase proteins by the liver, and stimulated production of other cytokines and colony-stimulating factors. IL-1β is a major proinflammatory cytokine whose local and circulating levels are tightly regulated to prevent aberrant activation of pathways that can lead to chronic inflammatory diseases. IL-1β accumulates as a biologically inactive procytokine in the cytoplasm of monocytes and macrophages. Its activation requires cleavage to a mature, secreted form by the protease, caspase-1. Activation of caspase-1 involves its oligomerization via assembly of multiprotein complexes termed inflammasomes. Under normal conditions the assembly of inflammasomes is regulated by adapter proteins that become active only in response in bacterial infection or tissue damage. However, some people express mutated versions of these adapter proteins, and this causes activation of inflammasomes and hyperproduction of IL-1β in the absence of microbial infection. The resulting overproduction of IL-1β has been linked to multiple inflammatory diseases including the periodic fever syndromes, Crohn disease, rheumatoid arthritis, and gout. Therapeutic agents, such as IL-1 receptor antagonist (Anakinra or Kineret®), are highly effective for the treatment of autoinflammatory syndromes. Notably, Anakinra is a recombinant version of a naturally occurring protein, human IL-1Ra (Ra for receptor antagonist), which is produced by the same cells that secrete IL-1α and IL-1β. Endogenous IL-1Ra is an important natural anti-inflammatory protein in arthritis, colitis, and other inflammatory diseases; maintenance of a balance between IL-1 and IL-1Ra production prevents the development or progression of such diseases. However, when endogenous IL-1 is overproduced in individuals with mutations in inflammasome regulatory proteins, the injection of recombinant IL-1RA acts to restore this balance.

Cytokine Receptors: Structure and Function

Cytokine receptors are multimeric receptors. Each subunit has a single transmembrane domain, a large extracellular amino-terminal domain for binding the cytokine, and an intracellular carboxy-terminal domain that contains different types of protein–protein interaction motifs but lacks intrinsic enzyme activity. Functional cytokine receptors exist as a stable **hetero-oligomeric complex** of two or more different receptor subunits. High-affinity binding of the cytokine usually requires interaction with at least two different receptor subunits. This coordinated binding of extracellular cytokine ligands triggers conformational changes in the intracellular domains of the receptor subunits that facilitate their rapid association with other intracellular signal-transducing enzymes. Cytokine receptors exhibit significant diversity in the structure of their individual subunits, as well as in their assembled multimeric complexes. Thus, different subfamilies recruit a broad range of intracellular signaling proteins. Among the most important of these associated proteins are **nonreceptor tyrosine kinases**, such as the src-family kinases and the **Janus kinases (JAKs)** (Figure 13.19). These tyrosine kinases are not integral membrane proteins, but exist as soluble or weakly membrane-associated proteins that become activated only when they associate with ligand-occupied cytokine receptors. They often phosphorylate the other subunits of the cytokine receptor on tyrosine residues which then act as recognition sites for the binding of other signaling proteins with SH2-interaction domains. Thus, several of the interleukin-type cytokine receptors recruit JAKs, which phosphorylate the receptors to generate binding sites for gene regulatory proteins known as **STATs (signal transducers and activators of transcription)**. Like SMAD proteins, unphosphorylated STAT proteins are cytosolic monomers. Subsequent tyrosine phosphorylation by activated JAKs induces dimerization which results in translocation of the complex to the nucleus and association with other gene regulatory proteins.

Other cytokine receptors recruit adapter proteins that initiate the assembly of protein kinase complexes that culminate in the cytosol-to-nucleus translocation of the **NFκB** (nuclear factor of activated B cells) complex, an important transcription factor for regulation of expression of genes involved in multiple types of immune and inflammatory responses. Many cytokine receptors also trigger activation of the MAP kinase cascades.

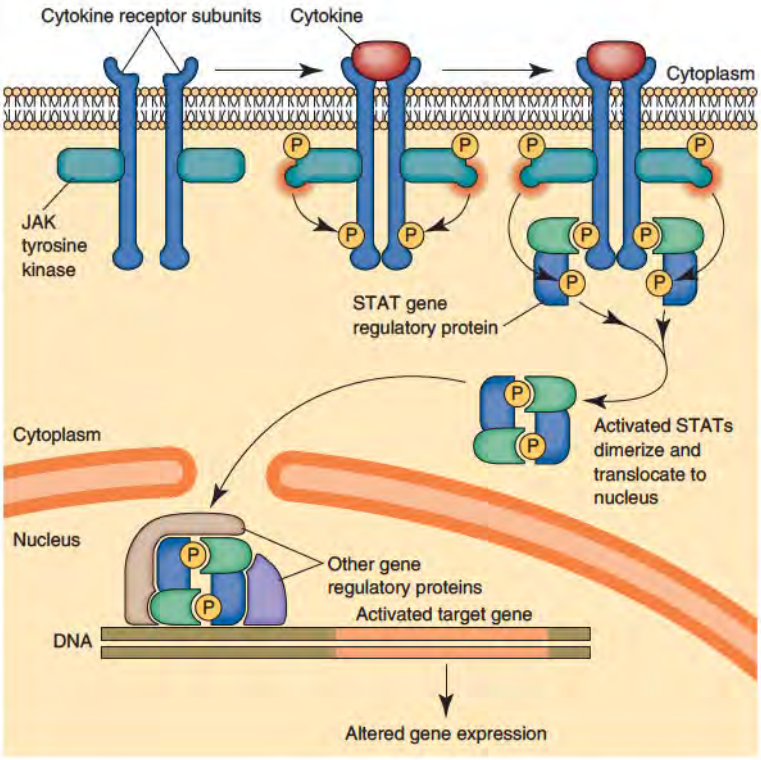

Figure 13.19 Intracellular signaling cascades triggered by prototypical noncatalytic cytokine receptor.

13.8 • G PROTEIN-COUPLED RECEPTORS

Physiological Roles and Extracellular Ligands

The superfamily of **G protein-coupled receptors** (GPCR) is targeted by an extraordinarily diverse range of agonistic ligands that include proteins, peptides, amino acid derivatives, catecholamines, lipids, nucleotides, and nucleosides (Figure 13.20). These ligands include hormones, neurotransmitters, and local mediators. The G protein-coupled receptors play important roles in endocrine, synaptic, paracrine, or autocrine signaling in virtually all

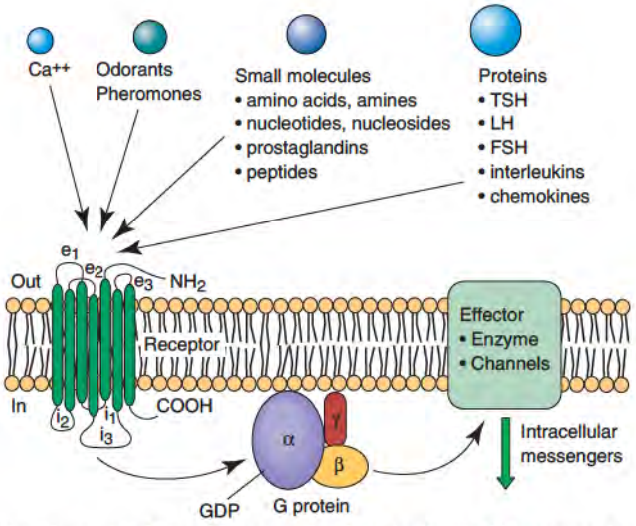

Figure 13.20 Major elements of signal transduction initiated by the 7-transmembrane domain G protein-coupled receptors.

CLINICAL CORRELATION 13.3

G Protein-Coupled Chemokine Receptors as Targets for the Human Immunodeficiency Virus (HIV)

Among the 1000 or so human genes that encode G protein-coupled receptors is the subgroup of chemokine receptors that are highly expressed in leukocytes (white blood cells). Chemokines compose approximately 50 polypeptide factors that are secreted by multiple cell types (*e.g.*, epithelial cells and stromal cells) within various tissues. They are agonistic ligands for 19 types of chemokine receptors that are differentially expressed in the various classes of leukocytes (*e.g.*, monocytes, T-lymphocytes, B-lymphocytes, natural killer cells), which execute critical immune and inflammatory responses within tissues invaded by foreign pathogens (protozoans, bacteria, or viruses). Chemokines function as: (1) chemotactic agents that recruit leukocytes to the infected tissue location,; (2) regulators of G protein-dependent signaling pathways involved in the rapid killing or sequestering of pathogens, and (3) inducers of gene expression that contribute to long-term adaptive immunity to pathogens. Not surprisingly, the disruption or disabling of chemokine receptor signaling can contribute to a wide range of infectious diseases. Of particular significance is the finding that human immunodeficiency virus (HIV) utilizes endogenous chemokine GPCR to infect and kill immune effector leukocytes.

HIV entry into leukocytes requires the direct interaction of the viral envelope glycoprotein (gp120) with extracellular surface proteins of the target host cell. The CD4 membrane protein, a critical immune receptor of helper T-lymphocytes, is a major target for gp120 binding. This explains why helper T cells are drastically reduced in most HIV-infected patients who develop AIDS (acquired immune deficiency syndrome). However, different strains of HIV preferentially infect T-lymphocytes (T-trophic virus) or monocyte-macrophages (M-trophic virus), and epidemiological analyses have revealed individuals who are highly resistant to infection by M-trophic strains of HIV. This resistance is due to mutations in the gene encoding CCR5, a chemokine receptor that is highly expressed in monocyte-macrophages; these mutations result in low or no expression of cell surface CCR5 protein. Thus, M-trophic strains of HIV require the presence of both the CCR5 and CD4, as co-receptors, to efficiently infect monocyte-macrophages.

CXCR4, a chemokine receptor that is highly expressed in T-lymphocytes, is a coreceptor with CD4 for binding the gp120 of T-trophic strains of HIV. Significantly, the ability of CCR5 and CXCR4 to bind gp120 does not require activation of the G_i-family proteins to which these receptors are normally coupled. Although G protein activation by CCR5 and CXCR4 is not obligatory for HIV entry, gp120 binding to these receptors does induce functional activation of the downstream G protein signaling cascades. It seems that activation of these signaling pathways within the HIV-infected cells may facilitate the chemo-attraction of naive uninfected leukocytes and so aid in propagation and dissemination of the virus within the infected subject. The identification of CCR5 and CXCR4 as HIV coreceptors has elicited intense interest in the development of antagonistic ligands that selectively attenuate gp120 binding and retard the colonization and spread of this devastating pathogen within infected subjects.

Sodhi, A., Montaner, S., and Gutkind, J. S. Viral hijacking of G protein-coupled receptor signaling networks. *Nat. Rev. Mol. Cell Biol.* 5:998, 2004.

tissues and cell types. It is estimated that several percent of the genes in the human genome encode GPCR. Ligands bind to GPCRs with affinities in the nanomolar to micromolar range, which is intermediate between the high affinity of enzyme-linked receptors and the low affinity of the ligand-gated channel receptors. Many important sensory proteins are G protein-coupled receptors including rhodopsin (see p. 958 and Figure 23.21) and the many receptors for perception of taste and smell, the actual ligands for which are largely unknown. Many GPCR are involved in the acute regulation of critical physiological responses such as cardiac contractility, metabolism, and complex behavior. These receptors or their downstream signaling pathways are the targets for many of the drugs most widely used in the treatment of human disease (Clin. Corr. 13.3 and 13.5).

Structure of G Protein-Coupled Receptors

When occupied by agonistic ligands, GPCRs act as GEFs for **heterotrimeric GTP-binding regulatory proteins (G proteins)** (see Figure 13.20), that interact with downstream effector proteins which are usually enzymes or ion channels. The GPCRs do not directly regulate effector proteins. Thus, even the earliest signaling events require the participation of at least five proteins: the receptor itself, the intermediary G protein (with its three distinct protein subunits), and the effector protein. The existence of multiple G protein types that can differentially couple to various receptors and effectors provides for considerable molecular diversity in the types of signal transduction pathways controlled by these receptors.

Despite the extreme diversity of the ligands for GPCR, the receptors themselves show a high degree of structural but not sequence similarity (see Figure 13.20). The crystal structure of bovine rhodopsin provides the essential topographical features of the GPCR family (see Figure 23.21). Each receptor is a single subunit membrane protein with seven α-helical transmembrane spanning domains. (GPCR have also been termed **heptahelical**, or **7-transmembrane, domain receptors**). Each has an extracellular amino-terminus, three extracellular loops, three intracellular loops, and an intracellular carboxy-terminus. The extracellular region provides sites for glycosylation and the extracellular loops contain essential cysteine residues for formation of interloop disulfide bridges. The transmembrane(TM)-spanning domains are homologous, but not identical among different GPCR. These form a pocket which often contains the critical amino acid residues for ligand binding. The intracellular loops, particularly the third loop, contain critical sequences for selective interaction with G proteins. The intracellular tail varies greatly in length and sequence among the different receptors, and contains sites that are involved in recognition or activation of G proteins. It also contains serine and threonine sites for phosphorylation by protein kinases. Phosphorylation of these residues plays important roles in the termination of signal transduction by activated GPCR.

The tertiary structure of GPCR within biological membranes involves a clustering of the seven transmembrane helices that controls the conformations and apposition of the intracellular loops and the carboxy-terminus. Large ligands such as polypeptide hormones bind to the extracellular loops whereas small ligands, such as acetylcholine and epinephrine, bind to the pocket formed by the membrane-spanning segments. In either case, binding causes a rearrangement of the membrane-spanning helices and changes the conformations of the intracellular loops and carboxy-terminus to expose recognition sites for particular G proteins. Thus, a GPCR occupied by an agonist can transiently form a complex with a G protein. An antagonist can bind to the receptor but does not cause appropriate rearrangement of the membrane-spanning domains or exposure of the G protein recognition sites on the intracellular loops and tail.

The transient interaction between the agonist-occupied receptor and its G protein affects the function of both. The functional changes in the G protein are described in the following section. The major change in the receptor following its binding to a G protein is that its affinity for the agonist is significantly reduced, and this usually leads to dissociation

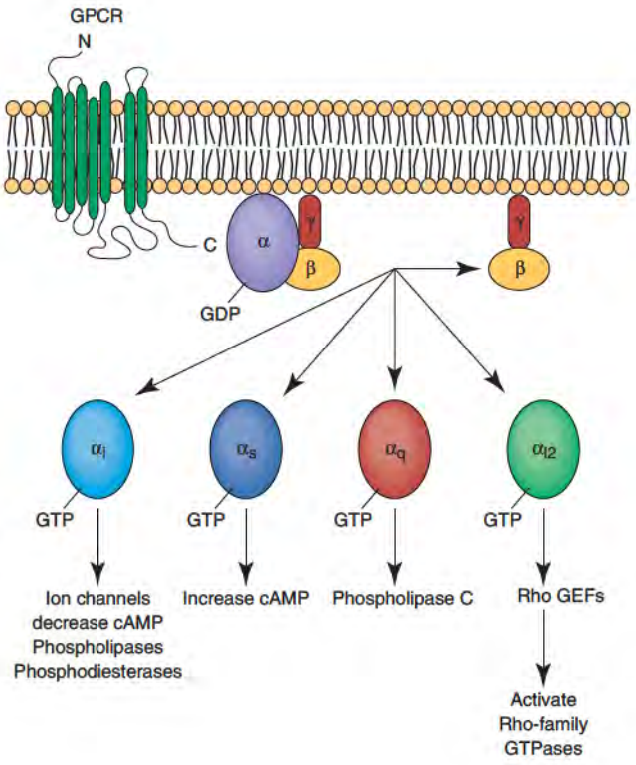

Figure 13.21 Major subclasses of heterotrimeric G proteins that are activated by G by the 7-transmembrane domain G protein-coupled receptors.

of the agonist. The agonist-free receptor assumes its inactive conformation with loss of its ability to interact with the G protein. The G protein dissociates from the receptor–G protein complex and returns the receptor to its inactive, ligand-free state.

Heterotrimeric G Proteins

G proteins that are functionally coupled to GPCR consist of heterotrimeric complexes of **α-, β-, and γ-subunits** (Figure 13.21). The α-subunit, the largest, is a relatively hydrophilic protein in the 39–46 kDa range. It contains the guanine nucleotide-binding site, the GTPase activity that is critical for proper regulation of the receptor–G protein interaction, and domains that interact with various effector proteins. Twenty distinct α-subunits are grouped into several subfamilies on the basis of both structural features and type of coupling to particular effector proteins and second-messenger cascades. The α_s-subunits (stimulatory α-subunit) of the **Gs** family stimulate **adenylate cyclase** and result in an increase in intracellular **cAMP** (Clin. Corr. 13.4). In contrast, the α_i- subunits (inhibitory α-subunits) of the **G_i** family inhibit adenylate cyclase and lower the cellular levels of cAMP. The α_o- and α_z-subunits, which also belong to the Gi family, predominantly modulate voltage-sensitive ion channels in excitable tissues. The G_i family also includes the α_t-subunits (t for transducin), the G proteins that transduce light perception by the rhodopsin-type GPCR that stimulate **cGMP phosphodiesterase** and rapidly decrease intracellular **cGMP**. The **Gq** family includes the α_q-, α_{11}-, α_{15}-, α_{16}-subunits that are coupled to **phospholipase C** and trigger increases in three second messengers: IP_3 (inositol trisphosphate), DAG (diacylglycerol), and Ca^{2+}. Finally, the α_{12}- and α_{13}-subunits of the **$G_{12/13}$** family stimulate **GEFs** for a variety of Rho-family small GTPases involved in cell migration, cell shape regulation, and cell division (Clin. Corr. 13.4).

CLINICAL CORRELATION 13.4

G Protein Mutations in Pituitary Gland Tumors and Endocrine Diseases

The pituitary gland plays a central role in regulating the endocrine status of mammals by secreting a variety of hormones that regulate the function of other organs including the liver, thyroid, adrenal, and reproductive glands. Release of these hormones is regulated by neurotransmitters, neuropeptides, and other hormones released by the hypothalamic region of the brain. For example, the hypothalamus and pituitary cells known as somatotrophs act in concert to control the release of Growth Hormone (GH), which regulates metabolism and cell growth in many peripheral tissues. The hypothalamus-derived Growth Hormone Releasing Hormone (GHRH) is an agonist for a G_s protein-coupled receptor which is expressed by pituitary somatotroph cells. Increased cAMP triggered by this receptor activates CREB-dependent transcription of the GH gene and results in increased synthesis and release of GH. Certain pituitary tumors cause the hypersecretion of GH, which in adults causes acromegaly, a condition characterized by abnormal growth patterns in many tissues. Such tumors are generally non-metastatic and believed to arise from the replication of single, transformed pituitary cells that have acquired a growth or survival advantage due to spontaneous mutations in key regulatory genes.

30%–40% of the GH-secreting pituitary tumors in humans express a mutated version of the GNAS1 gene that encodes the α_s-subunit of G_s protein. The mutated gene, termed *gsp*, results from single amino acid substitutions in residues that play critical roles in the binding and hydrolysis of GTP. Such mutations greatly diminish GTPase activity and thereby cause the constitutive activation of G_s and adenylate cyclase. The increase in adenylate cyclase activity markedly increases cAMP generation, protein kinase A (PKA) activation, the PKA-dependent phosphorylation of CREB and other cAMP-sensitive gene regulatory proteins, and, as a consequence, the expression of cAMP-inducible genes such as that for GH. Similar *gsp* mutations have been found in pituitary corticotroph tumors that hypersecrete ACTH (adrenocorticotropic hormone) with consequent overproduction of glucocorticoid hormones by the adrenal cortex.

The two amino acids altered in these naturally occurring *gsp* mutants were identified by *in vitro* biochemical studies as significant for the regulation of GTPase activity. Arginine-201, which is replaced by cysteine in the most common *gsp* mutant, is the acceptor site for the covalent ADP-ribosylation induced by cholera toxin. Glutamine-227, which is replaced by alanine or other amino acids in some *gsp* mutations, is a conserved glutamine located in the switch-II domain that undergoes large conformational movements depending on whether GTP or GDP is bound to the α-subunit. Substitution of this glutamine residue within all known α-subunits cause decreased GTPase activity, and it is widely used to generate constitutively active versions of the various G proteins for transgenic animal studies.

Lania, A., Mantovani, G., and Spada, A. Genetics of pituitary tumors: Focus on G protein mutations. *Exp. Biol. Med.* 228:1004, 2003.

The β(~35 kDa)- and γ (10 kDa) **subunits** are very hydrophobic proteins and, under non-denaturing conditions, are isolated as a **dimeric complex**. Purified $\beta\gamma$ complexes isolated from one G protein can often be recombined with the unique, purified α-subunit of a second G protein to produce a heterotrimer, which is functionally indistinguishable from the native heterotrimer of the second G protein. The $\beta\gamma$ complex is necessary for the interaction of the α subunit with receptors. In addition, the $\beta\gamma$ complexes from some activated G proteins also directly interact with, and activate, a variety of downstream effector proteins. For example, G_i-derived $\beta\gamma$ dimers control the opening of certain K^+ channels in the heart, thereby inducing cardiac myocyte hyperpolarization and a slowing of heart rate.

The G Protein Cycle

In their basal state, the $\alpha\beta\gamma$ heterotrimeric complex has GDP at the nucleotide-binding site of the α-subunit (Figure 13.22). The rate of release of GDP in the presence of unoccupied receptors (basal conditions) is low but not zero. The intrinsic GTPase activity of the α-subunit converts GTP into GDP and P_i. While the Pi is readily released, the GDP remains bound for a much longer time. This sequential release makes the GTPase reaction irreversible. The α-GDP displays high affinity for the $\beta\gamma$ dimer, and the heterotrimer is therefore regenerated. Consequently, in the unstimulated steady state, only a small fraction of the G protein molecules is in the active conformation (GTP bound). On interaction of a heterotrimeric complex with agonist-occupied GPCR, the rate of release of GDP is increased by over an order of magnitude. This allows GTP, which is much more abundant than GDP in the cytosol, to bind to the α-subunit and to trigger dissociation of α-GTP from the $\beta\gamma$ dimer. The released α-subunits and $\beta\gamma$ dimers then interact with appropriate

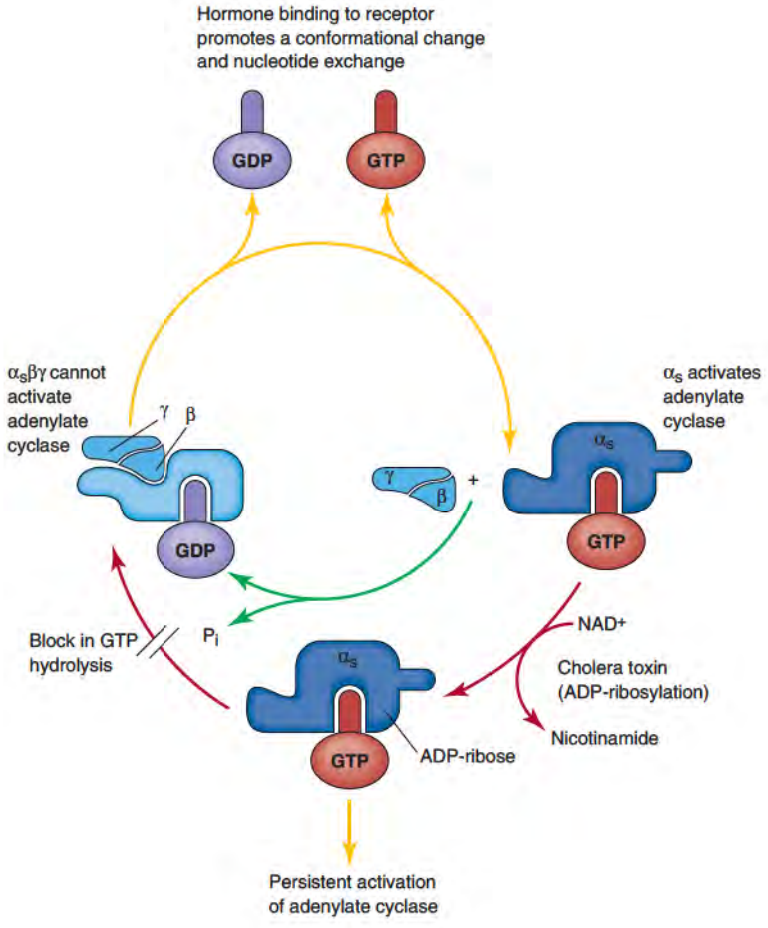

Figure 13.22 Activation and inactivation cycle of a heterotrimeric G protein.

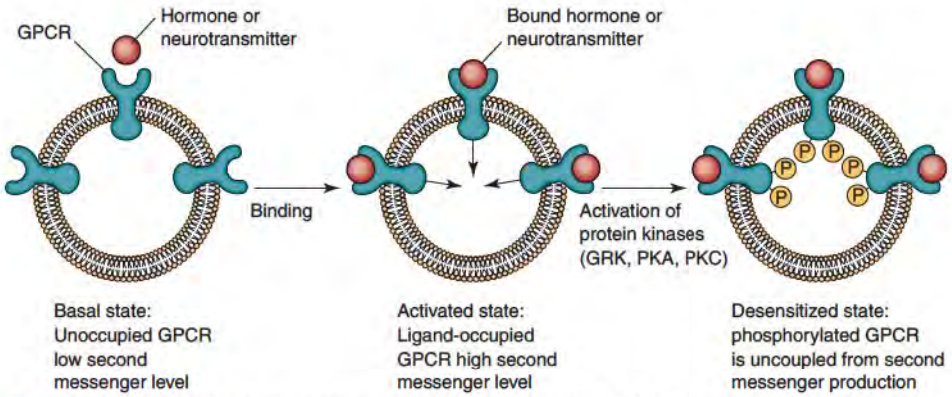

Figure 13.23 Receptor phosphorylation as a major mechanism for the desensitization/ inactivation of G protein-coupled receptors.

downstream effector enzymes to change second-messenger levels. Activation of G proteins by agonist-occupied GPCR is catalytic rather than stoichiometric. Thus, depending on the type of GPCR, one molecule of agonist-occupied receptor may serially interact with 10–100 molecules of trimeric G protein; this results in major signal amplification at the earliest stages of GPCR activation. Although the intrinsic GTPase activity of the released α-subunits ensures that the dissociation of $\alpha\beta\gamma$ heterotrimeric complex will be transient, the overall repetition rate of the cycle will be increased as long as there are agonist-bound GPCR in the cell's plasma membrane.

Termination of Signaling by G protein-Coupled Receptors

Many of the small ligands for GPCR can be rapidly metabolized or inactivated by extracellular enzymes and most receptors exhibit rapid **desensitization** or adaptation. Although some of this adaptation is due to receptor internalization and down-regulation, the primary mechanism for rapid GPCR desensitization involves phosphorylation of the receptor that results in loss of function (Figure 13.23). The phosphorylated receptors cannot efficiently activate G proteins. Two families of protein kinases phosphorylate GPCR and induce desensitization. Second-messenger-dependent protein kinases, such as cAMP-dependent **protein kinase A (PKA)**, phosphorylate many types of GPCR regardless of whether the receptor is in an agonist-occupied or agonist-free conformation. GPCR-specific protein kinases (**GRKs**) are also known as β **ARKs** (βAR kinases) because the β-adrenergic receptor (βAR) was their first identified substrate (Clin. Corr. 13.5). In contrast to PKA and other second-messenger-regulated kinases, β ARKs only phosphorylate GPCR when they are occupied by agonistic ligands.

Effects of Bacterial Toxins on Heterotrimeric G Proteins

Some α-subunits of G proteins contain arginine or cysteine residues that can be ADP-ribosylated by exotoxins (cholera or pertussis toxins) secreted from some bacterial pathogens, such as *Vibrio cholerae* or *Bordetella pertussis* (see Figure 13.22, p. 526). These toxins possess NAD glycohydrolase activity that catalyzes breakdown of NAD^+ into nicotinamide and ADP-ribose, and ADP-ribosyl transferase activity that catalyzes transfer of the ADP-ribose moiety to the G protein α-subunit. These toxin-catalyzed ribosylation reactions interfere with the normal function of the G protein and cause abnormal signal transduction and regulation of cell function. For example, ADP-ribosylation of the Gs α-subunits by cholera toxin represses the intrinsic GTPase activity thereby causing constitutive dissociation of the GTP-bound α-subunits from the $\beta\gamma$ dimers even when GPCR is not occupied by agonist. This chronic increase in GTP-bound α_s induces continuous activation of the adenylate cyclase and cAMP production. In the large intestine, this increase in cAMP results in a sustained PKA-mediated phosphorylation of chloride channels that normally regulate salt and water transport; the hyperactivation of these channels severely disrupts salt and water transport and results in life-threatening diarrhea.

CLINICAL CORRELATION 13.5

Alterations in β-Adrenergic Receptor Signaling in Congestive Heart Failure

In congestive heart failure the heart fails to pump blood in amounts sufficient for adequate perfusion of peripheral tissues. Heart failure results from adaptations of cardiac myocytes for the maintenance of cardiac output following myocardial injury or from excessive hemodynamic burdens, such as high blood pressure. These adaptations include myocardial hypertrophy and activation of sympathetic nerve output, especially the release of norepinephrine and epinephrine from cardiac adrenergic nerves, which augments myocardial contractility. These adaptive mechanisms ultimately become inadequate and result in a progressive decrease in cardiac performance.

This shift from adaptive to maladaptive response is particularly evident in changes with the β-adrenergic receptor signaling system. In normal cardiac myocytes, epinephrine activates the G_s-coupled β1- and β2-adrenergic receptors that simulate adenylate cyclase, increase cAMP accumulation, and activate protein kinase A (PKA). PKA phosphorylates L-type dihydropyridine-sensitive Ca^{2+} channels and phospholamban, an allosteric regulator of cardiac sarcoplasmic reticulum (SR) Ca^{2+}-translocating ATPase. Phosphorylation of former increases the time these channels stay open in response to depolarization and results in enhanced Ca^{2+} influx. Unphosphorylated phospholamban represses the function of the SR Ca^{2+}ATPase pump. When phospholamban is phosphorylated by PKA, this inhibitory effect is relieved and results in an increased rate and extent of Ca^{2+} pumping by the SR. The combined action of enhanced plasma membrane Ca^{2+} influx (through the L-type channels) and enhanced Ca^{2+} sequestration within the SR results in greater Ca^{2+}-induced Ca^{2+} release from the SR during subsequent cardiac action potentials. Thus, during adrenergic stimulation, more Ca^{2+} is released during each action potential resulting in a stronger contraction (positive inotropic effect). However, the released Ca^{2+} is also more rapidly sequestered by the SR resulting in a more rapid cycle of contraction/ relaxation (positive chronotropic effect). Thus, at the whole organ level, β-adrenergic stimulation of heart results in both stronger contractions and more blood pumped per heart contraction (stroke volume) and a more rapid contraction/relaxation cycle (heart rate). Cardiac output (stroke volume × heart rate) is increased to deliver more blood to the systemic circulation. However, this means the heart will do more work (higher-energy output) and will require a higher delivery of oxygen and metabolites (fatty acids and glucose) to generate that energy.

Because of reduced myocardial function due to chronic disease, heart failure triggers an increased secretion of epinephrine/norepinephrine to provide a compensatory hyperactivation of the inotropic signaling responses described. While this initially increases activation of the β1 and β2 receptors, it also induces their chronic desensitization and down-regulation. Moreover, these β receptors increasingly activate other signaling cascades. For example, β1 receptors stimulate cascades that are predominantly maladaptive, such as decreased expression of survival genes and increased activation of proapoptotic signals. During development of heart failure there is a decrease in the ratio of β1-subtype receptors to β2-subtype receptors. Heart failure also increases activity of the GRK2/βAR-kinase that phosphorylates the receptors and uncouples them from activation of G protein-dependent signaling pathways.

Although it may seem paradoxical, the treatment of heart failure is based on β-adrenergic antagonists (β-blockers), most commonly **metoprolol** or bisoprolol, which are highly selective for the β1 receptors. The effectiveness of β-blocker therapy seems to involve repression of the maladaptive signaling pathways activated by β1-receptors. Recent clinical studies have reported the usefulness of **carvedilol**, which nonselectively blocks both β1- and β2-adrenergic receptors, but also antagonizes α1-adrenergic receptors that are highly expressed in vascular smooth muscle cells. These receptors activate the Gq/phospholipase C cascade and release of IP_3-sensitive Ca^{2+} pools to cause contraction of smooth muscle with consequent constriction of blood vessels. Antagonism of these latter responses decreases the resistance to blood flow and the amount of work required by the heart to deliver effective cardiac output.

Lohse, M. J., Englehardt, S., and Eschenhagen, T. What is the role of β-adrenergic signaling in heart failure? *Circ. Res.* 93:896, 2003.

13.9 • CYCLIC AMP-BASED SIGNAL TRANSDUCTION

Regulation of Cyclic AMP Synthesis and Degradation

Many metabolic and behavioral responses to different hormones and neurotransmitters are mediated by increase in intracellular cAMP. The use of cAMP as a second messenger is largely limited to GPCRs. Cells actively regulate both the synthesis and degradation of this second messenger. cAMP synthesis is catalyzed by **adenylate cyclases** that use ATP as a substrate to produce cAMP and pyrophosphate (PPi) (Figure 13.24). The normal basal level of cAMP in cytosol is $\sim 10^{-7}$ to 10^{-6} M. During maximal hormonal stimulation, the cAMP concentration can increase 2- to 100-fold depending on cell type. At least six genes that encode different subtypes of adenylate cyclase have been identified. All are integral membrane proteins with 12 membrane-spanning domains, one catalytic domain within the intracellular segment connecting transmembrane segments six and seven, and a second

catalytic domain at the intracellular carboxy-terminus. The various subtypes are expressed in tissue-specific patterns and can be differentially regulated by particular signaling proteins. All adenylate cyclase isoforms are positively regulated by the α_s-subunits of G_s proteins. However, the $\beta\gamma$-subunit complex from various G proteins (including G_s) can stimulate some adenylate cyclase isoforms while inhibiting others. The α_i-subunits from G_i proteins can directly inhibit certain subtypes of adenylate cyclase (Figure 13.25).

The breakdown of cAMP is catalyzed by **cyclic nucleotide phosphodiesterases (PDEs)** that hydrolyze the cyclic diester bond to produce AMP (Figure 13.24). The activity of these PDEs can be regulated by both hormones and certain drugs. Cellular cAMP can be increased by inhibition of the PDEs. Xanthine derivatives, such as theophylline and caffeine, inhibit PDEs and result in increased cAMP levels in the absence of hormonal stimulation.

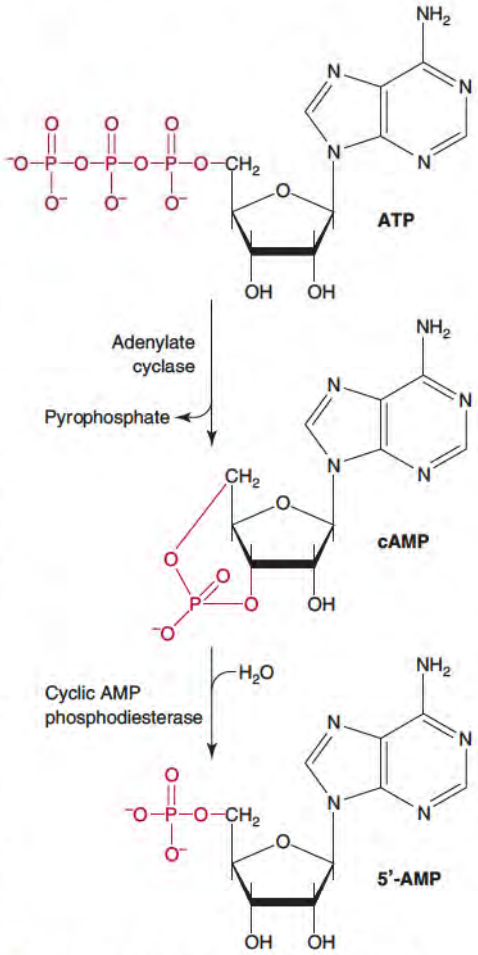

Figure 13.24 Synthesis and degradation of cyclic AMP by adenylate cyclases and cyclic nucleotide phosphodiesterases.

Intracellular Signaling Mechanisms of Cyclic AMP

cAMP-dependent **protein kinase A (PKA)** mediates most of the effects of cAMP (Figure 13.26, p. 530). PKA is a tetramer composed of two regulatory subunits (R-subunits), which contain the cAMP-binding sites, and two catalytic subunits (C-subunits), which contain the kinase activity. The tetrameric form cannot catalyze phosphorylation of target proteins. On the cooperative binding of several cAMP molecules to the regulatory subunits, the tetramer dissociates and the free catalytic subunits become active. Many of the protein substrates of the cAMP-dependent kinase are themselves kinases with specific target enzymes. This underscores the cascading nature of this (and most other) receptor-linked signaling systems. Specific phosphatases dephosphorylate the phosphorylated proteins and thus inactivate the cAMP-mediated signaling cascade. These phosphatases are subject to receptor-linked regulation.

cAMP profoundly alters cellular metabolism by altering both the activity and expression of many catabolic enzymes, including enzymes involved in lipid and in carbohydrate metabolism. Metabolic regulation by cAMP often involves the PKA-mediated regulation of *secondary* kinases or phosphatases by changing the phosphorylation states of the latter enzymes. PKA can also phosphorylate several types of plasma membrane ion channels or ion transporters and lead to either altered membrane potential or the activation/inhibition of the influx of regulatory ions such as Ca^{2+}. Because neurotransmitters, such as serotonin, dopamine, and epinephrine, interact with GPCR that regulate G_s or G_i, the ability of cAMP and PKA to modulate ion channel activity is a critical component of regulation in the central nervous system.

Increased cAMP in eukaryotic cells rapidly alters the transcription and expression of the genes coding for important metabolic enzymes, polypeptide hormones, and ion transport proteins. The dissociation of catalytic subunits from the regulatory subunits exposes nuclear localization sequences on the catalytic subunits and facilitates their

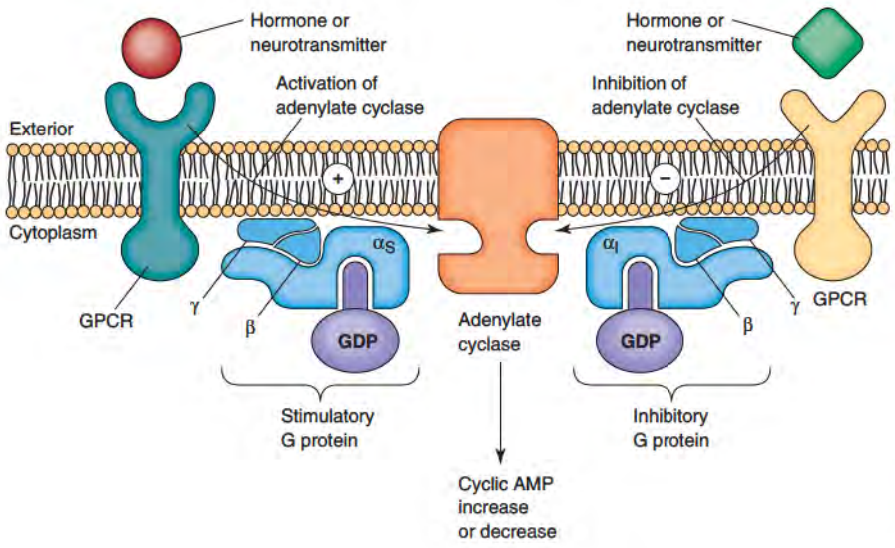

Figure 13.25 Positive and negative regulation of adenylate cyclase effector enzymes by G_s- and G_i-family heterotrimeric G proteins.

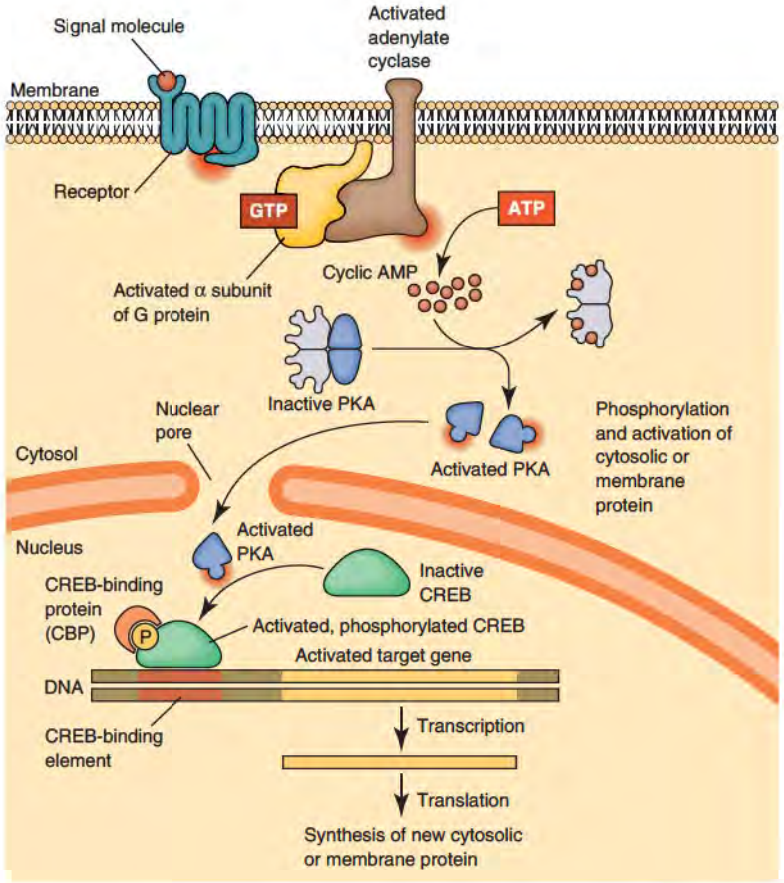

Figure 13.26 Role of protein kinase A in the intracellular signaling cascades regulated by cyclic AMP.
Redrawn based on figure from Alberts, B., et al. *Molecular Biology of the Cell,* 4th ed. New York: Garland Science, 2002.

cytosol-to-nucleus translocation (Figure 13.26). The intranuclear PKA induces phosphorylation and activation of cAMP-regulated proteins called **CREBs** to control the expression of genes that contain cAMP-sensitive regulatory elements (**CRE**) within the 5′-flanking regions of many cyclic AMP-responsive genes. In this way, the transient increases in cAMP triggered by GPCR at the cell surface can be translated into long-lasting changes in nuclear gene expression and cell function.

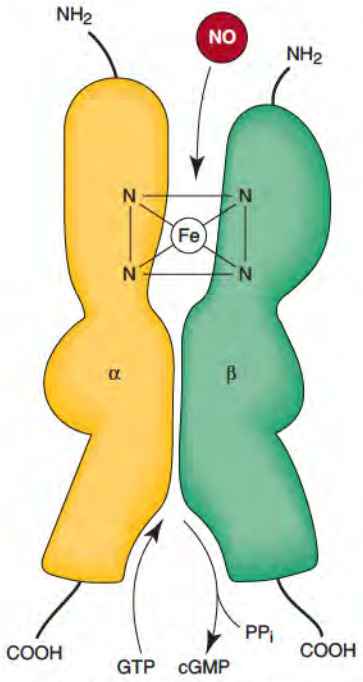

Figure 13.27 NO binding to soluble guanylate cyclase.

13.10 • CYCLIC GMP-BASED SIGNAL TRANSDUCTION

Regulation of Cyclic GMP Synthesis and Degradation

cGMP is an important second messenger in the regulation of muscle and nonmuscle contractility, in visual signal transduction, and in blood volume homeostasis. Cellular levels of cGMP are dynamically regulated by a balance between synthetic (**guanylate cyclases**) and degradative (**cGMP phosphodiesterases**) enzymes. The two major types of gua-nylate cyclase in mammalian cells are fundamentally different from the adenylate cyclase. A **membrane-associated guanylate cyclase** activity resides in the catalytic domains of the enzyme-linked receptors for the hormone **atrial natriuretic factor (ANF)** secreted from cardiac myocytes of the atrium in response to increases in circulating blood volume and/or pressure. ANF receptors are expressed primarily in vascular smooth muscle cells and in renal cells. This receptor has a large extracellular domain for binding ANF, a single transmembrane domain, and a relatively short intracellular catalytic domain. ANF binding stimulates catalytic activity via receptor dimerization and binding of regulatory proteins to the hormone-occupied receptor (see Figures 22.32, p. 914, and 22.33, p. 915). In contrast to the tissue-restricted expression of the ANF receptor–guanylate cyclase, a cytosolic form of guanylate cyclase is present in most cell

CLINICAL CORRELATION 13.6

Nitric Oxide/cGMP Signaling as Therapeutic Targets in Cardiac and Vascular Disorders

The endothelial cells that line the internal surfaces of all blood vessels are major sources of the nitric oxide used for the relaxation of vascular smooth muscle cells. In these myocytes, cGMP generation by the soluble guanylate cyclase is stimulated by nitric oxide generated by adjacent endothelial cells. cGMP induces myocyte relaxation and vasodilation of blood vessels with increased blood flow to nearby tissue. Similar changes can be produced by drugs that increase nitric oxide production. cGMP levels are also regulated by phosphodiesterases (PDE) that convert cGMP to GMP. Thus, drugs that inhibit vascular isoforms of PDE improve blood flow to particular tissues.

Angina pectoris is the formal name for chest pain suffered by patients with different types of cardiac insufficiency. Nitroglycerin is commonly prescribed and rapidly alleviates angina (see Clin. Corr. 11.10, p. 451). It is metabolized to nitric oxide and also binds directly to nitric oxide–sensitive proteins (like soluble guanylate cyclase). Thus, it can induce smooth muscle relaxation and vasodilation. How nitroglycerin alleviates angina is not completely understood. The coronary arteries and cardiac microvasculature during coronary insufficiency are likely maximally dilated due to local ischemia. Thus, nitroglycerin probably alleviates angina by decreasing cardiac workload and myocardial oxygen requirement via vasodilatory effects on the veins that return blood to the heart (preload), and by decreasing peripheral blood pressure (afterload) through vasodilatory effects on systemic arteries.

Viagra® is the trade name for Sildenafil citrate that is used to treat erectile dysfunction. It inhibits selectively the type 5 cyclic nucleotide phosphodiesterase (PDE5) that is highly expressed in vascular smooth muscle. It is 80- to 4000-fold less potent as an inhibitor of other cyclic nucleotide PDE isoforms, including PDE3 which is predominantly expressed in cardiac muscle. It is only 10-fold more selective for PDE5 versus PDE6, which is the predominant PDE in the retina. When blood vessels in erectile tissue are vasodilated in response to released NO and activation of guanylate cyclase, the inhibition of cGMP breakdown by Viagra leads to higher and more sustained levels of cGMP accumulation and PKG activation. This increases the vasodilation in erectile tissue. High doses of Viagra can lead to mild alterations in color vision due to side effects on the retinal PDE6.

Ignarro, L. J., Napoli, C., and Lascalzo, J. Nitric oxide donors and cardiovascular agents modulating the bioactivity of nitric oxide, *Circ. Res.* 90:21, 2001.

types (Figure 13.27). This **soluble guanylate cyclase** is a dimeric complex of 82-kDa and 70-kDa subunits. Each dimer constitutively binds a molecule of **heme**. In the absence of gaseous ligands that bind to this heme group, soluble guanylate cyclase has a very low rate of catalysis. However, binding of **nitric oxide (NO)** to the heme group induces conformational changes that greatly increase activity of the guanylate cyclase. Thus, a major stimulus for cGMP accumulation in most cells is an elevated level of NO. NO is generated by **nitric oxide synthases (NOS)** (p. 447). Because NO readily permeates biological membranes, it can be produced in one type of cell, for example, a vascular endothelial cell, and rapidly diffuse into neighboring cell types, for example, vascular smooth muscle cells, where it activates soluble guanylate cyclase. Accumulation of cGMP in smooth muscle triggers rapid and sustained relaxation of the contractile apparatus (Clin. Corrs. 13.6).

cGMP degradation is catalyzed by several soluble or weakly membrane-associated **cGMP phosphodiesterases** (PDE). Although some appear to be passive catabolic enzymes (i.e., not directly regulated), the cGMP-dependent PDE in the light-sensing cells of the retina is an effector enzyme for the trimeric G protein transducin (p. 963).

Intracellular Signaling Mechanisms of Cyclic GMP

Cyclic GMP exerts most of its second messenger effects by activating **cGMP-sensitive protein kinases (PKG)** that are widely expressed in many tissues. Depending on cell type, PKG phosphorylates a variety of important targets, including enzymes involved in metabolism, structural proteins, and ion transport proteins. For example, stimulation of PKG in smooth muscle and nonmuscle cells results in the coordinated phosphorylation of many proteins that act to inhibit Ca^{2+}-dependent contraction or motility. These include: (1) proteins that attenuate Ca^{2+} release channels of the endoplasmic reticulum, (2) myosin light chain phosphatases that repress myosin interaction with actin, and (3) K^+ channels that induce plasma membrane hyperpolarization and thereby repress voltage-gated Ca^{2+} influx. cGMP also acts as a direct (i.e., PKG-independent) regulator of cyclic nucleotide-gated cation channels expressed in certain sensory tissues such as the retina.

13.11 • CALCIUM-BASED SIGNAL TRANSDUCTION

Regulation of Cytosolic Ca^{2+} Concentration

Ca^{2+} is an important intracellular regulator of many fundamental cell functions including: contraction in all types of muscle, secretion of hormones and neurotransmitters, cell division, directed migration of nonmuscle cells, and regulation of gene expression. Cells respond to many types of hormones and neurotransmitters with rapid and transient increases in cytosolic Ca^{2+} that then binds to a variety of Ca^{2+}-dependent regulatory proteins. Increases in cytosolic Ca^{2+} are elicited by opening of either Ca^{2+} channels in the plasma membrane or Ca^{2+} channels in the endoplasmic reticulum (ER). This released Ca^{2+} can be rapidly reaccumulated by the ER to terminate the response to the hormone/neurotransmitter.

The basal concentration of free Ca^{2+} in the cytosol of most cell types is maintained at approximately 10^{-7} M (Figure 13.28). Small increases in cytosolic free Ca^{2+} to 10^{-6} M rapidly and maximally activate the various Ca^{2+}-regulated cell functions. Because extracellular Ca^{2+} concentration is 10^{-3} M, there is a 10,000-fold concentration gradient for Ca^{2+} across the plasma membrane and the driving force for rapid Ca^{2+} influx is further increased by the inside-negative membrane potential. In excitable cells, such as neurons and muscle cells, Ca^{2+} influx involves voltage-gated Ca^{2+} channels (see Table 12.10, p. 481). This type of Ca^{2+} signaling pathway is generally initiated by the ion channel receptors for excitatory neurotransmitters, such as acetylcholine, glutamate, serotonin, and ATP. The plasma membrane also contains two transport systems, the Na^+/Ca^{2+} antiport transporter and the Ca^{2+}-transporting ATPase that efficiently pump the excess Ca^{2+} out of the cytosol (Figure 13.28).

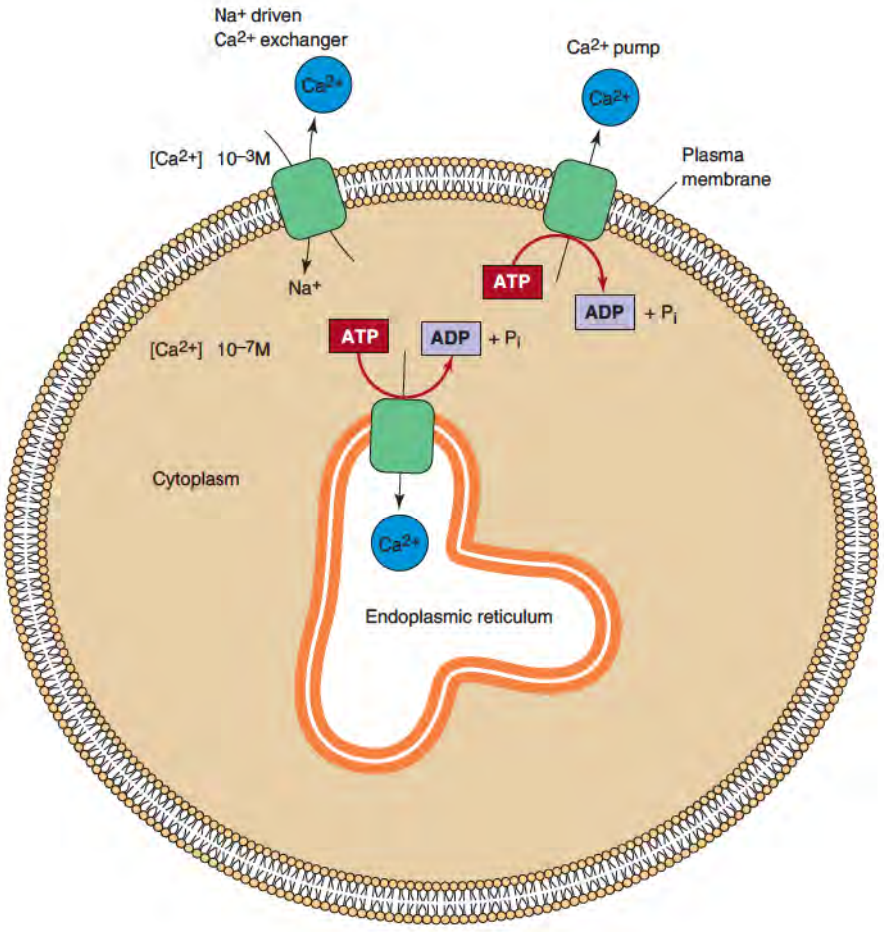

Figure 13.28 Role of plasma membrane and organellar Ca^{2+} transport proteins in the regulation and compartmentation of intracellular Ca^{2+} pools.

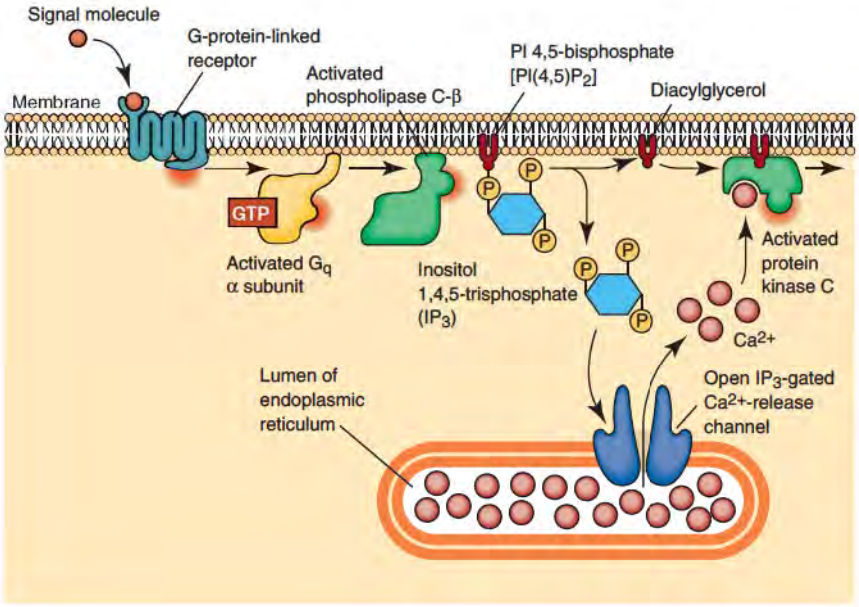

Figure 13.29 Mobilization of endoplasmic reticulum Ca^{2+} pools and activation of protein kinase C by receptors that stimulate the phospholipase C-mediated hydrolysis of inositol phospholipids.

Ca^{2+} ions are efficiently concentrated within the ER (termed sarcoplasmic reticulum or SR in muscle cells) by Ca^{2+}-transporting ATPase pumps. This ATPase permits Ca^{2+} to accumulate to a concentration of about 1 mM (10^{-3} M) within the lumen of the ER/SR; this is equivalent to the concentration of Ca^{2+} in the extracellular space. This accumulated Ca^{2+} can be released into the cytosol via two types of ER/SR-localized Ca^{2+} channels that are regulated by signals generated by many types of cell surface receptors. The first is a very widely expressed channel known as the **1,4,5-inositol trisphosphate (IP_3) receptor (IP3R)** or **IP_3-gated Ca^{2+} channel** (Figure 13.29). IP_3, a second messenger, is rapidly generated when phospholipase C is stimulated by different hormones or neurotransmitters. A different ligand-gated Ca^{2+} release channel is expressed in the ER/SR of skeletal and cardiac muscle. This is the **ryanodine receptor** (RyR) or ryanodine-sensitive Ca^{2+} release channel because it binds the drug ryanodine (Figure 13.30). In cardiac muscle, the RyR channels are gated by the Ca^{2+} that enters through plasma membrane voltage-gated Ca^{2+} channels sensitive to channel-blocking drugs known as dihydropyridines. This interplay of multiple Ca^{2+} channels to regulate cardiac muscle function is termed Ca^{2+}-induced Ca^{2+} release. In skeletal muscle, RyR channels open via direct protein–protein interactions with the voltage- and dihydropyridine-sensitive Ca^{2+} channels; this regulation is possible because SR in skeletal muscle forms direct contacts with specialized invaginations of the plasma membrane.

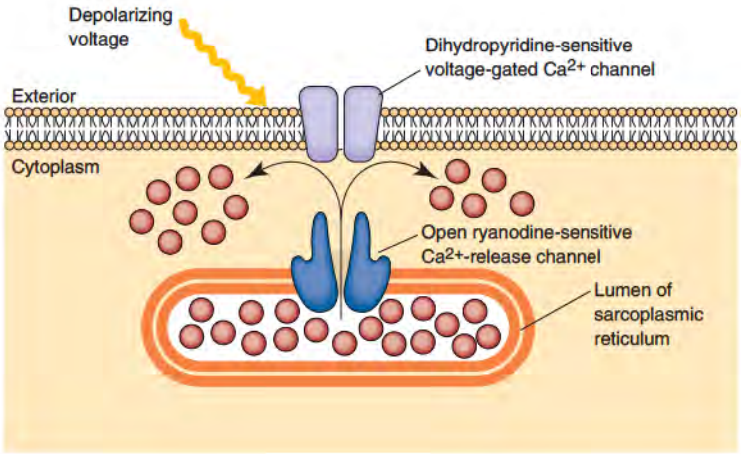

Figure 13.30 Mobilization of sarcoplasmic reticulum Ca^{2+} pools in striated muscle cells by depolarization-induced activation of ryanodine-sensitive Ca^{2+} release channels.

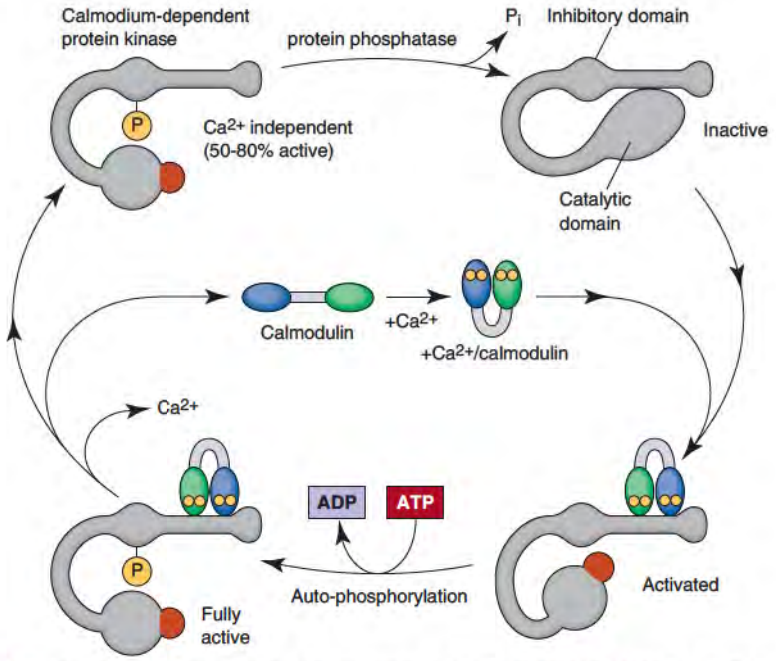

Figure 13.31 Regulation of calmodulin and calmodulin-regulated protein kinases by Ca^{2+}. Redrawn based on figure from Alberts, B., et al. *Molecular Biology of the Cell,* 4th ed. New York: Garland Science, 2002.

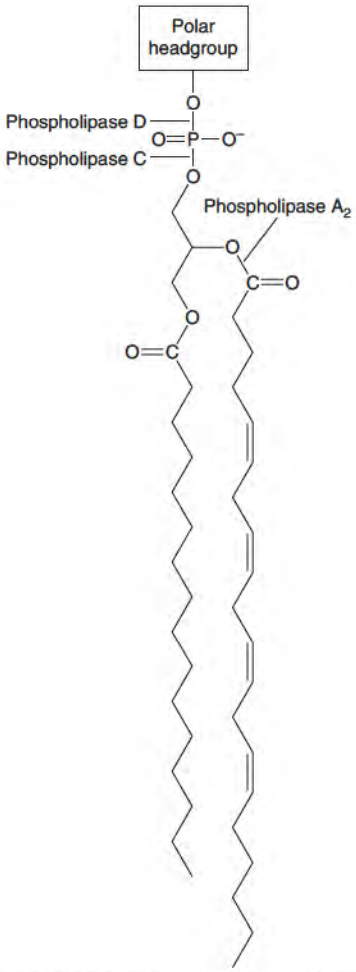

Figure 13.32 Major classes of phospholipases used during receptor-mediated signal transduction.

Calcium Activation of Calmodulin-Dependent Protein Kinases and Phosphatases

Increased cytosolic Ca^{2+} results in activation of various calcium-binding regulatory proteins. Some, such as troponin-C, which regulates contraction in striated muscles, are highly specialized and expressed in only a few tissues (see Figure 23.35, p. 976). In contrast, **calmodulin (CaM)** (p. 493) is a ubiquitously expressed protein that mediates the regulatory actions of Ca^{2+} on a broad range of cellular functions via its ability to activate Ca^{2+}-sensitive effector proteins that include serine/threonine-specific protein kinases (Figure 13.31), phosphatases, and nitric oxide synthases (see Figure 11.17, p. 444). On binding of Ca^{2+}, calmodulin undergoes conformational changes that facilitate its interaction with the downstream effector proteins. Some calmodulin-dependent kinases, such as myosin light chain kinase , target only specific proteins whereas other forms, such as the multifunctional CaM Kinase II, can phosphorylate a broad range of protein substrates. Altering the activity of these proteins is the primary mechanism by which increased Ca^{2+} alters cellular behavior. CaM-kinase II also becomes autophosphorylated when bound to calmodulin, and this autophosphorylation allows CaMKII to remain active long after cytosolic Ca^{2+} has returned to a resting level. CaM-kinases can phosphorylate and modulate a wide range of enzymes, ion channels, contractile proteins, and gene regulatory proteins.

13.12 • PHOSPHOLIPID-BASED SIGNAL TRANSDUCTION

Regulated Phospholipid Metabolism as a Component of Intracellular Signaling Pathways

Signal transduction by many cell surface receptors involves activation of one or more phospholipases that catalyze the hydrolysis of different classes of phospholipids (e.g., inositol or choline phospholipids). Several classes of phospholipases catalyze the production of distinct products that act as second messengers or regulators of second-messenger production (Figure 13.32). **Phospholipase C (PI-PLC)** hydrolyses inositol phospholipids to yield **inositol phosphates** and

diacylglycerols as second messengers. Inositol phospholipids can be further phosphorylated by **phosphoinositide-3-kinase (PI-3K)** to produce **phosphatidylinositol-3,4,5-trisphosphate (PIP_3)**, another second messenger whose function is described in the following. **Phospholipase D (PLD)** predominantly hydrolyses choline or ethanolamine phospholipids to produce **phosphatidic acid** that is subsequently hydrolysed by phosphatidic acid phosphohydrolyases (PAP) to yield diacylglycerol. **Phospholipase A2 (PLA2)** attacks various phospholipids to produce free fatty acids, such as arachidonic acid, and lyso-phospholipids.

Regulation of Phospholipase C and Phospholipase D

As previously described, many G protein-coupled receptors and receptor tyrosine kinases stimulate the release of Ca^{2+} from the endoplasmic reticulum by activating the production of **1,4,5-inositol trisphosphate (IP_3)**. This water-soluble second messenger is derived from the hydrolysis of **phosphatidylinositol-4,5-bisphosphate (PIP_2)**, a relatively minor membrane phospholipid that is generated by phosphorylation of two hydroxyls on the inositol residue of phosphatidylinositol. Hydrolysis of PIP_2 is catalyzed by C-type phospholipases (**PLC**) with high selectivity for inositol phospholipids (Figure 13.32) and generates two second messengers: (1) the water soluble product IP_3 and (2) **diacylglycerol (DAG)**, a hydrophobic product. **PI-PLCβ** enzymes are activated by interaction with either the α-subunits of $G_{q/11}$-family G proteins or the $\beta\gamma$-subunits of G_i-family. In contrast, the **PI-PLCγ** enzymes are activated by tyrosine phosphorylation and association with receptor tyrosine kinases. Some nonreceptor tyrosine kinases also phosphorylate PLC enzymes.

In addition to IP_3, the activation of PI-PLCβ and PI-PLCγ results in accumulation of DAG. However, the magnitude of receptor-induced production of DAG in many cell types cannot be ascribed solely to the breakdown of PIP_2. Although PIP_2 hydrolysis yields small amounts of DAG over short periods, the hydrolysis of more abundant phospholipids, such as phosphatidylcholine (PC), underlies most of the sustained production of DAG triggered in response to receptor activation. Consequently, PC hydrolysis by PLC and **phospholipase D (PLD)** mediates the regulation of cellular processes that require prolonged elevation of DAG. PC-PLD and PC-PLC are indirectly activated during receptor stimulation by a complex network of primary signals that include Ca^{2+}, small GTPases, and protein kinase C.

Diacylglycerol and Protein Kinase C

Diacylglycerol (DAG), which results from breakdown of PIP_2 or PC, binds to and activates members of the **protein kinase C (PKC)** family (see Figure 13.29, p. 533). Inactive PKCs exist as soluble, cytosolic proteins in which the N-terminus (containing the DAG-binding sites) occludes the C-terminus (containing binding sites for substrate proteins and ATP). When DAG is generated in membranes, PKC binds to it, and this results in unfolding and exposure of the substrate- and ATP-binding domains of the kinase. Other N-terminal sites on PKC enzymes bind to acidic phospholipids and facilitate association of PKC with the membrane. Some isoforms of PKC contain Ca^{2+}-binding sites in their N-terminal domains so that increased cytosolic Ca^{2+} potentiates PKC binding to membranes. Activation of PKC enzymes results in serine/threonine phosphorylation of many substrate proteins, which in turn, elicit a number of cellular responses. Like cAMP-dependent protein kinases and calmodulin-dependent protein kinases, PKC isozymes phosphorylate: (1) transcription factors involved in regulation of gene expression, (2) ion channels and transporters and (3) other types of protein kinases. Some PKC isozymes also trigger the various MAP kinase cascades that control multiple gene regulatory proteins. The ability of PKC enzymes to regulate directly or indirectly the phosphorylation of transcription factors underlies the critical role of PKC in regulating the growth, differentiation, or death of many cells and tissues.

PIP_3, Phosphatidylinositol 3-Kinases, and Protein Kinase B

Inositol phospholipids are substrates for inositol lipid kinases that specifically phosphorylate inositol at the 3′-OH . These **phosphatidylinositol 3-kinases (PI3-kinases)** compose a family of signaling proteins. Some associate with, and are activated by, tyrosine

phosphorylated growth factor receptors or activated cytokine receptors via SH-2 domain interactions. Others are activated by the $\beta\gamma$ dimers derived from activated G proteins. PI-3 kinases predominantly phosphorylate phosphatidylinositol-4,5-bisphosphate to produce **phosphatidylinositol-3,4,5-trisphosphate (PIP_3)**, which does not act as a substrate for PLC, but has critical roles as a second messenger in the regulation of membrane trafficking, cell motility, and activation of cell survival signaling pathways (Figure 13.33). The **Akt/protein kinase B (PKB)** family are major mediators of PIP_3 action. Active PKB potentiates cell survival by repressing the activity of certain cell death signaling pathways and regulates other proteins and kinases involved in glucose transport and glycogen metabolism.

Phospholipase A_2 and Generation of Arachidonic Acid Metabolites

Occupancy of cell surface receptors in many cell types triggers the release of **arachidonic acid (AA)** from membrane phospholipids. The release of AA is catalyzed by members of the family of phospholipase A_2 (**PLA_2**) enzymes (see Figure 13.32, p. 534). The regulation of PLA_2 is complex but includes Ca^{2+}, which seems to control the translocation of some PLA_2 isoforms from cytosol to membranes, and kinase-mediated phosphorylation. Arachidonic acid can be rapidly metabolized to multiple oxidation products collectively known as **eicosanoids** (p. 737); these include prostaglandins, thromboxanes, and leukotrienes. In contrast to other second messengers, such as cyclic nucleotides or Ca^{2+}, eicosanoids are generally secreted from the cells in which they are produced to act as extracellular agonists for cell surface receptors in neighboring cells. The eicosanoids are formed by virtually all cell types and play fundamental paracrine/autocrine roles in processes such as inflammation, blood clotting, control of vascular tone, renal function, and others.

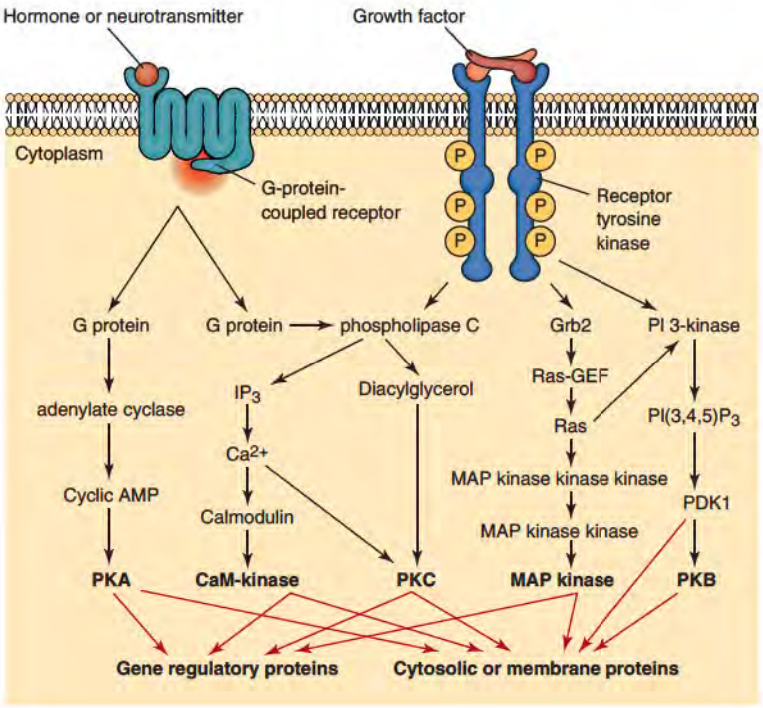

Figure 13.34 Cross-talk and integration among the major intracellular signaling cascades regulated by different cell surface receptors. Redrawn based on figure from Alberts, B., et al. *Molecular Biology of the Cell,* 4th ed. New York: Garland Science, 2002.

13.13 • INTEGRATION OF SIGNAL TRANSDUCTION PATHWAYS INTO SIGNAL TRANSDUCTION NETWORKS

Depending on their tissue localization and degree of specialization, individual cells may be genetically programmed to respond to many distinct extracellular signaling molecules. Many important intracellular signaling cascades can be regulated synergistically by receptors of various types and families (Figure 13.34). For example, the MAP kinase pathways can be regulated by G protein-coupled receptors and growth factor receptor kinases. This "cross-talk" provides cells the ability to integrate signals from multiple extracellular stimuli into unique and particular patterns of altered cellular response. In other cases, different second-messenger-activated kinases may phosphorylate distinct residues on a common target protein, such as a transcription factor, to produce either divergent or convergent changes in gene expression patterns. Thus, the integrated response of a cell to activation of a particular cell-surface receptor will often vary depending on what other cell surface receptors are activated simultaneously. For example, a receptor that normally induces specialized gene expression in a particular cell type may trigger the programmed death of that same cell if other cell surface receptors are being simultaneously activated or, in some cases, are not being activated. Although modern cell biology has made significant advances in defining the basic components and sequential steps of individual signaling pathways, a major challenge remains in understanding how these individual pathways are integrated into signal transduction networks.

Key Terms

juxtacrine signaling
receptor
endocrine signaling
hormone
local mediator
paracrine signaling
autocrine signaling
neurotransmitter
growth factor
synaptic signaling
second messenger
agonist
antagonist
cytokine
G protein-coupled receptor
ligand
effector protein
phospholipase
phosphatase
potency
ligand-gated ion channel receptor
nuclear receptor
receptor desensitization
adapter protein
enzyme-linked receptor
guanylate cyclase
serine/threonine kinase
tyrosine kinase
MAP kinase
small GTPase
heterotrimeric G protein
adenylate cyclase
receptor internalization
cyclic nucleotide
cyclic nucleotide phosphodiesterase
Ca^{+} influx channel
Ca^{+} release channel
calmodulin
eicosanoid
second-messenger-regulated protein kinase

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. The type of intercellular signaling in which one cell can communicate with another over long distances is called
   - **A.** autocrine.
   - **B.** endocrine.
   - **C.** juxtacrine.
   - **D.** paracrine.
   - **E.** synaptic.

2. Intracellular receptors
   - **A.** usually bind hydrophobic ligands.
   - **B.** may be located either in the cytosol or nucleus in unbound state.
   - **C.** when bound to their ligand, regulate gene transcription.
   - **D.** when bound to their ligand, function as dimeric complexes binding to specific DNA sequences.
   - **E.** all of the above.

3. A cell surface receptor
   - **A.** reacts only with molecules too large to cross the plasma membrane.
   - **B.** when bound to its ligand, could result in activation of an enzymatic cascade.
   - **C.** always opens an ion channel when bound to its ligand.
   - **D.** must produce a second messenger when it binds to its ligand.
   - **E.** is usually also called GPCR.

4. Cells can terminate signal transduction by cell surface receptors by
   - **A.** reducing agonist availability in the vicinity of the target cell.
   - **B.** internalizing and degrading the receptor–agonist complex.
   - **C.** modifying the receptor so that it is inactive or desensitized.
   - **D.** all of the above.
   - **E.** none of the above.

5. Calmodulin is
   - **A.** a nonspecific kinase.
   - **B.** a protein that binds Ca^{2+}.
   - **C.** a second messenger.
   - **D.** an activator of nitric oxide synthase.
   - **E.** a protein channel that facilitates the influx of Ca^{2+}.

6. The guanylate cyclase that responds to NO
   - **A.** is in the catalytic domain of a membrane receptor.
   - **B.** is also activated when atrial natriuretic factor (ANF) binds to its receptor.
   - **C.** increases activity because of a conformational change when NO binds to its heme.
   - **D.** is a monomeric enzyme.
   - **E.** is found only in smooth muscle cells.

Questions 7 and 8: Manic depression may be caused by overactivity of certain central nervous system cells, perhaps caused by abnormally high levels of hormones or neurotransmitters which stimulate phospholipid-based signal transduction (e.g., from phosphatidylinositol [PI]). Lithium has been used for many years to treat manic depression. In the presence of Li^+, the PI system is slowed despite continued stimulation and cells become less sensitive to these stimuli. Li^+ may have two functions, inhibition of the phosphatase that dephosphorylates inositol trisphosphate and direct interference with the function of G proteins.

7. The PI system begins with activation of phospholipase C, which initiates a sequence of events including all of the following except
   - **A.** activation of IP_3 by action of a phosphatase.
   - **B.** increase in intracellular Ca^{2+} concentration.
   - **C.** release of diacylglycerol (DAG) from a phospholipid.
   - **D.** activation of protein kinase C.
   - **E.** phosphorylation of certain cytoplasmic proteins.

8. Which of the following statements concerning G proteins is correct?
   - **A.** G proteins bind the appropriate hormone at the cell surface.
   - **B.** GTP is bound to G protein in the resting state.
   - **C.** α-Subunit may be either stimulatory or inhibitory because it has two forms.
   - **D.** Adenylate cyclase can be activated only if α- and β-subunits of G protein are associated with each other.
   - **E.** Hydrolysis of GTP is necessary for G protein subunits to separate.

Questions 9 and 10: Growth hormone releasing hormone (GHRH) produced by the hypothalamus binds to its pituitary receptor and leads to the production of growth hormone (GH) because of increase in cyclic AMP. Certain pituitary tumors result in hypersecretion of GH because of a mutation that produces a G_s-α protein with a greatly diminished GTPase activity.

9. Elements leading to increased cyclic AMP in response to GHRH binding to its receptor include
   - **A.** activation of a monomeric G protein.
   - **B.** activation of adenylate cyclase by α_s-subunit of a G_s protein.
   - **C.** activation of cyclic nucleotide phosphodiesterase.
   - **D.** activation of protein kinase A.
   - **E.** all of the above.

10. Low GTPase activity in the mutated protein results in consitutive activation of G_s and adenylate cyclase because
    - **A.** GTP-bound α-subunit does not reform the $\alpha\beta\gamma$ trimer.
    - **B.** GTP-bound G protein binds more strongly to the membrane receptor.
    - **C.** GTP reacts directly with adenylate cyclase to activate it.
    - **D.** the trimeric form of the G protein is stabilized.
    - **E.** adenylate cyclase is phosphorylated more readily.

Questions 11 and 12: The ErbB/HER family of receptor tyrosine kinase genes are linked to many different types of human cancers. Overexpression of any of these genes would lead to an increase in the various receptors. ErbB2 encodes the HER2 protein. This receptor does not bind any known extracellular growth factor, but it does form dimers with other growth-factor-bound HER receptors. Even modest overexpression of HER2 can alter normal cell growth regulation.

11. Which of the following statements about receptor tyrosine kinases is correct?
    - **A.** The catalytic domain is on the N-terminal end.
    - **B.** Activation of the kinase requires ATP.
    - **C.** Growth factor binding to the receptor triggers dimerization which activates the kinase activity.
    - **D.** Active tyrosine kinase can phosphorylate other proteins but not itself.
    - **E.** All of the above.

12. Ras protein is a critical regulator in cell proliferation, and its activity is enhanced by activated tyrosine kinase. Elements of its action include all of the following except
    A. formation of cyclic GMP.
    B. adaptor proteins binding to phosphorylated tyrosines on receptor tyrosine kinase.
    C. recruitment and stimulation of Ras-activating protein.
    D. exchange of GDP for GTP on the Ras protein.
    E. initiation of a cascade in which several kinases are activated sequentially by phosphorylation.

Problems

13. How does elevation of cyclic AMP in eukaryotic cells lead to altered transcription of certain genes?

14. How do excitatory and inhibitory neurotransmitters differ in their effects on ligand-gated ion channels?

Answers

1. **B** A hormone is released into the blood and travels to the target tissue. A: One cell type is both the sender and target. C: This is contact-dependent signaling. D: The cells are in the immediate vicinity of each other. E: This is a type of paracrine signaling used by nerve cells.
2. **E** A: Things like steroid hormones. B: Once bound to ligand, cytosolic receptors translocate to the nucleus. C and D: They bind to upstream regulatory elements and either enhance or repress transcription.
3. **B** This is one of the ways that signal transduction occurs. A: They also react with very hydrophilic signaling molecules. C and D: These are additional ways in which cell surface receptors can act. E: This is true only if the receptor is coupled to a G protein.
4. **D** These are all possible.
5. **B** This is a ubiquitous Ca^{2+}-binding protein. A: Ca^{2+}-calmodulin regulates some kinases but not this one. C: Second messengers are usually small molecules or ions. D: It is the Ca^{2+}–calmodulin complex that regulates. E: Calmodulin binds the Ca^{2+} that enters but is not part of the channel to allow it to enter.
6. **C** The soluble enzyme has low activity when heme has not bound a gaseous molecule. A and B: The membrane-bound enzyme is stimulated when ANF binds its receptor but not by NO. D: It is a dimer. E: The soluble enzyme is present in most cell types.
7. **A** IP_3 is the active form. Action of phosphatase on it renders it inactive as it is converted to inositol. B: IP_3 causes release of calcium. C and D: This is the other second messenger, and it activates protein kinase C. E: This is what protein kinase C does.
8. **C** Which form is released depends on the specific hormone and receptor that have interacted. A: Receptor binds the hormone and the complex interacts with G protein. B and E: GDP is bound to the resting enzyme. Its replacement by GTP causes α-subunit to dissociate. Actually hydrolysis of GTP allows subunits to reassociate. D: α-subunit, when dissociated from the other two, interacts with the enzyme to either activate or inhibit it depending on whether it is an α_s or an α_i.
9. **B** Adenylate cyclase then converts ATP to cAMP. A: G protein-coupled receptors are all heterotrimeric. C: This would decrease cAMP by hydrolyzing it to AMP. D: Cyclic AMP activates protein kinase, not the other way.
10. **A** α-GTP dissociates from the $\beta\gamma$ dimer. B: G proteins do not bind to the receptor. C: It is the α-GTP that activates the enzyme. D: See A. E: Activation of adenylate cyclase is a conformational change, not phosphorylation.
11. **C** This is why HER2 alters growth even though it does not bind a growth factor. A: The N-terminal end is extracellular and site of binding of the ligand; the catalytic site must be on an intracellular domain. B: Dimerization causes the activation; once activated it uses ATP to phosphorylate proteins. D: The first protein phosphorylated is the receptor itself, which then attracts other proteins to be phosphorylated.
12. **A** This is not a mechanism that produces a small second messenger. B to E: These are the sequential steps.
13. Cyclic AMP binding to protein kinase A causes dissociation of catalytic from regulatory subunits, exposing nuclear localization sequences on catalytic subunits. These can translocate to the nucleus where they can phosphorylate and activate cAMP-regulated gene regulatory proteins (CREBs), which control genes containing cAMP-sensitive regulatory elements (CREs).
14. Excitatory neurotransmitters (e.g., acetylcholine, glutamate) bind to cation-selective receptors and allow ions like Na^+ to enter, depolarizing the membrane. Inhibitory neurotransmitters (e.g., GABA, glycine) bind to anion-selective receptors and allow anions like Cl^- to enter, hyperpolarizing the membrane.

Key Concepts

- Energy is conserved in living organisms by oxidation of metabolic fuels and stored as the *high-energy* bond of ATP to provide energy for biosynthetic reactions, muscle contraction, and active ion transport.
- Gibbs free-energy predicts the direction of an enzymatic reaction and is related to the equilibrium constant.
- Pyruvate, the end product of glucose metabolism, is oxidatively decarboxylated to acetylCoA by the regulated pyruvate dehydrogenase complex.
- AcetylCoA, the end product of carbohydrate, lipid, and protein catabolism, is oxidized by the tricarboxylic acid cycle located in the mitochondrial matrix, producing NADH and $FADH_2$.
- NADH and $FADH_2$ are oxidized by the electron transport chain, organized in four large enzyme complexes in the inner mitochondrial membrane, by transferring electrons in a series of steps to the terminal electron acceptor oxygen.
- The energy released during the oxidative reactions of the electron transport chain is conserved as a proton and charge gradient across the inner mitochondrial membrane. The gradient drives the synthesis of ATP catalyzed by ATP synthase. This process is called oxidative phosphorylation.
- Transport systems located in the inner mitochondrial membrane facilitate movement of substrates and intermediates into and out of the mitochondrial matrix.

- Mammalian mitochondria have a unique circular DNA that encodes proteins of the electron transport chain, ATP synthase, and mitochondrial ribosomal RNA. Diseases result from mutations in mitochondrial genes.
- Stepwise transfer of electrons to oxygen results in formation of superoxide anions (O_2^-), hydrogen peroxide (H_2O_2), and hydrogen free radicals (OH·), which cause cell damage by lipid peroxidation, protein oxidation, and DNA mutations.

14.1 • ENERGY-PRODUCING AND ENERGY-UTILIZING SYSTEMS

Living cells depend on a complex, intricately regulated system of energy-producing and energy-utilizing chemical reactions called metabolism. Metabolism consists of two contrasting processes, **catabolism** and **anabolism**, which together constitute the chemical changes that convert foodstuffs into usable forms of energy and into complex biological molecules. Catabolism is responsible for degradation of ingested foodstuffs or stored fuels such as carbohydrate, lipid, and protein into either usable or storable forms of energy. Catabolic reactions generally result in conversion of large complex molecules to smaller molecules (ultimately CO_2 and H_2O), and in mammals often require consumption of O_2. Energy-utilizing reactions perform various necessary, and in many instances tissue-specific functions, for example, nerve impulse conduction, muscle contraction, growth, and cell division. Catabolic reactions are generally exergonic with the released energy generally trapped in the formation of ATP. The oxidative reactions of catabolism transfer reducing equivalents to the coenzymes NAD^+ and $NADP^+$ to form NADH and NADPH. Anabolic pathways are responsible for biosynthesis of large molecules from smaller precursors and require input of energy either in the form of ATP or reducing equivalents of NADPH (see Figure 10.28, p. 391).

ATP Links Energy-Producing and Energy-Utilizing Systems

The relationship between energy-producing and energy-utilizing functions of cells is illustrated in Figure 14.1. Energy is derived from oxidation of metabolic fuels utilized by the organism usually as carbohydrate, lipid, and protein. The proportion of each fuel utilized as an energy source depends on the tissue and the dietary and hormonal state of the organism. For example, mature erythrocytes and adult brain in the fed state use only carbohydrate as a source of energy, whereas the liver of a diabetic or fasted individual metabolizes primarily lipid to meet the energy demands. Energy may be consumed during performance of various energy-linked (work) functions, some of which are indicated in Figure 14.1. Note that liver and pancreas are primarily involved in biosynthetic and secretory work functions, whereas cardiac and skeletal muscles convert metabolic energy into mechanical energy during muscle contraction.

The essential link between energy-producing and energy-utilizing pathways is the nucleoside triphosphate **adenosine 5′-triphosphate (ATP)** (Figure 14.2). ATP is a purine (adenine) nucleotide in which adenine is linked by a glycosidic bond to D-ribose. Three phosphoryl

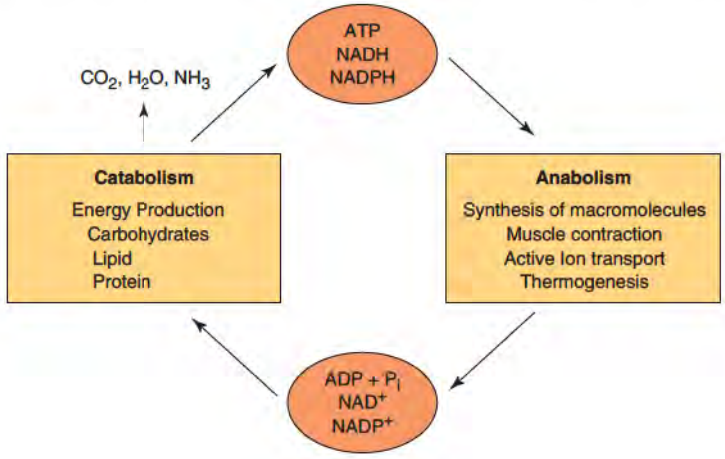

Figure 14.1 Energy relationships between energy production (catabolism) and energy utilization (anabolism). Oxidative breakdown of foodstuffs is an exergonic process releasing free energy and reducing power that are trapped as ATP and NADH or NADPH respectively. Anabolic processes are endergonic and use chemical energy stored as ATP and NADPH.

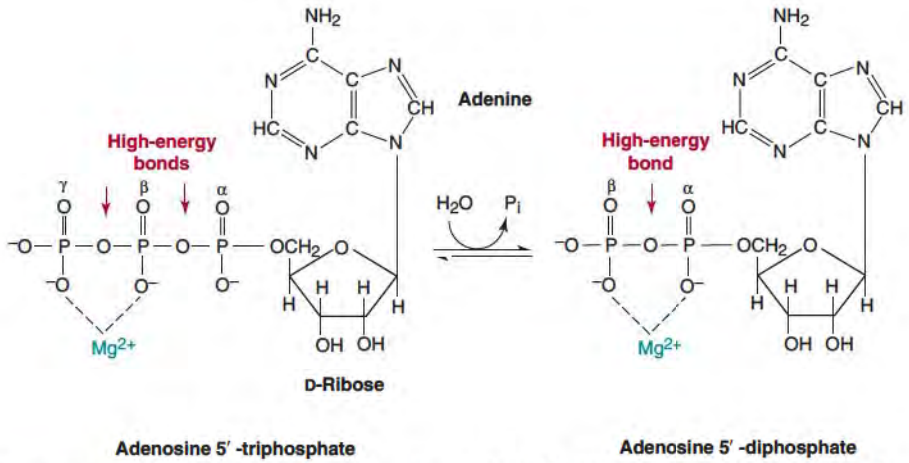

Figure 14.2 **Structure of ATP and ADP complexed with Mg^{2+}.** High-energy bonds are highlighted.

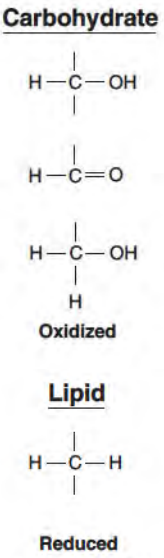

Figure 14.3 **Oxidation states of typical carbon atoms in carbohydrates and lipids.**

groups are esterified to the 5 position of the ribose moiety. The two terminal phosphoryl groups (i.e., β and γ) are energy-rich phospho-anhydride bonds or **high-energy bonds**. Synthesis of ATP as a result of a catabolic process or consuming ATP in an energy-linked process involves formation and either hydrolysis or transfer of the terminal phosphate group of ATP. This nucleotide is chelated with a divalent metal cation such as magnesium under physiological conditions.

NAD^+ and NADPH in Catabolism and Anabolism

Many catabolic processes are oxidative in nature because the carbons in the substrates, carbohydrates, fats and proteins, are in a partially or highly reduced state (Figure 14.3). **Reducing equivalents** are released from substrates as protons and electrons, which are transferred to **nicotinamide adenine dinucleotide (NAD^+)** by enzymes called dehydrogenases with formation of NADH (see Figure 10.28, p. 391). The reducing equivalents of NADH are transported into mitochondria and transferred by the electron transport chain to O_2 as the ultimate electron acceptor (p. 562). The oxidative reactions in mitochondria are exergonic; the energy produced is used for synthesis of ATP in a process called **oxidative phosphorylation**. The reductive and oxidative reactions of the NAD^+−NADH cycle are central in conversion of the chemical energy of carbon compounds in foodstuffs into that of phosphoanhydride bonds of ATP. This process, called energy transduction, will be discussed in detail later in this chapter.

Anabolism, by contrast, is largely a reductive process as small, more highly oxidized molecules are converted into large complex molecules (Figure 14.4). The reducing power used in biosynthesis of highly reduced compounds, such as fatty acids, is provided by NADPH (p. 391), a 3′ phosphorylated NADH.

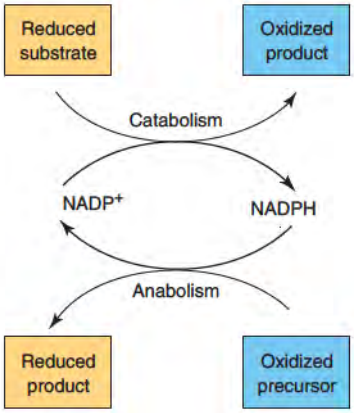

Figure 14.4 **Transfer of reducing equivalents during catabolism and anabolism using NADPH and NADH.**

14.2 • THERMODYNAMIC RELATIONSHIPS AND ENERGY-RICH COMPONENTS

Living cells interconvert different forms of energy and also exchange energy with their surroundings. The principles of **thermodynamics** govern reactions of this type. Knowledge of these principles facilitates a perception of how energy-producing and energy-utilizing reactions occur within the same cell and how an organism is able to accomplish various work functions.

The **first law of thermodynamics** states that energy can neither be created nor destroyed. This law of energy conservation stipulates that, although energy may be converted from one form to another, the total energy in a system remains constant. For example, chemical energy available in a metabolic fuel such as glucose is converted in glycolysis to the chemical energy of ATP. In skeletal muscle, chemical energy involved in energy-rich phosphate

bonds of ATP is converted to mechanical energy during muscle contraction. The energy of an osmotic electropotential gradient of protons across the mitochondrial membrane is converted to chemical energy during ATP synthesis.

The **second law of thermodynamics** is concerned with **entropy**. Entropy, denoted by *S*, is a measure or indicator of the degree of disorder or randomness in a system. Entropy is viewed as the energy in a system that is unavailable to perform useful work. All processes, whether chemical or biological, tend to progress toward a situation of maximum entropy. Hence, living systems that are highly ordered are never at equilibrium with their surroundings as equilibrium in a system results when the randomness or disorder (entropy) is at a maximum. In biological systems, therefore, it is nearly impossible to quantitate entropy changes as such systems are rarely at equilibrium. For simplicity and because of its inherent utility in these considerations, a quantity termed **free energy** is employed.

Free Energy Is Energy Available for Useful Work

The free energy (denoted by G or Gibbs free energy) of a system is that portion of the total energy that is available for useful work. It is defined by

$$\Delta G = \Delta H - T\Delta S$$

In this expression for a system proceeding toward equilibrium at a constant temperature and pressure, ΔG is the change in free energy, ΔH is the change in enthalpy or the heat content, T is the absolute temperature, and ΔS is the change in entropy. If ΔG of a reaction is equal to zero, the process is at equilibrium and there is no net flow in either direction. Furthermore, any process that exhibits a negative ΔG (free-energy change) proceeds spontaneously toward equilibrium in the direction written, in part, due to an increase in entropy or disorder in the system. Such a process releases energy and is **exergonic**. A process that exhibits a positive ΔG will proceed spontaneously in the reverse direction written. Energy from some other source must be applied to allow it to proceed toward equilibrium. This process is termed **endergonic**. Note that the sign and value of ΔG do not predict how fast the reaction will go.

The rate of a given reaction depends on the free energy of activation but not on the magnitude of ΔG. In addition, the change in free energy in a biochemical process is the same regardless of the path or mechanism used to attain the final state. The change in free energy for a chemical reaction is related to the equilibrium constant. For example, a reaction may be described as

$$A + B \rightleftharpoons C + D$$

with the equilibrium constant expressed as

$$K_{eq} = [C][D]/[A][B]$$

Under standard conditions, when reactants and products are initially present at 1-M concentrations, at 1-Atm pressure and 1 M $[H^+]$ or pH 0, the standard free-energy change is defined as ΔG^0. Biochemists have modified this expression so that the standard free energy is calculated at pH 7.0 ($[H^+] = 10^{-7}$ M) where biological reactions generally occur. Under these conditions the change in free energy is expressed as $\Delta G^{0'}$ and K'_{eq}. Since the value of $\Delta G^{0'}$ is zero at equilibrium, the following relationship is described:

$$\Delta G^{0'} = -RT \ln K'_{eq}$$

where R is the gas constant, which is 1.987 cal/mol × °K, or 8.134 J/mol × °K, depending on whether the resultant free-energy change is expressed in calories (cal) or joules (J) per mole, and T is the absolute temperature in degrees Kelvin (K).

Hence, if the **equilibrium constant** is determined, the standard free-energy change ($\Delta G^{0'}$) also can be calculated. The relationship between $\Delta G^{0'}$ and K'_{eq} is illustrated in Table 14.1. When the equilibrium constant is less than 1, the reaction is endergonic and $\Delta G^{0'}$ is positive. When the equilibrium constant is greater than 1, the reaction is exergonic and $\Delta G^{0'}$ is negative.

As discussed, $\Delta G^{0'}$ of a reaction represents the free energy available in a reaction when substrates and products are present at 1 M concentrations. This situation does not occur in

TABLE 14.1 • Values of K_{eq} and $\Delta G^{0'}$

K_{eq}	$\Delta G^{0'}$ (kcal/mol)	$\Delta G^{0'}$ (kJ/mol)
10^{-4}	5.46	22.8
10^{-3}	4.09	17.1
10^{-2}	2.73	11.4
10^{-1}	1.36	5.7
1	0	0
10	−1.36	−5.7
10^{2}	−2.73	−11.4
10^{3}	−4.09	−17.1
10^{4}	−5.46	−22.8

cells, as biomolecules are rarely present at 1 M concentration. Hence, an expression related to actual intracellular concentrations of substrates and products provides insight into work available in a reaction. The expression for ΔG at any concentration of substrate or product includes the energy change for a 1 M concentration of substrate and product to reach equilibrium ($\Delta G^{0'}$) and the energy change to reach a 1 M concentration of substrates and products.

$$\Delta G = \Delta G^{0'} + RT\ln([C][D]/[A][B])$$

For example, in a muscle cell the concentration of ATP = 8.1 mM, of ADP = 0.93 mM, and of P_i = 8.1 mM. If $\Delta G^{0'}$ for the reaction: ATP + HOH ↔ ADP + P_i is 32.1 kJ/mol at 37°C, pH 7.4, then the overall ΔG for the reaction is

$$\Delta G = \Delta G^{0'} + RT\ln([ADP][P_i]/[ATP])$$

$$\Delta G = \Delta G^{0'} + RT\ln(0.93 \times 10^{-3})$$

$$\Delta G = -32.1 \text{ kJ/mol} + (-17.5 \text{ kJ/mol}) = -49.6 \text{ kJ/mol}$$

These calculations demonstrate that considerably more free energy is available to perform work in a muscle cell than indicated by the value of $\Delta G^{0'}$. Moreover, synthesis of ATP in muscle cells under these conditions, the reverse reaction, would require +50.1 kJ/mol of energy.

In energy-producing and energy-utilizing metabolic pathways, free-energy changes of individual enzymatic reactions are additive, for example,

$$A \rightarrow B \rightarrow C \rightarrow D$$

$$\Delta G^{0'}_{A\rightarrow D} = \Delta G^{0'}_{A\rightarrow B} + \Delta G^{0'}_{B\rightarrow C} + \Delta G^{0'}_{C\rightarrow D}$$

Although any given enzymatic reaction in a sequence may have a positive free-energy change, as long as the sum of all free-energy changes is negative, the pathway will proceed. Another way of expressing this principle is that enzymatic reactions with positive free-energy changes may be coupled to or driven by reactions with negative free-energy changes. In a metabolic pathway such as glycolysis, various reactions either have positive $\Delta G^{0'}$ values or $\Delta G^{0'}$ values close to zero, whereas other reactions have large and negative $\Delta G^{0'}$ values, which drive the entire pathway. The crucial consideration is that the sum of $\Delta G^{0'}$ values of all reactions in a pathway must be negative in order for such a pathway to be thermodynamically feasible. As for all chemical reactions, individual enzymatic reactions in a metabolic pathway or the pathway as a whole would be facilitated if the concentrations of reactants (substrates) exceed those of products.

Caloric Value of Dietary Components

During complete stepwise oxidation of glucose, a primary metabolic fuel in cells, a large quantity of energy is made available. This is illustrated in the equation

$$C_6H_{12}O_6 + 6\,O_2 \rightarrow 6\,CO_2 + 6\,H_2O;\ \Delta G^{0'} = -2864 \text{ kJ/mol } (-684 \text{ kcal/mol})$$

When this process occurs under aerobic conditions in most cells, it is possible to conserve approximately one-half of this "available" energy as 38 molecules of ATP. The caloric values for oxidation of other metabolic fuels are listed in Table 14.2. Carbohydrates and proteins (amino acids) have a caloric value of 12–16 kJ/g, while lipid (i.e., palmitate, a long-chain

TABLE 14.2 • Free-Energy Changes and Caloric Values for Total Metabolism of Various Metabolic Fuels

Compound	*Molecular Weight*	$\Delta G^{0'}$ *kJ/mol*	$\Delta G^{0'}$ *kcal/mol*	*Caloric Values kJ/g*	*Caloric Values kcal/g*
Glucose	180	−2,864	−684	15.9	3.81
Lactate	90	−1,361	−325	15.1	3.62
Palmitate	256	−9,987	−2,393	38.8	9.30
Tripalmitin	809	−31,772	−7,612	38.8	9.30
Glycine	75	−976	−233	13.0	3.12

(*b*) **Pyrophosphate**

Figure 14.5 (*a*) Resonance forms of phosphate. (*b*) Structure of pyrophosphate.

fatty acid, or a triacylglycerol) has a value nearly three times greater. The reason that more energy is derived from lipid than from carbohydrate or protein relates to the average oxidation state of carbon atoms in these substances. Carbon atoms in carbohydrates are considerably more oxidized (or less reduced) than those in lipids (see Figure 14.3). Hence during sequential breakdown of lipid many more reducing equivalents (a reducing equivalent is defined as a proton plus an electron, i.e., $H^+ + e^-$) can be extracted than from carbohydrate.

Compounds Are Classified on the Basis of Energy Released on Hydrolysis of Specific Groups

The two terminal phosphoryl groups of ATP are high-energy bonds, since free energy of hydrolysis of a phosphoanhydride bond is much greater than that of a simple phosphate ester. High-energy is not synonymous with stability of the chemical bond in question, nor does it refer to the energy required to break such a bond. The concept of high-energy compounds implies that products of their hydrolytic cleavage are in more stable forms than the original compound. As a rule, phosphate esters (low-energy compounds) exhibit negative $\Delta G^{0'}$ values of hydrolysis of 42 kJ/mol, whereas high-energy bonds have negative $\Delta G^{0'}$ values of 21−63 kJ/mol. Phosphate esters such as glucose 6-phosphate and glycerol 3-phosphate are low-energy compounds.

There are various reasons why certain compounds or bonding arrangements are energy rich. First, products of hydrolysis of an energy-rich bond may exist in more **resonance forms** than the precursor molecule. The more possible resonance forms in which a molecule can exist stabilize that molecule. The resonance forms for inorganic phosphate (P_i) are indicated in Figure 14.5. Fewer resonance forms can be written for ATP or pyrophosphate (PP_i) than for phosphate (P_i).

Second, many high-energy bonding arrangements contain groups of similar electrostatic charges located in close proximity to each other. Like charges repel one another, and consequently hydrolysis of highly charged energy-rich bonds alleviates this situation and lends stability to products of hydrolysis. Third, hydrolysis of certain energy-rich bonds results in formation of an unstable compound, which may isomerize spontaneously to form a more stable compound. Hydrolysis of phosphoenolpyruvate is an example of this type of compound (Figure 14.6). The $\Delta G^{0'}$ is considerable for isomerization, and the final product, in this case pyruvate, is much more stable. Finally, if a product of hydrolysis of a high-energy bond is an undissociated acid, dissociation of the proton and its subsequent buffering may contribute to the overall $\Delta G^{0'}$ of the hydrolytic reaction. In general, any property or process that stabilizes products of hydrolysis tends to confer a high-energy character to that compound. The high-energy character of **3′,5′-cyclic adenosine monophosphate (cAMP)** has been attributed to the fact that its phosphodiester bond is strained as it bridges the 3′ and 5′ positions on ribose. The energy-rich character of thiol ester compounds such as **acetyl CoA** or succinyl CoA results from the relatively acidic character of the thiol group. Hence, the thioester bond of acetyl CoA is nearly equivalent in energy to a phosphoanhydride bond.

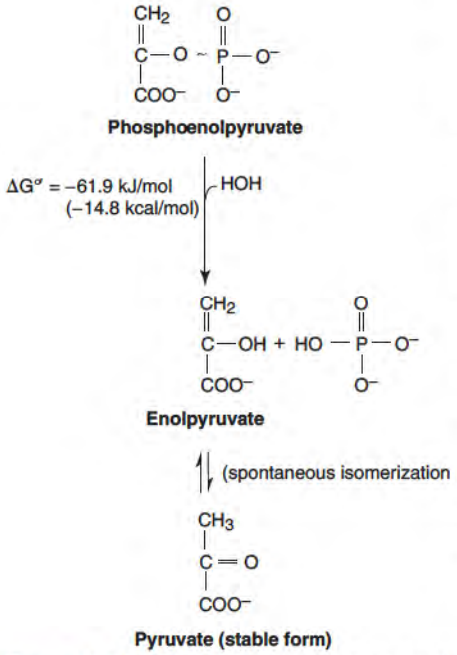

Figure 14.6 Hydrolysis of phosphoenolpyruvate indicating the free energy released.

Free-Energy Changes Can Be Determined from Coupled Enzyme Reactions

The $\Delta G^{0'}$ value of hydrolysis of the terminal phosphate of ATP is difficult to determine simply because the K_{eq} of the reaction is far to the right.

$$ATP + HOH \rightleftharpoons ADP + P_i + H^+$$

However, $\Delta G^{0'}$ of hydrolysis of ATP is determined indirectly because of the additive nature of free-energy changes discussed above. Hence, free energy of hydrolysis of ATP is determined by adding $\Delta G^{0'}$ of an ATP-utilizing reaction such as hexokinase to $\Delta G^{0'}$ of a reaction that cleaves phosphate from the product of the hexokinase reaction, glucose 6-phosphate (G6P), as indicated here.

$$\text{Glucose} + ATP \xrightarrow{\text{hexokinase}} G6P + ADP + H^+ \quad \Delta G^{0'} = -16 \text{ kJ/mol}$$

$$G6P + HOH \xrightarrow{\text{glucose 6-phosphatase}} ADP + P_i + H^+ \quad \Delta G^{0'} = -14 \text{ kJ/mol}$$

Free energies of hydrolysis for other energy-rich compounds are determined in a similar fashion.

High-Energy Bond Energies of Various Groups Can Be Transferred from One Compound to Another

Energy-rich compounds can transfer various groups to an acceptor compound in a thermodynamically feasible fashion in the presence of an appropriate enzyme. The energy-rich intermediates of glycolysis, 1,3-bisphosphoglycerate and phosphoenolpyruvate, can transfer their high-energy phosphate moieties to ADP in the phosphoglycerate kinase and pyruvate kinase reactions, respectively (Figure 14.7). The $\Delta G^{0'}$ values of these reactions are −18.8 and −31.3 kJ/mol, respectively, and hence transfer of "high-energy" phosphate is thermodynamically possible, and ATP synthesis is the result. ATP can transfer its terminal phosphoryl group to form a compound of relatively similar high-energy character (i.e., creatine phosphate in the creatine kinase reaction [Figure 14.7]) or compounds of considerably lower energy, such

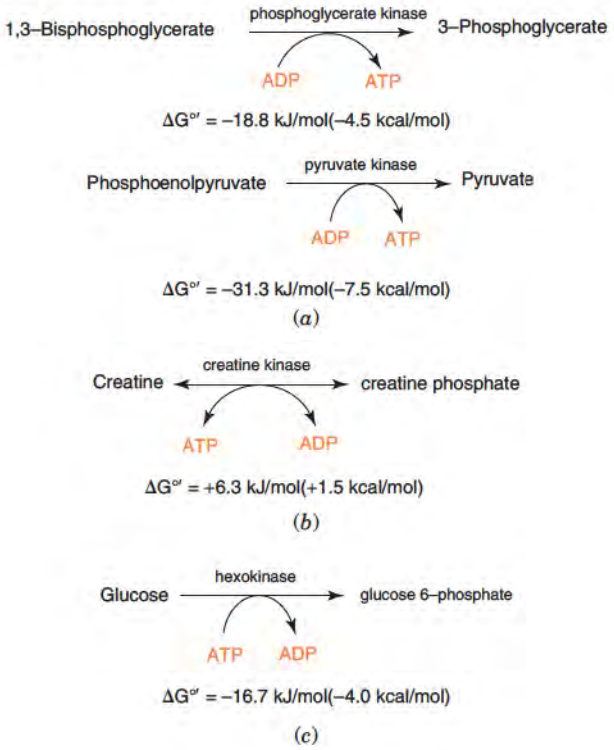

Figure 14.7 Examples of reactions involved in transfer of "high-energy" phosphate.

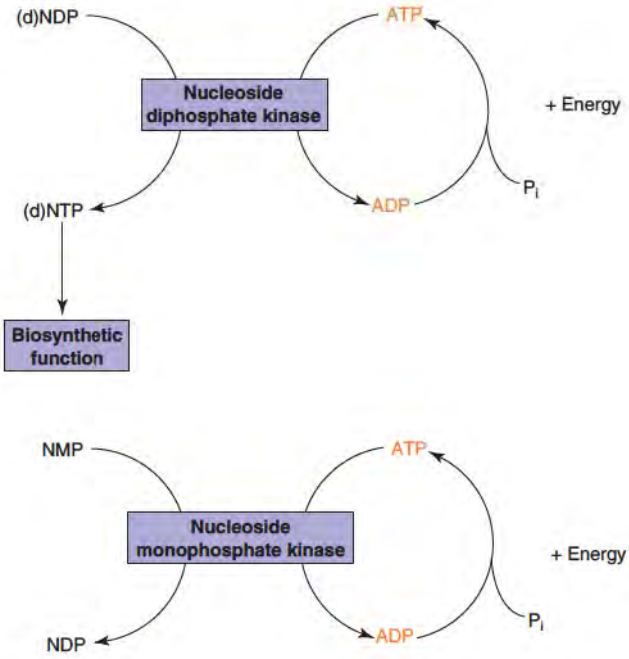

Figure 14.8 Nucleoside diphosphate kinase and nucleoside monophosphate kinase reactions. *N* represents any purine or pyrimidine base; (d) indicates a deoxyribonucleotide.

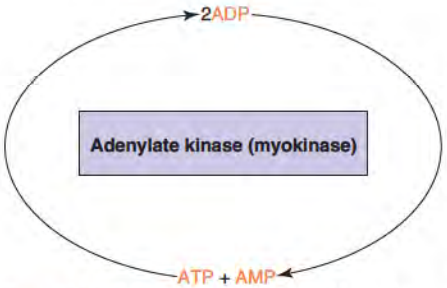

Figure 14.9 Adenylate kinase (myokinase) reaction.

as glucose 6-phosphate in the hexokinase reaction (Figure 14.7). Such transfers are crucial in linking energy-producing and energy-utilizing metabolic pathways in living cells.

Although adenine nucleotides are mainly involved in energy generation or conservation, various nucleoside triphosphates, including ATP, are involved in energy transfer in biosynthetic pathways. The guanine nucleotide GTP is the source of energy in gluconeogenesis and protein synthesis, whereas UTP (uracil) and CTP (cytosine) are utilized in glycogen and lipid synthesis, respectively (see p. 27 for structures). The energy in the phosphate bonds of ATP may be transferred to other nucleotides by nucleoside diphosphate kinase or nucleoside monophosphate kinase (Figure 14.8). Two nucleoside diphosphates are converted to a nucleoside triphosphate and a nucleoside monophosphate in various nucleoside monophosphate kinase reactions, such as that of adenylate kinase (Figure 14.9). Thus, the terminal energy-rich phosphate bond of ATP may be transferred to appropriate nucleotides and utilized in a variety of biosynthetic processes.

14.3 • SOURCES AND FATES OF ACETYL COENZYME A

The acetate group that serves as the source of fuel for the **tricarboxylic acid (TCA)** cycle is derived from the major energy-generating metabolic pathways of cells. These include oxidation of long-chain fatty acids by β-oxidation, breakdown of ingested or stored carbohydrate by **glycolysis**, oxidation of the **ketone bodies (acetoacetate** and **β-hydroxybutyrate)**, oxidation of ethanol, and oxidative breakdown of certain amino acids (Figure 14.10). All of these eventually result in production of the two-carbon unit **acetyl coenzyme A**. Coenzyme A (CoA or CoASH), consists of β-mercaptoethylamine, the vitamin **pantothenic acid**, and the adenine nucleotide, adenosine 3′-phosphate 5′-diphosphate (Figure 14.11). In cells, coenzyme A exists as the reduced thiol (CoASH), which forms high-energy thioester bonds with acyl groups and is involved in acyl group transfer reactions in which CoA serves as acceptor, then donor, of the acyl group. Various metabolic pathways involve only acyl CoA derivatives, for example, β-oxidation of fatty acids and branched-chain amino acid degradation. Because CoA is a large, hydrophilic molecule, it and its derivatives such as acetyl CoA, are not freely transported across cellular membranes. This has necessitated evolution of certain transport or shuttle mechanisms by which various intermediates or groups are

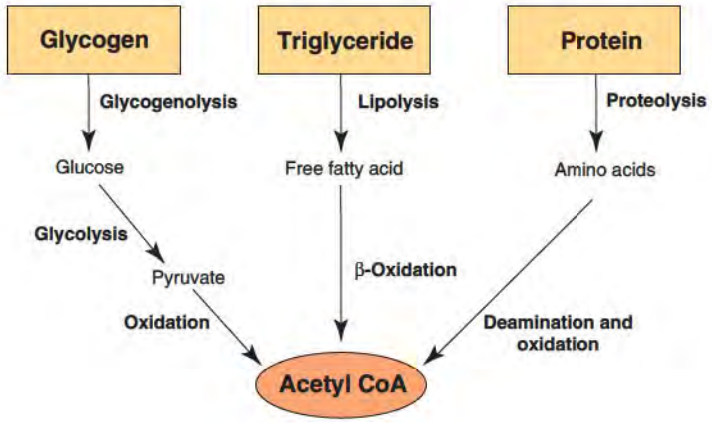

Figure 14.10 General precursors of acetyl CoA. Carbohydrates, lipids, and proteins are broken down to form acetyl CoA.

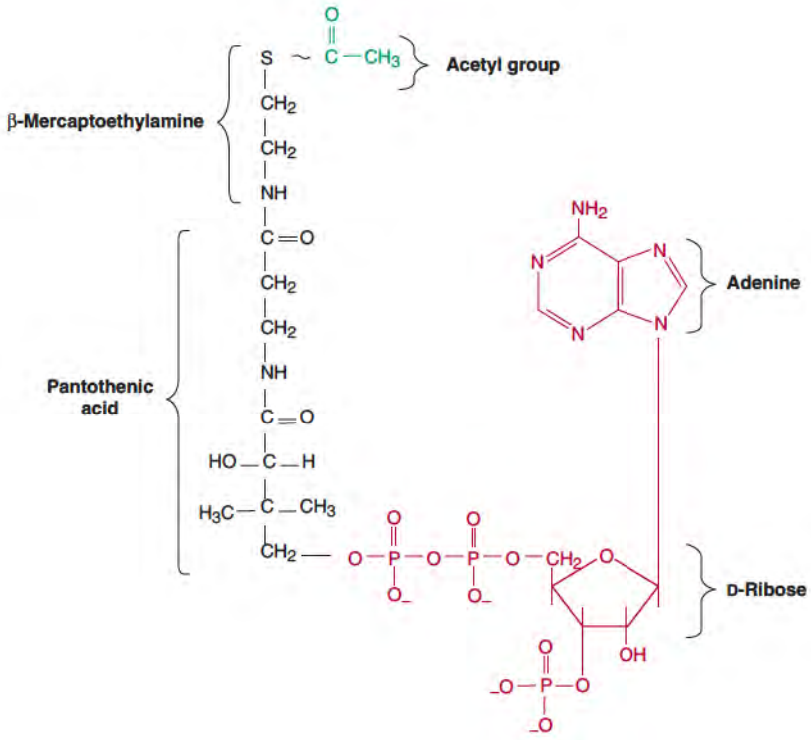

Figure 14.11 Structure of acetyl CoA. Note the presence of pantothenic acid, one of the B vitamins essential for humans.

transferred across membranes. Such acyl transferase reactions for acetyl groups and long-chain acyl groups will be discussed in Chapter 16. Since the thiol ester bond in acyl CoA derivatives is an energy-rich bond, these compounds are effective donors of acyl groups in acyl transferase reactions. To synthesize an acyl CoA derivative, two high-energy bonds of ATP must be expended, such as in the **acetate thiokinase** reaction

$$\text{Acetate} + \text{CoASH} + \text{ATP} \xrightarrow{\text{acetate kinase}} \text{acetyl CoA} + \text{AMP} + \text{PP}_i$$

Metabolic Sources and Fates of Pyruvate

During aerobic glycolysis (p. 592), glucose or other hexoses are converted to pyruvate, the end product of this cytosolic pathway. Pyruvate is also formed in degradation of amino acids such as alanine or serine and has several fates depending on the tissue and its metabolic state. The fates of pyruvate and types of reactions in which it participates are indicated in Figure 14.12. The oxidative decarboxylation of pyruvate in the **pyruvate dehydrogenase** reaction is discussed next; see page 753 for a discussion of other reactions involving pyruvate.

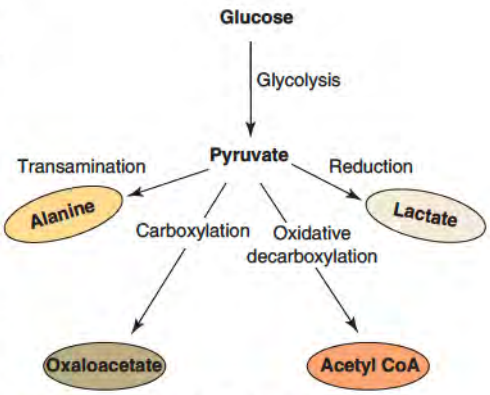

Figure 14.12 Metabolic fates of pyruvate. Pyruvate is at a crossroads of metabolism. It can be converted to lactate, alanine, oxaloacetate, or acetyl CoA depending on the needs of the cell.

TABLE 14.3 • Pyruvate Dehydrogenase Complex of Mammals

Enzyme	*Number of Subunits*	*Prosthetic Group*	*Reaction Catalyzed*
Pyruvate dehydrogenase	20 or 30	TPP	Oxidative decarboxylation of pyruvate
Dihydrolipoyl transacetylase	60	Lipoamide	Transfer of the acetyl group to CoA
Dihydrolipoyl dehydrogenase	6	FAD	Regeneration of the oxidized form of lipoamide and transfer of electrons to NAD

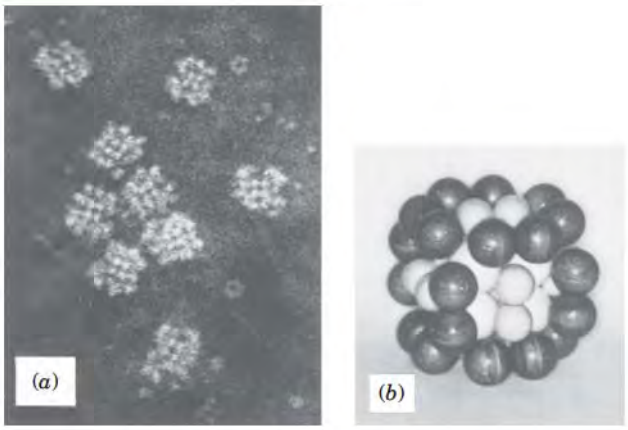

Figure 14.13 Pyruvate dehydrogenase complex from *E. coli*. (*a*) Electron micrograph. (*b*) Molecular model. Pyruvate Dehydrogenase Is a Multienzyme Complex

Pyruvate is converted to acetyl CoA by the pyruvate dehydrogenase multienzyme complex

$$\text{Pyruvate} + \text{NAD}^+ + \text{CoASH} \longrightarrow \text{acetyl CoA} + \text{CO}_2 + \text{NADH} + \text{H}^+$$

$$\Delta G^{0'} = -33.4 \text{ kJ/mol}$$

The mechanism of this reaction is more complex than might be inferred from the overall stoichiometry. Three of the cofactors, **thiamin pyrophosphate** (TPP), **lipoamide**, and **flavin adenine dinucleotide** (FAD) are bound to subunits of the complex. The reaction has a $\Delta G^{0'}$ of −33.4 kJ/mol and hence is irreversible under physiological conditions. The mammalian pyruvate dehydrogenase complex contains three types of catalytic subunits associated in a multienzyme complex of mass 7 to 8.5 × 10^6 kDa for the complex from kidney, heart, or liver. The catalytic subunits and their associated cofactors are presented in Table 14.3.The arrangement of the catalytic subunits of pyruvate dehydrogenase (Figure 14.13) in a multiprotein complex provides for greater efficiency in the overall reaction as the intermediates are tightly bound to the subunits and are not released into the surrounding medium.

The mechanism of the reaction is illustrated in Figure 14.14. The functional group of TPP participates in the formation of a covalent intermediate. Lipoic acid is linked by an amide bond with a lysine on each transacetylase subunit and is called lipoamide, while FAD is tightly bound to each dihydrolipoyl dehydrogenase subunit. The structure of FAD is presented in Figure 10.33 (p. 392).

Pyruvate Dehydrogenase Is Strictly Regulated

The pyruvate dehydrogenase complex is regulated in two ways. First, two products of the reaction, acetyl CoA and NADH, inhibit the complex in a competitive fashion, as feedback inhibitors. Second, the pyruvate dehydrogenase complex undergoes phosphorylation and dephosphorylation. The complex is active when dephosphorylated and inactive when phosphorylated. Inactivation is accomplished by a Mg^{2+}-ATP-dependent **protein kinase**, which is tightly associated with the complex. Activation is accomplished by a **phosphoprotein phosphatase**, which is also associated with the complex and functions in a Mg^{2+}- and

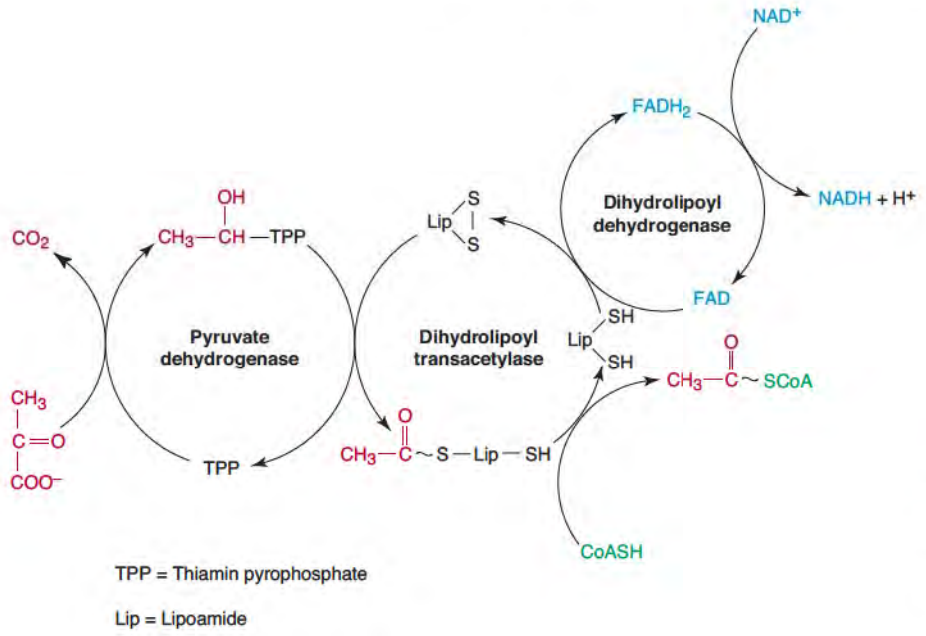

Figure 14.14 Mechanism of the pyruvate dehydrogenase multienzyme complex. Pyruvate dehydrogenase catalyzes oxidative decarboxylation of pyruvate and transfer of the acetyl group first to lipoamide. Dihydrolipoyl transacetylase transfers the acetyl group from lipoamide to coenzyme A. Dihydrolipoyl dehydrogenase oxidizes reduced lipoamide.

Ca^{2+}-dependent manner. The differential regulation of the pyruvate dehydrogenase kinase and phosphatase is the key to the overall regulation of the complex. Products of the enzyme stimulate the protein kinase reaction, leading to an inactivation of the complex (Figure 14.15). Activity of the complex is stimulated by Mg^{2+} and Ca^{2+}, a potent activator of the protein phosphatase. These effects of Ca^{2+} may play an important role in skeletal muscle where the release of Ca^{2+} during contraction should activate the protein phosphatase stimulating the oxidation of pyruvate and hence energy production. Finally, administration of insulin activates pyruvate dehydrogenase in adipose tissue, and catecholamines, such as epinephrine, activate pyruvate dehydrogenase in cardiac tissue (Clin. Corr. 14.1).

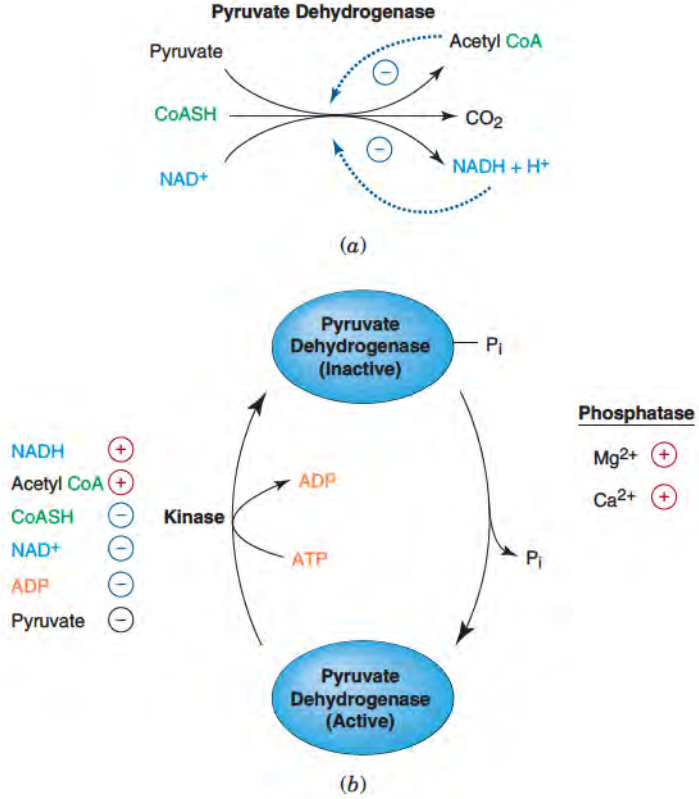

Figure 14.15 Regulation of the pyruvate dehydrogenase multienzyme complex. (*a*) Pyruvate dehydrogenase is inhibited by its products, acetylCoA, and NADH. (*b*) Pyruvate dehydrogenase is also inactivated by phosphorylation and activated by dephosphorylation. The phosphatase is stimulated by Mg^{2+} and Ca^{2+} ions. The kinase is stimulated by ATP, NADH, and acetylCoA and inhibited by CoASH, NAD^+, and ADP.

CLINICAL CORRELATION 14.1

Pyruvate Dehydrogenase Deficiency

A variety of disorders of pyruvate metabolism have been detected in children. Some involve deficiency of the catalytic or regulatory subunits of the pyruvate dehydrogenase complex. Children with pyruvate dehydrogenase deficiency usually exhibit elevated serum levels of lactate, pyruvate, and alanine, which produce a chronic lactic acidosis. They frequently exhibit severe neurological defects, which generally result in death. The diagnosis of pyruvate dehydrogenase deficiency is usually made by assaying the enzyme complex and/or its enzymatic subunits in cultures of skin fibroblasts taken from the patient. Some patients respond to dietary management in which a diet low in carbohydrates is administered. Patients may be in shock from lactic acidosis since decreased delivery of O_2 inhibits pyruvate dehydrogenase and increases anaerobic metabolism. Some patients have been treated with dichloroacetate, an inhibitor of the protein kinase subunit of the pyruvate dehydrogenase complex. Complete inhibition of the kinase, which inhibits the enzyme, will therefore activate the enzyme complex.

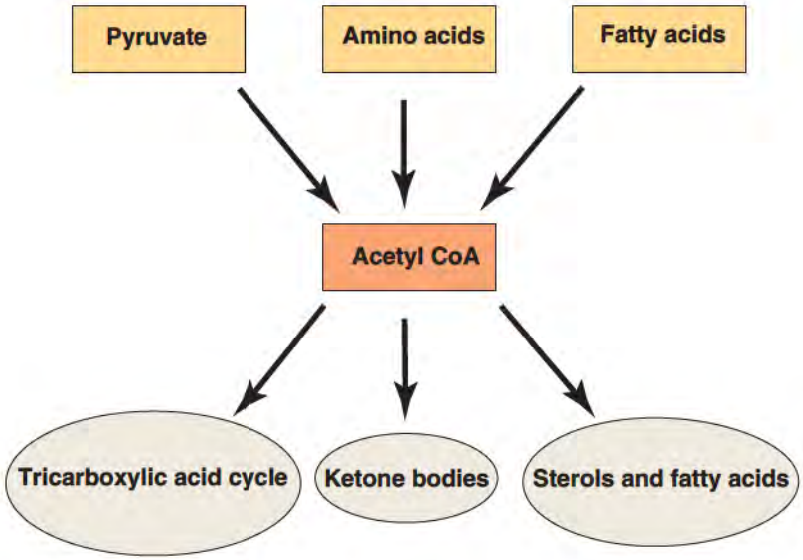

Figure 14.16 Sources and fates of acetylCoA.

Acetyl CoA Is Used in Several Different Pathways

Fates of acetyl CoA generated in the mitochondrial matrix include (1) complete oxidation of the acetyl group in the TCA cycle for energy generation; (2) conversion of excess acetyl CoA into the **ketone bodies**, acetoacetate and β-hydroxybutyrate in **liver**; and (3) transfer of acetyl units as citrate to the cytosol with subsequent synthesis of long-chain fatty acids (p. 680) and sterols (Figure 14.16).

14.4 • THE TRICARBOXYLIC ACID CYCLE

Acetyl CoA produced in the energy-generating catabolic pathways of most cells is completely oxidized to CO_2 in a cycle of reactions termed the **tricarboxylic acid (TCA) cycle**. This cycle is also called the **citric acid cycle** or the **Krebs cycle** after Sir Hans Krebs who postulated its essential features in 1937. The primary location of enzymes of the TCA cycle is in mitochondria, although isozymes of some enzymes are present in the cytosol. This location is appropriate as the pyruvate dehydrogenase complex and the fatty acid β-oxidation sequence, the two primary sources of acetyl CoA, are also located in mitochondria. Four reactions of the TCA cycle transfer electrons to either NAD^+ or FAD. The resulting NADH or $FADH_2$ is then oxidized by the mitochondrial **electron transport chain** (the **electron transfer chain** or **respiratory chain**) to generate energy that is used to form ATP by **oxidative phosphorylation**

(p. 572). The enzymes of the electron transport chain and those involved in ATP synthesis are exclusively localized in mitochondria. Figure 14.17 is an overview of the reactions of the TCA cycle. In the first step, the acetyl moiety of acetyl CoA is condensed with oxaloacetate (a 4-carbon dicarboxylic acid) to form citrate (a 6-carbon tricarboxylic acid). After rearrangement of the carbons of citrate, two oxidative decarboxylation reactions produce two molecules of CO_2, two molecules of NADH + H^+, one molecule of succinate (a 4-carbon dicarboxylic acid), and a high-energy bond in GTP. Two more oxidations produce another NADH + H^+ plus one $FADH_2$ and regenerate oxaloacetate.

In summary, the substrate of the TCA cycle is the two-carbon unit acetyl CoA and the products of a complete turn of the cycle are two CO_2, one high-energy phosphate bond (as GTP), three NADH, and one $FADH_2$. The NADH and $FADH_2$ are subsequently oxidized by the electron transport chain with the production of nine ATPs (see p. 573 for yields of ATP during oxidation of the coenzymes). Hence, 10 ATPs or its equivalent (GTP) are produced during oxidation of one acetate by the TCA cycle.

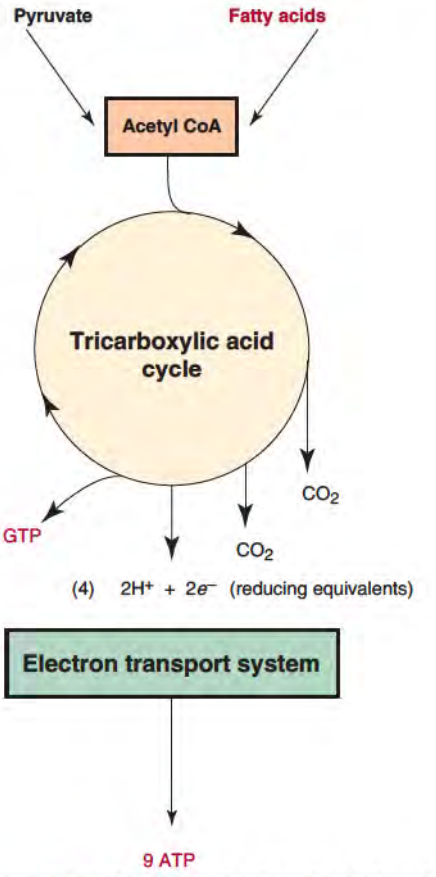

Figure 14.17 General description of oxidation of foodstuffs to provide energy for ATP synthesis within mitochondria. Acetyl CoA produced by oxidation of pyruvate and fatty acids is metabolized by the tricarboxylic acid cycle to reducing equivalents, which are oxidized by the electron transport system. Energy released during the oxidative process is used to drive synthesis of ATP.

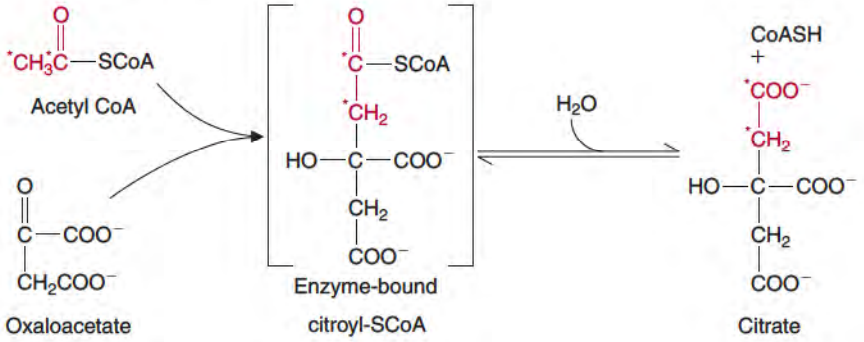
Reactions of the Tricarboxylic Acid Cycle

The individual reactions of the TCA cycle are presented in Figure 14.18. The initial step of the cycle is catalyzed by **citrate synthase**, in the mitochondrial matrix. This highly exergonic reaction commits acetyl groups to **citrate** formation and complete oxidation in the cycle. As shown below citrate synthase condenses an acetyl moiety to the α-keto carbon of the dicarboxylic acid **oxaloacetate**. The citroyl-SCoA intermediate remains bound to the catalytic site on citrate synthase.



CITRATE SYNTHASE

The equilibrium of this reaction is far toward citrate formation with a $\Delta G^{0'}$ near −38 kJ/mol. Note that the intramitochondrial concentration of oxaloacetate is very low (less than 1 μM); however, the strong, negative $\Delta G^{0'}$ drives the reaction forward. The low concentration of oxaloacetate, which is below the K_m of the reaction, may also be a major factor controlling this reaction.

Citrate is converted to **isocitrate** in a reversible reaction catalyzed by **aconitase** in which the hydroxyl group of citrate is exchanged for a H atom on an adjacent carbon. The hydroxyl group is thus located next to the carboxyl group of isocitrate where oxidative decarboxylation can occur. Conversion of citrate to isocitrate occurs on aconitase without release of the intermediate **cis-aconitate**. Aconitase contains a nonheme iron–sulfur cluster that is involved in the catalytic mechanism. The overall equilibrium of the reaction favors the formation of citrate.

Fluoroacetate is a potent inhibitor of the cycle, although it does not inhibit directly any of the enzymes of the cycle. Fluoroacetate is converted to fluorocitrate, which is a potent inhibitor of aconitase. Fluoroacetyl CoA is formed by acetyl CoA synthetase and converted to fluorocitrate by citrate synthase. Fluoroacetate is lethal in small doses and has been used as a rat poison; the LD_{50}, the lethal dose for 50% of animals consuming it, is 0.2 mg per kilogram of body weight.

Isocitrate dehydrogenase converts isocitrate to α-ketoglutarate in an oxidative decarboxylation reaction with concomitant reduction of NAD^+ to NADH + H^+. The isocitrate dehydrogenase of mammalian mitochondria requires NAD^+ as acceptor of reducing equivalents, has a mass of 380 kDa, and consists of eight identical subunits. The reaction requires a divalent metal cation (e.g., Mn^{2+} or Mg^{2+}) for removal of the β carboxylate of oxalosuccinate.

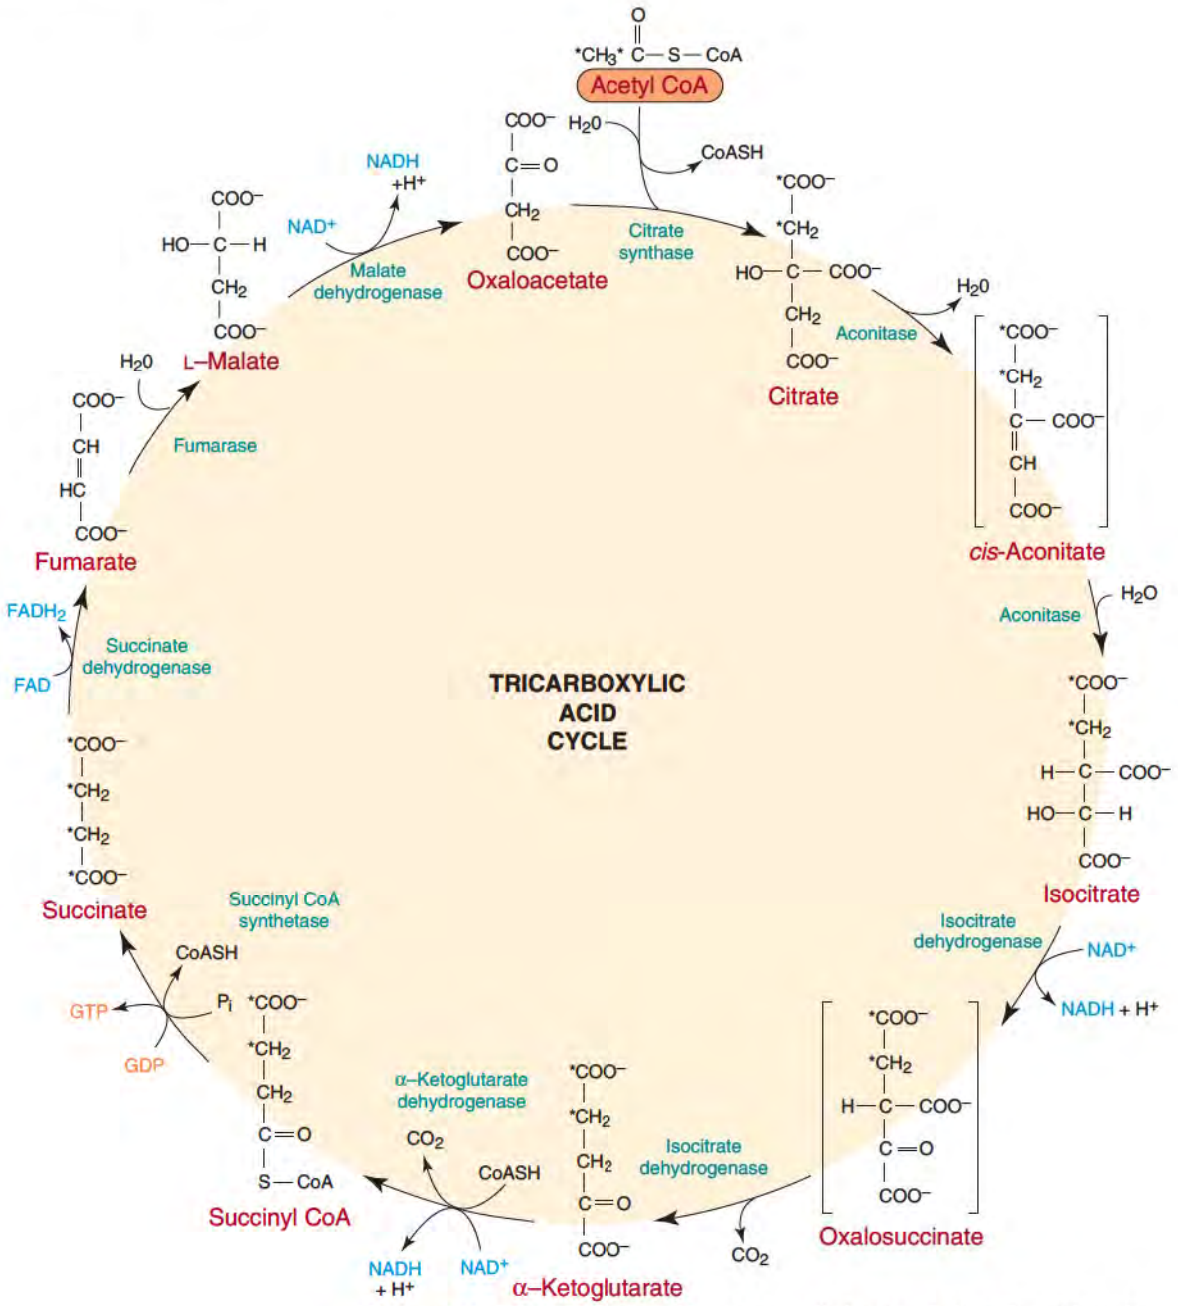


Figure 14.18 The tricarboxylic acid cycle. Asterisked carbons indicate fate of the carbons of the acetyl group.

The equilibrium of this reaction lies strongly toward α-ketoglutarate formation with a $\Delta G^{0\prime}$ of nearly −21 kJ/mol.

Mitochondria also contain an isocitrate dehydrogenase that requires $NADP^+$. The $NADP^+$-linked enzyme is also found in the cytosol, where it provides reducing equivalents for cytosolic reductive processes.

Conversion of α-ketoglutarate to succinyl CoA is catalyzed by the **α-ketoglutarate dehydrogenase** complex, which is nearly identical to the pyruvate dehydrogenase complex in terms of the individual reactions catalyzed and its structural features. Again, **thiamin pyrophosphate**, **lipoic acid**, CoASH, **FAD**, and NAD^+ participate in the catalytic mechanism. The complex consists of subunits of α-ketoglutarate dehydrogenase, **dihydrolipoyl transsuccinylase**, and dihydrolipoyl dehydrogenase. The equilibrium of the reaction lies strongly toward succinyl CoA formation with a $\Delta G^{0\prime}$ of −33 kJ/mol. In this reaction the second molecule of CO_2 and the second reducing equivalents (i.e., NADH + H^+) of the cycle are produced. The product of this reaction, **succinyl CoA**, is an energy-rich thiol ester similar to acetyl CoA.

The energy-rich character of the thiol ester linkage of succinyl CoA is conserved by **substrate-level phosphorylation** in the next step of the cycle. **Succinyl-CoA synthetase** (or **succinate thiokinase**) converts succinyl CoA to succinate and, in mammalian tissues, results in the phosphorylation of GDP to GTP. This reaction is freely reversible with a $\Delta G^{0'} = -3.0$ kJ/mol and the catalytic mechanism involves an enzyme-succinyl phosphate intermediate.

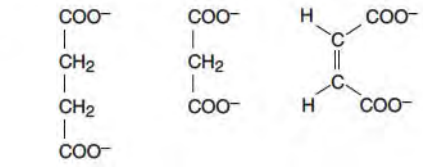
$$\text{Succinyl CoA} + P_i + \text{Enz} \rightarrow \text{Enz-succinyl phosphate} + \text{CoASH}$$

$$\text{Enz-succinyl phosphate} \rightarrow \text{Enz-phosphate} + \text{succinate}$$

$$\text{Enz-phosphate} + \text{GDP} \rightarrow \text{Enz} + \text{GTP}$$

The enzyme is phosphorylated on the 3 position of a histidine residue during the reaction; this conserves the energy of the thioester for formation of GTP. The GTP is used for the mitochondrial synthesis of protein, RNA and DNA.

Succinate is oxidized to fumarate by **succinate dehydrogenase**, a complex enzyme tightly bound to the inner mitochondrial membrane. Succinate dehydrogenase is composed of a 70-kDa subunit that contains the substrate binding site (FAD covalently bound to a histidine residue), a 30-kDa subunit that contains three **iron–sulfur centers** (**nonheme iron**), and two small hydrophobic proteins. The enzyme is a typical flavoprotein in which electrons and protons are transferred from the substrate through covalently bound FAD and the iron–sulfur centers in which the nonheme iron undergoes oxidation and reduction. The electrons are then transferred to coenzyme Q for further transport through the electron transfer chain, as will be discussed in Section 14.6. Succinate dehydrogenase is strongly inhibited by malonate and oxaloacetate and is activated by ATP, P_i, and succinate. Malonate inhibits succinate dehydrogenase competitively with respect to succinate because of the very close structural similarity between malonate and succinate (Figure 14.19).



Succinate **Malonate** **Maleate**

Figure 14.19 Structures of succinate, a TCA cycle intermediate; malonate, an inhibitor of succinate dehydrogenase, and the cycle; and maleate, a compound not involved in the cycle.

Fumarate is then hydrated to form L-malate by fumarase. **Fumarase** is a homo-tetramer (200 kDa) and is stereospecific for the trans form of substrate (the cis form, maleate, is not a substrate; (Figure 14.19). The reaction is freely reversible under physiological conditions. Clin. Corr. 14.2 describes a genetic deficiency of fumarase.

The final reaction in the cycle is catalyzed by malate dehydrogenase in which the reducing equivalents are transferred to NAD^+ to form NADH + H^+. The equilibrium of the reaction lies far toward L-malate formation with a $\Delta G^{0'} = +29$ kJ/mol. This endergonic reaction is pulled in the forward direction by the action of citrate synthase and other reactions, which remove oxaloacetate.

The NADH produced by the three NAD^+-linked dehydrogenases in the TCA cycle is oxidized rapidly to NAD^+ by the respiratory chain, thus favoring the forward direction of malate dehydrogenase.

Conversion of the Acetyl Group of Acetyl CoA to CO_2 and H_2O Conserves Energy

The TCA cycle (see Figure 14.18) is the terminal oxidative pathway for most metabolic fuels. Two-carbon moieties in the form of acetyl CoA are oxidized completely to CO_2 and H_2O, and four oxidative steps result in the formation of 3 NADH + H^+ and 1 $FADH_2$, which are used subsequently for ATP generation. Oxidation of each NADH + H^+ results in formation of 2.5 ATP by oxidative phosphorylation, whereas oxidation of $FADH_2$ formed in the succinate dehydrogenase reaction yields 1.5 ATPs. A high-energy bond is formed as GTP in the succinyl-CoA synthetase reaction. Hence the net yield of ATP or its equivalent (i.e., GTP) for the complete oxidation of an acetyl group in the TCA cycle is 10.

Tricarboxylic Acid Cycle Is a Source of Biosynthetic Intermediates

The previous discussion of the TCA cycle has concentrated on its role in the oxidative breakdown of acetyl groups to CO_2 and H_2O, formation of reduced coenzymes, and synthesis of ATP. Overall, the TCA cycle is the final common pathway for breakdown of

CLINICAL CORRELATION 14.2

Fumarase Deficiency (OMIM 606812)

Deficiency of enzymes of the TCA cycle is rare indicating the importance of this pathway for survival. Several cases, however, have been reported of severe deficiency of fumarase in mitochondria and cytosol of tissues (e.g., blood lymphocytes). The disease is characterized by severe neurological impairment, encephalomyopathy, and dystonia developing soon after birth. Urine contains abnormally high amounts of fumarate and elevated levels of succinate, α-ketoglutarate, citrate, and malate. The mitochondrial and cytosolic isozymes of fumarase are derived from a single gene. In affected patients, both parents had half-normal levels of enzyme activity but were clinically normal, as expected for an autosomal recessive disorder. The first mutation characterized in the gene for fumarase contains a glutamine substituted for a glutamate residue 319.

Bourgeron, T., Chretien, D., Poggi-Bach, J., et al. Mutation of the fumarase gene in two siblings with progressive encephalopathy and fumarase deficiency. *J. Clin. Invest.* 93:2514, 1994.

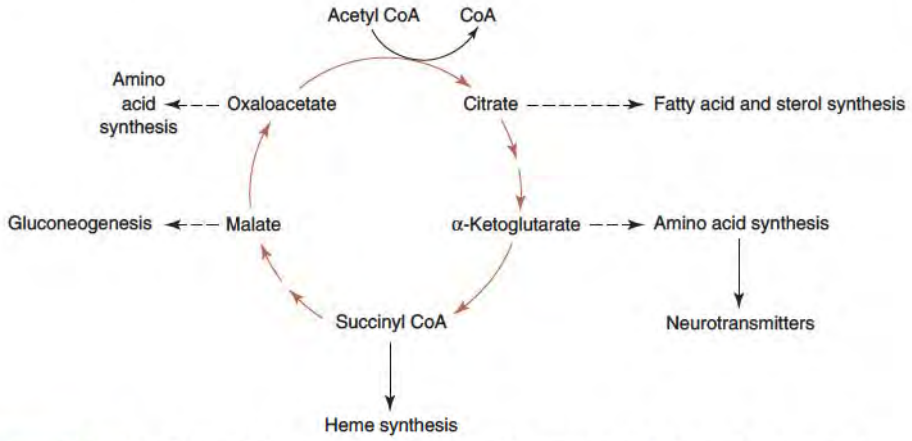


Figure 14.20 The TCA cycle is a source of precursors for amino acid, fatty acid, and glucose synthesis.

foodstuffs; however, as summarized in Figure 14.20, the four-, five- and six-carbon intermediates generated in the reactions of the TCA cycle are important intermediates in **biosynthetic processes**. Succinyl CoA, malate, oxaloacetate, α-ketoglutarate, and citrate are all precursors in the biosynthesis of important cellular compounds.

Transamination converts α-ketoglutarate to glutamate, which can leave mitochondria and be converted into several other amino acids. In nervous tissue, α-ketoglutarate is converted to the neurotransmitters, glutamate and γ-aminobutyric acid (GABA). Glutamate is also produced from α-ketoglutarate by the mitochondrial enzyme glutamate dehydrogenase in the presence of NADH or NADPH and ammonia. The amino group incorporated into glutamate can then be transferred to form various amino acids by different aminotransferases. These enzymes and the relevance of the incorporation or release of ammonia into or from α-keto acids are discussed in Chapter 19.

Succinyl CoA represents a metabolic branch point (Figure 14.21) as it may be formed either from α-ketoglutarate in the TCA cycle or from methylmalonyl CoA in the final steps in the breakdown of odd-chain-length fatty acids or the branched-chain amino acids valine

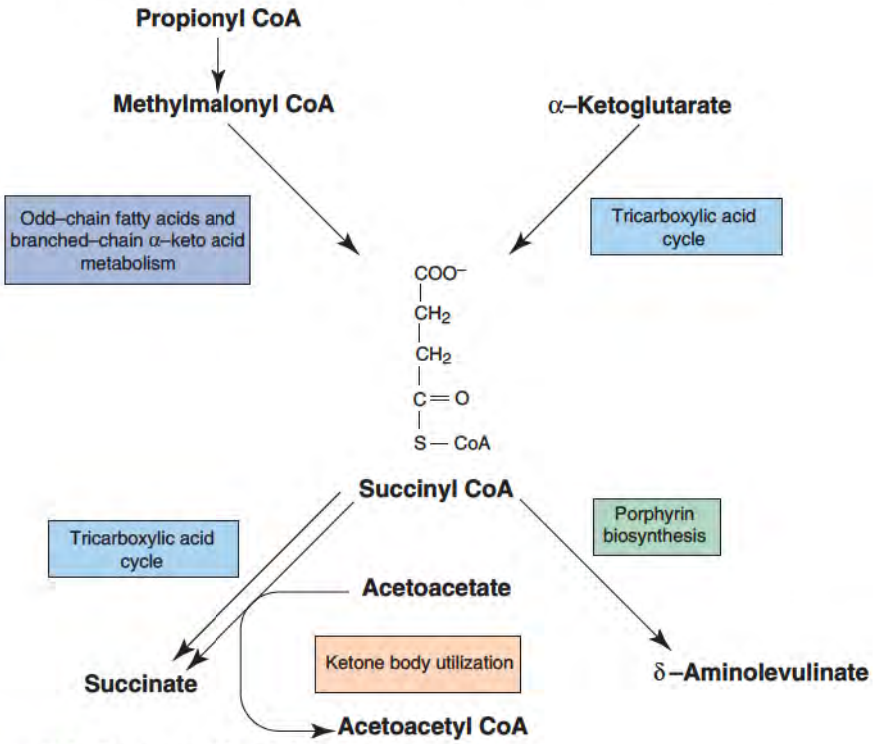

Figure 14.21 Sources and fates of succinyl CoA.

and isoleucine. Succinyl CoA may also be converted to succinate or condensed with glycine to form Δ-aminolevulinate, the initial reaction in porphyrin biosynthesis (p. 791).

Oxaloacetate is transaminated to aspartate the precursor of asparagine and of the pyrimidines cytosine, uracil, and thymine. Oxaloacetate is converted to **phosphoenolpyruvate (PEP)**, a key intermediate in **gluconeogenesis** (p. 619). Oxaloacetate cannot cross the inner mitochondrial membrane but is converted to malate, which is transported on a specific carrier out of mitochondria and oxidized to oxaloacetate, which is then converted to PEP (p. 580).

Citrate is exported from mitochondria into cytosol. **Citrate lyase** converts it to oxaloacetate and acetyl CoA, a precursor for synthesis of long-chain fatty acids and sterols. The oxaloacetate is rapidly reduced to malate, which is converted by **malic enzyme** to pyruvate and NADPH, a source of reducing equivalents for biosynthetic processes in cytosol. In addition, citrate is a regulatory effector of other metabolic pathways (p. 684).

Anaplerotic Reactions Replenish Intermediates of the Tricarboxylic Acid Cycle

In its role in catabolism, the TCA cycle oxidizes acetyl CoA with release of two CO_2 molecules. Indeed, oxaloacetate, the acceptor of the acetate group, is regenerated during the cycle. However, metabolic pathways in all tissues remove intermediates of the cycle for biosynthetic pathways. Hence, in order to maintain a functional cycle, a source of four-carbon acids is required to replenish the loss of oxaloacetate. The reactions that supply four- or five-carbon intermediates to the cycle are called **anaplerotic** (meaning "filling up") reactions (Figure 14.22). The most important is catalyzed by **pyruvate carboxylase**, which converts pyruvate and CO_2 to oxaloacetate (Figure 14.23). The enzyme contains a biotin molecule linked to the ε amino group of a lysine residue by an amide bond. The biotin binds CO_2 in the presence of ATP and Mg^{2+} ions and then transfers it to pyruvate as a carboxyl group (p. 1079). Levels of pyruvate carboxylase are high in both liver and nervous tissues, because these tissues experience a constant efflux of intermediates from the TCA cycle, which are used for gluconeogenesis in liver and neurotransmitter synthesis in nervous tissues.

Some amino acids are sources of four- or five-carbon intermediates. Glutamate is converted by glutamate dehydrogenase to α-ketoglutarate in mitochondria. Aspartate is converted to oxaloacetate by transamination, whereas valine and isoleucine are broken down to propionyl CoA that enters the TCA cycle as succinyl CoA. Amino acids derived from muscle breakdown become an important source of malate for gluconeogenesis during fasting (p. 845).

Activity of Tricarboxylic Acid Cycle Is Carefully Regulated

Various factors regulate the TCA cycle. First, the supply of acetyl units, whether derived from pyruvate (by glycolysis) or fatty acids (by β-oxidation), is crucial in determining the

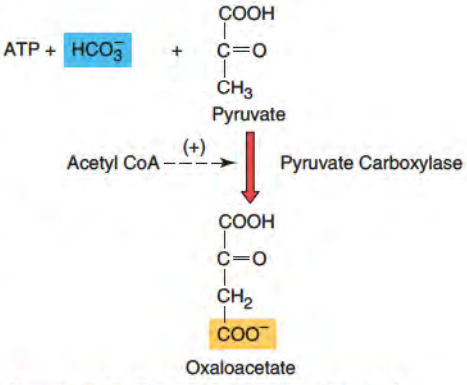

Figure 14.23 Pyruvate carboxylase reaction. Acetyl CoA is an essential activator of pyruvate carboxylase.

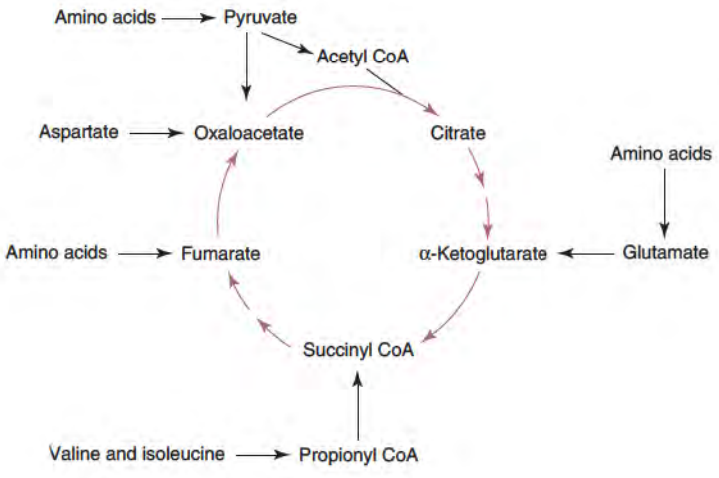

Figure 14.22 Anaplerotic reactions replenish intermediates of the TCA cycle.

rate of the cycle. Regulation of the pyruvate dehydrogenase complex, the transport of fatty acids into mitochondria, and β-oxidation of fatty acids are effective determinants of cycle activity. Second, because the dehydrogenases of the cycle are dependent on a continuous supply of NAD^+ and FAD, their activities are very stringently controlled by the respiratory chain that oxidizes NADH and $FADH_2$. As discussed in Section 14.7, the activity of the respiratory chain is coupled obligatorily to generation of ATP in reactions of oxidative phosphorylation, a regulatory process called **respiratory control**. Consequently, activity of the TCA cycle is very dependent on the rate of ATP synthesis (and hence the rate of electron transport), which is strongly affected by availability of ADP, phosphate, and O_2. Hence, an inhibitory agent or any metabolic condition that interrupts the supply of O_2, the continuous supply of ADP, or the source of reducing equivalents (e.g., substrate for the cycle) results in decreased activity of the TCA cycle. In general, these control mechanisms of the TCA cycle provide a coarse control of the cycle.

A variety of effector-mediated regulatory interactions between various intermediates or nucleotides and individual enzymes of the cycle have been postulated to exert a fine control of the cycle. Some of these effectors are shown in Figure 14.24. Note that the physiological relevance of many of these regulatory interactions has not been established.

Purified citrate synthase is inhibited by ATP, NADH, succinyl CoA, and long-chain acyl CoA derivatives; however, these effects have not been demonstrated under physiological conditions. The most probable means for regulating the citrate synthase reaction is the availability of the substrates, acetyl CoA and oxaloacetate. As discussed, very low concentrations of oxaloacetate (lower than the K_m for oxaloacetate on citrate synthase) are present in mitochondria.

The NAD^+-linked isocitrate dehydrogenase, often considered to be the key regulatory enzyme of the TCA cycle, is stimulated by Ca^{2+} ions, ADP, and AMP and is inhibited by ATP and NADH. Hence, under high-energy conditions (i.e., high ATP/ADP + P_i and high $NADH/NAD^+$ ratios), the activity of this dehydrogenase is inhibited. By contrast, during periods of low energy, the activity of this enzyme and consequently of the TCA is stimulated. Respiratory control by the electron transport chain coupled to ATP synthesis thus regulates the TCA cycle at the NAD^+-linked isocitrate dehydrogenase step by affecting levels of ADP and NAD^+.

The α-ketoglutarate dehydrogenase complex is inhibited by ATP and GTP, NADH, and succinyl CoA, whereas Ca^{2+} activates the complex in certain tissues. Unlike the pyruvate

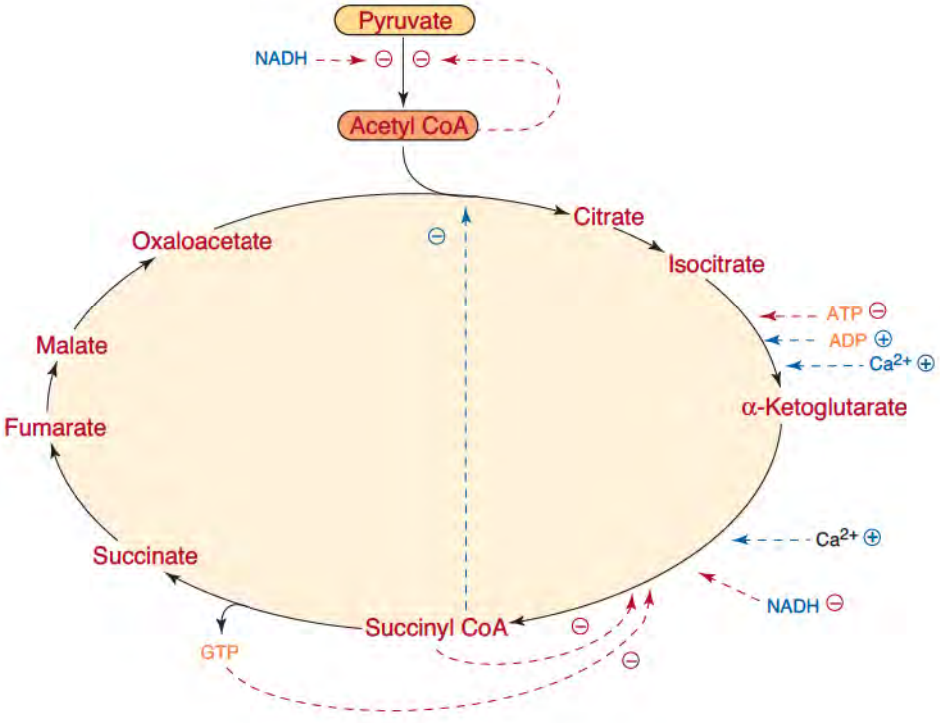

Figure 14.24 Examples of regulatory interactions in the TCA cycle.

dehydrogenase complex, the α-ketoglutarate dehydrogenase complex is not regulated by a protein-kinase-mediated phosphorylation.

The stimulation of both isocitrate and α-ketoglutarate dehydrogenases by Ca^{2+} occurs at concentrations that initiate muscle contraction and activate phosphorylase b during gycogenolysis. These effects of Ca^{2+} ensure that tension development and energy supply in muscle tissue are integrated following nerve stimulation.

14.5 • STRUCTURE AND COMPARTMENTATION BY MITOCHONDRIAL MEMBRANES

The final steps in breakdown of carbohydrates and fatty acids are located in mitochondria where energy released during oxidation of NADH and $FADH_2$ is transduced into chemical energy of ATP by the process of **oxidative phosphorylation**. Consequently, mitochondria are often called the powerhouse of the cell. The role of a tissue in aerobic metabolic functions and its need for energy is reflected in the number and activity of its mitochondria (Figure 14.25). Cardiac muscle is highly aerobic, needing a constant supply of ATP. Approximately one-half of the cytoplasmic volume of cardiac cells consists of mitochondria, which contain numerous invaginations of the inner membrane called **cristae** and, consequently, a high concentration of the enzyme complexes of the electron transport chain. The liver is also highly aerobic with each mammalian hepatocyte containing 800–2000 mitochondria. By contrast, erythrocytes contain no mitochondria and obtain energy only from glycolysis.

Mitochondria have different shapes, depending on the cell type. In Figure 14.25, mitochondria from liver are nearly spherical, whereas those found in cardiac muscle are oblong or cylindrical and contain more numerous cristae than liver mitochondria.

Winborn, Department of Anatomy, University of Texas Health Science Center at San Antonio, and the Electron Microscopy Laboratory, Department of Pathology, University of Texas Health Science Center at San Antonio.

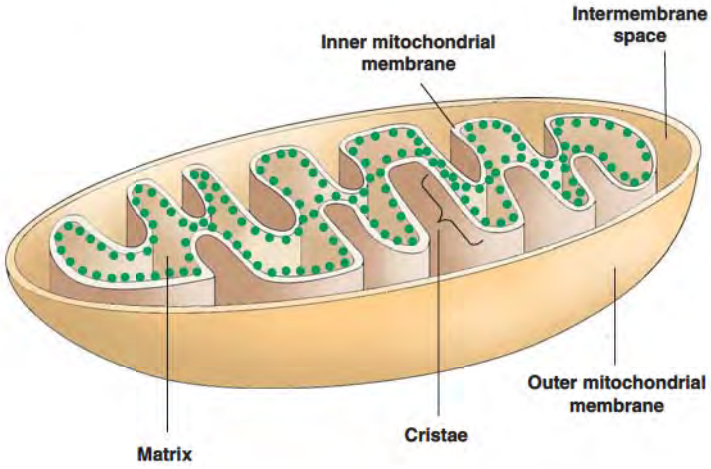

Figure 14.26 Diagram of submitochondrial compartments. Green spheres represent localization of the F_1 portion of ATP synthase on the inner mitochondrial membrane.

Inner and Outer Mitochondrial Membranes Have Different Compositions and Functions

Mitochondria contain an **outer membrane** and a structurally and functionally more complex **inner membrane** (Figure 14.26); the space between the membranes is the **intermembrane space.** Enzymes involved in transfer of energy from the γ-phosphoryl bond of ATP, such as adenylate kinase, creatine kinase, and nucleoside diphosphate kinase, are located in the intermembrane space (Table 14.4). The outer membrane consists of about 30%−40% lipid and 60%−70% protein, with relatively few enzymatic or transport proteins. It is rich in the integral membrane protein called **porin** (or **VDAC**, voltage-dependent anion channel) consisting of β-sheets, which form a channel that permits the passage through the membrane of particles of up to 10 kDa. Monoamine oxidase and kynurenine hydroxylase, of importance in nervous tissues for removal of neurotransmitters, are located on the outer surface of the outer membrane.

The inner membrane consists of 80% protein and is rich in unsaturated fatty acids. In addition, **cardiolipin** (diphosphatidylglycerol) is present in high concentrations. The enzyme complexes of electron transport and oxidative phosphorylation are located in this membrane as are various dehydrogenases and several transport systems involved in transferring substrates, metabolic intermediates, and adenine nucleotides between cytosol and matrix. The inner membrane appears to be invaginated into folds or **cristae**, which increase the surface area (Figure 14.26).

TABLE 14.4 • Enzymes of Mitochondrial Subcompartments

Outer Membrane	*Intermembrane Space*	*Inner Membrane*	*Matrix*
Monoamine oxidase	Adenylate kinase	Succinate dehydrogenase	Pyruvate dehydrogenase complex
Kynurenine hydroxylase	Nucleoside diphosphate kinase	F_1F_0 ATP synthase	Citrate synthase
Nucleoside diphosphate kinase	Creatine kinase	NADH dehydrogenase	Isocitrate dehydrogenase
Phospholipase A		β-Hydroxybutyrate dehydrogenase	α-Ketoglutarate dehydrogenase complex
Fatty acyl CoA synthetases		Cytochromes *b*, c_1, *c*, *a*, a_3	Aconitase
NADH: cytochrome *c* reductase (rotenone-insensitive)		Carnitine: acyl CoA transferase	Fumarase
			Succinyl CoA synthetase
Choline phosphotransferase		Adenine nucleotide translocase	Malate dehydrogenase
		Mono-, di-, and tricarboxylate transporters	Fatty acid β-oxidation system
			Glutamate dehydrogenase
		Glutamate–aspartate transporters	Glutamate–oxaloacetate transaminase
		Glycerol 3-phosphate dehydrogenase	Ornithine transcarbamoylase
			Carbamoyl phosphate synthetase I
			Heme synthesis enzymes

The space inside the inner membrane, the **matrix**, contains the enzymes of the TCA cycle with the exception of succinate dehydrogenase which is bound to the inner membrane, enzymes for fatty acid oxidation, and some enzymes of porphyrin (p. 791) and urea synthesis (p. 759). In addition, **mitochondrial DNA** (**mtDNA**), ribosomes, and proteins necessary for transcription of mtDNA and translation of mRNA are located in the matrix.

14.6 • ELECTRON TRANSPORT CHAIN

During the reactions of fatty acid oxidation and the TCA cycle, reducing equivalents derived from oxidation of substrates are transferred to NAD^+ and FAD (forming NADH and $FADH_2$) which are then oxidized by the **electron transport chain**, a system of electron carriers located in the inner membrane (Figure 14.27). In the presence of O_2, electron transfer chain converts reducing equivalents into utilizable energy, as ATP, by oxidative phosphorylation. The complete oxidation of NADH and $FADH_2$ by the electron transport chain produces approximately 2.5 and 1.5 mol of ATP per mole of reducing equivalent transferred to O_2, respectively.

Oxidation–Reduction Reactions

The mitochondrial electron transport consists of a sequence of linked oxidation–reduction reactions. Such reactions transfer electrons from a suitable electron donor (**reductant**) to a suitable electron acceptor (**oxidant**). In some oxidation–reduction reactions only electrons are transferred from reductant to oxidant (e.g., electron transfer between cytochromes).

$$\text{Cytochrome } c\,(Fe^{2+}) + \text{cytochrome } a\,(Fe^{3+}) \rightarrow$$
$$\text{cytochrome } c\,(Fe^{3+}) + \text{cytochrome } a\,(Fe^{2+})$$

whereas in others, both electrons and protons (hydrogen atoms) are transferred (e.g., electron transfer between NADH and FAD).

$$NADH + H^+ + FAD \rightarrow NAD^+ + FADH_2$$

An oxidant and its reductant form a **redox couple**, or pair. The ease with which an electron donor (reductant) gives up its electrons to an electron acceptor (oxidant) is expressed as the **oxidation–reduction potential** of the system. This is measured in volts as an **electromotive force** (emf) of a half-cell made up of an oxidation-reduction couple when compared to a standard reference half-cell (usually the hydrogen electrode reaction). The potential of the standard hydrogen electrode is set by convention at 0.0 V at pH 0.0; however, in biological systems where pH is 7.0, the reference hydrogen potential is −0.42 V. The potentials for a variety of important biochemical reactions are tabulated in Table 14.5. To interpret the

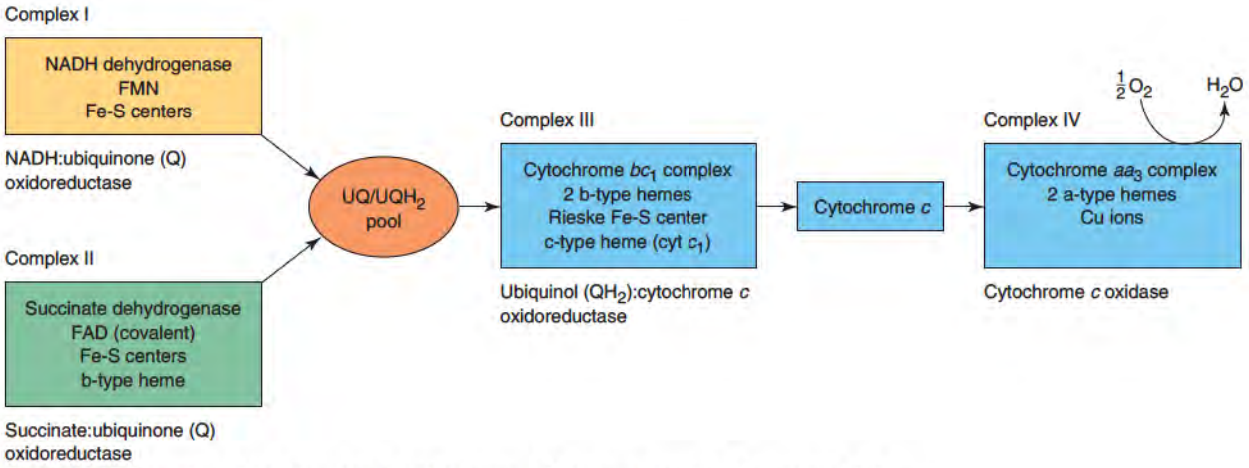

Figure 14.27 Overview of the complexes and pathways of electron transfer in mitochondrial electron transport chain.

TABLE 14.5 • Standard Oxidation–Reduction Potentials for Various Biochemical Reactions

Oxidation–Reduction System	*Standard Oxidation–Reduction Potential E_0' (V)*
Acetate + $2H^+$ + $2e^-$ $\rightleftharpoons$ acetaldehyde	−0.60
$2H^+$ + $2e^-$ $\rightleftharpoons$ H_2	−0.42
Acetoacetate + $2H^+$ + $2e^-$ $\rightleftharpoons$ β-hydroxybutyrate	−0.35
NAD^+ + $2H^+$ + $2e^-$ $\rightleftharpoons$ NADH + H^+	−0.32
Acetaldehyde + $2H^+$ + $2e^-$ $\rightleftharpoons$ ethanol	−0.20
Pyruvate + $2H^+$ + $2e^-$ $\rightleftharpoons$ lactate	−0.19
Oxaloacetate + $2H^+$ + $2e^-$ $\rightleftharpoons$ malate	−0.17
Coenzyme Q_{ox} + $2e^-$ $\rightleftharpoons$ coenzyme Q_{red}	+0.10
Cytochrome *b* (Fe^{3+}) + e^- $\rightleftharpoons$ cytochrome*b* (Fe^{2+})	+0.12
Cytochrome *c* (Fe^{3+}) + e^- $\rightleftharpoons$ cytochrome*c* (Fe^{2+})	+0.22
Cytochrome *a* (Fe^{3+}) + e^- $\rightleftharpoons$ cytochrome*a* (Fe^{2+})	+0.29
$½O_2$ + $2H^+$ + $2e^-$ $\rightleftharpoons$ H_2O	+0.82

data in the table, recall that the reductant of a redox pair with a large negative potential will give up its electrons more readily than redox pairs with smaller negative or positive potentials. Compounds with large negative potentials are strong reducing agents. By contrast, a strong oxidant (e.g., one characterized by a large positive potential) has a very high affinity for electrons and acts to oxidize compounds with more negative standard potentials.

The **Nernst equation** characterizes the relationship between standard oxidation–reduction potential of a redox pair (E_0'), observed potential (E), and ratio of concentrations of oxidant and reductant in the system.

$$E = E_0' + 2.3(RT/nf)\ \log([\text{oxidant}]/[\text{reductant}])$$

where E equals the observed potential and E_0' is the standard potential when all of reactants are present under standard conditions. R is gas constant of 8.3 J/mol × °K, T is absolute temperature in kelvin units (K), n is number of electrons being transferred, and f is the Faraday constant of 96,500 J/V.

From standard oxidation–reduction potentials of a diverse variety of biochemical reactions, one can predict direction of electron flow or transfer when more than two redox pairs are linked together by the appropriate enzyme. For example, Table 14.5 shows that the NAD^+−NADH pair has a standard potential of −0.32 V, and the pyruvate–lactate pair has a standard potential of −0.19V. This means that electrons will flow from NAD^+− NADH to pyruvate–lactate as long as lactate dehydrogenase is present as indicated here.

$$\text{Pyruvate} + \text{NADH} + H^+ \rightarrow \text{lactate} + NAD^+$$

Reducing equivalents are produced in NAD^+-and FAD-linked dehydrogenase reactions, which have standard potentials at or close to that of NAD^+−NADH. The electrons are subsequently transferred through the electron transfer chain, which has as its terminal acceptor the O_2–water couple with a standard redox potential of +0.82 V.

Free-Energy Changes in Redox Reactions

Differences in oxidation–reduction potentials between two redox pairs are similar to free-energy changes in chemical reactions, in that both quantities depend on concentration of reactants and products of the reaction and the following relationship exists:

$$\Delta G^{0'} = -nf\ \Delta E_0'$$

Using this expression, free-energy change for electron transfer reactions can be calculated if potential difference between two oxidation-reduction pairs is known. Hence, for the mitochondrial electron transfer chain in which electrons are transferred between the

NAD^+–NADH couple ($E_0' = -0.32$ V) and the $1/2O_2$–H_2O couple ($E_0' = +0.82$ V), the free-energy change for this process can be calculated.

$$\Delta G^{0'} = -nf\,\Delta E_0' = -2 \times 96.5\ \text{kJ/V} \times 1.14\ \text{V}$$

$$\Delta G^{0'} = -219\ \text{kJ/mol}$$

where 96.5 is the Faraday constant in kJ/V and n is the number of electrons transferred; for example, in the case of NADH → O_2, $n = 2$. The free energy available from the potential span between NADH and O_2 in the electron transfer chain is capable of generating more than enough energy to synthesize three molecules of ATP per two reducing equivalents or two electrons transported to O_2. In addition, because of the negative sign of the free energy available in the electron transfer, this process is exergonic and proceeds, if the necessary enzymes are present.

Mitochondrial Electron Transport Is a Multi-component System

The final steps in the overall oxidation of foodstuffs—carbohydrates, fats and amino acids-result in formation of NADH and $FADH_2$ in the matrix. The electron transport chain oxidizes these reduced cofactors by transferring electrons in a series of steps to O_2, the terminal electron acceptor, while capturing the free energy of the reactions to drive the synthesis of ATP (Figure 14.27, p. 561). During removal of electrons from the coenzymes, protons are pumped from the matrix to the intermembrane space to form an electrochemical gradient across the inner membrane, which provides energy for synthesis of ATP. The carriers that transfer electrons from NADH to O_2 have standard redox potentials that span the range from −0.32 V that of the most electronegative electron donor NADH to +0.82 V the most electropositive electron acceptor O_2 (Figure 14.28). The mitochondrial electron carriers, however, are not organized in a linear arrangement but are grouped into four large complexes (complexes I–IV) that catalyze different partial reactions of the electron transport chain (see Figure 14.27).

Complex I, NADH-ubiquinone oxidoreductase, catalyzes the transfer of electrons from NADH to **ubiquinone (UQ)** or **coenzyme Q (CoQ)**; **complex II**, succinate-ubiquinone oxidoreductase or succinate dehydrogenase, transfers electrons from succinate to coenzyme Q; **complex III**, or the **cytochrome bc_1 complex**, ubiquinol-cytochrome *c* reductase, transfers electrons from ubiquinol (reduced form of ubiquinone denoted as **$CoQH_2$** or **UQH_2**) to **cytochrome *c***; and **complex IV**, cytochrome *c* oxidase, transfers electrons from cytochrome *c* to O_2 (see Figure 14.27). Another complex, the **ATP synthase**, or **complex V**, uses energy of the electrochemical gradient for synthesis of ATP. Complexes I–IV consist of electron carriers that include **flavoproteins**, which contain tightly bound FMN or FAD and can transfer one or two electrons, the heme-containing proteins **cytochromes**, (cytochromes *b*, c_1, *c*, *a*, and a_3) that transfer one electron from Fe^{2+} of heme, **iron–sulfur proteins** that

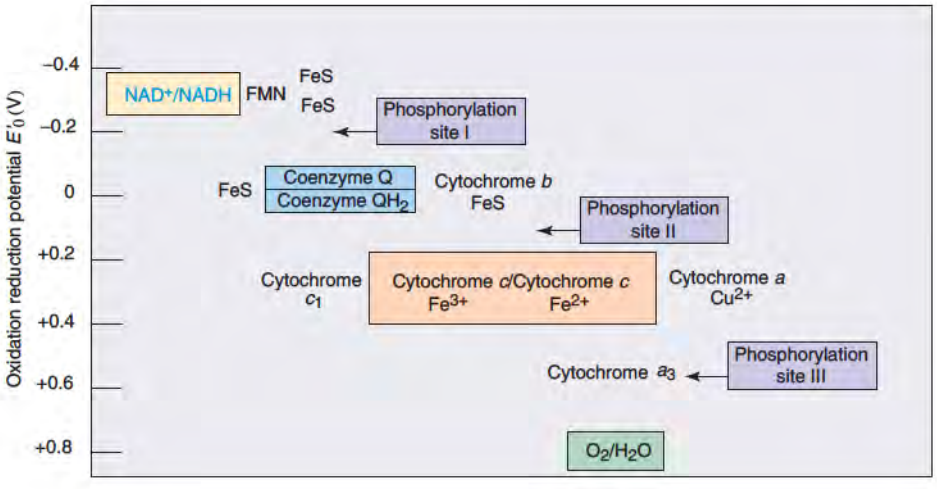

Figure 14.28 Oxidation–reduction potentials of the mitochondrial electron transport chain carriers listed from the most negative (NAD^+/NADH) to the most positive (O_2/H_2O).

contain bound inorganic Fe and S and transfer one electron, and **copper** in complex IV (cytochrome *c* oxidase) that transfers one electron. UQ participates in one or two electron transfer reactions.

Complex I: NADH–Ubiquinone Oxidoreductase

Complex I, the most complicated found in mammalian mitochondria, contains a minimum of 40 different polypeptides with a total mass of approximately 1 MDa. A simpler complex I containing 14 subunits, which catalyzes similar electron transfer and proton pumping reactions, is present in bacterial membranes where structure and enzymatic activity have been extensively investigated. Complex I transfers electrons from NADH to ubiquinone (coenzyme Q) coupled with the transport of four protons across the membrane, thus contributing to the proton-motive force required for the synthesis of ATP. Both the mammalian and bacterial forms of complex I have a characteristic L-shaped structure with a long hydrophobic arm localized in the membrane and a peripheral hydrophilic arm protruding into the mitochondrial matrix (Figure 14.29). Electrons are transferred from NADH to

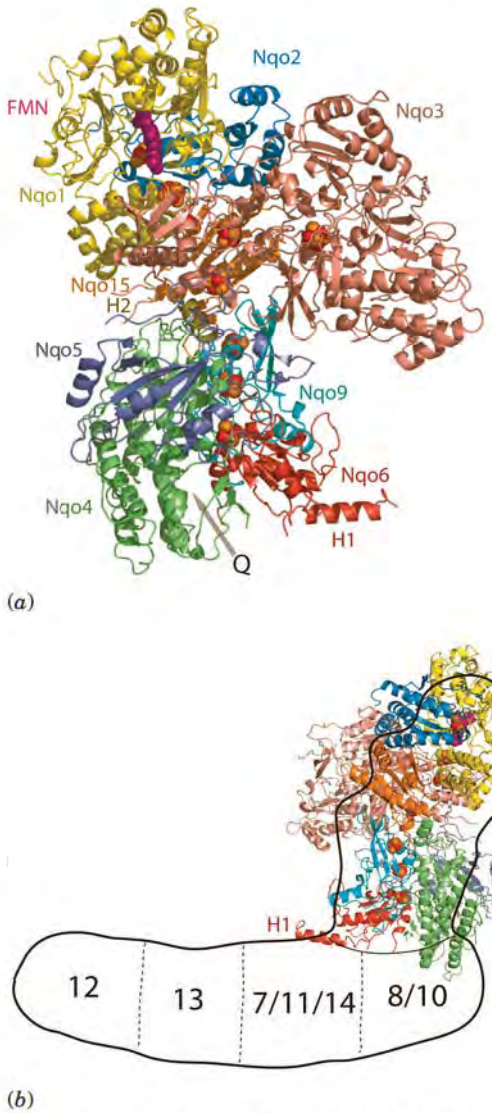

Figure 14.29 Model of the crystal structure of the hydrophilic domain of complex I. (*a*) Side view with the membrane arm located beneath and extending to the right. Each subunit is represented by a different color with FMN indicated by magenta spheres. (*b*) View indicating the proposed attachment of the peripheral domain to the membrane domain of complex I.

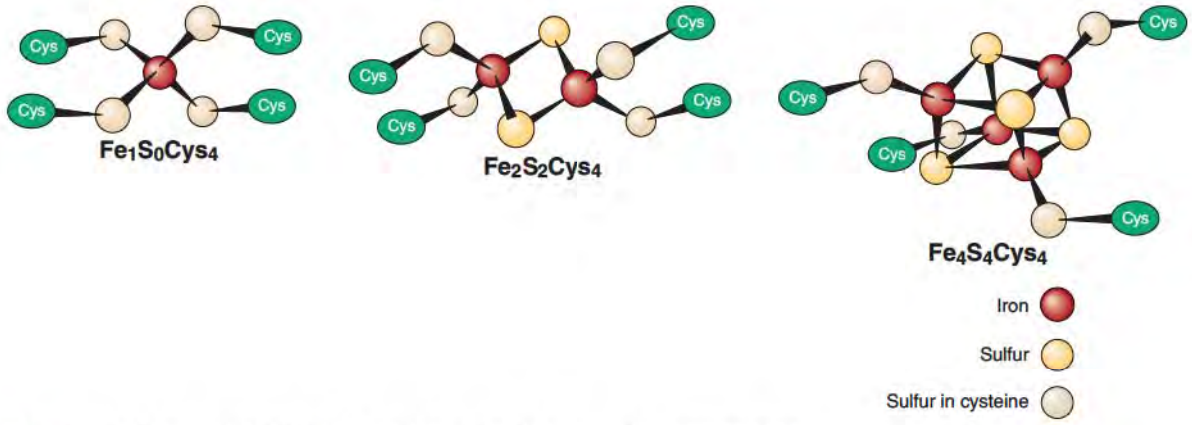

Figure 14.30 Structures of iron–sulfur centers. Yellow, inorganic sulfur; gray, sulfur in cysteine; and red, iron.

FMN, flavin mononucleotide (see Figure 10.32, p. 566), which is tightly bound to a subunit in the hydrophilic arm of complex I.

$$NADH + H^+ + FMN \rightarrow NAD^+ + FMNH_2$$

The electrons are then transferred one at a time via a series of FeS centers, of both the 2Fe2S and 4Fe4S types (Figure 14.30), located in different subunits of the hydrophilic arm of complex I. These iron–sulfur clusters subsequently reduce a membrane-embedded ubiquinone to form ubiquinol (Figure 14.31). During transfer of two electrons to ubiquinone by complex I, four protons are also translocated across the inner membrane to the intermembrane space by a mechanism suggested to involve proteins located in the hydrophobic membrane arm of complex I.

Mutations in subunits of complex I have been shown to lead to a number of neurodegenerative diseases. In addition, complex I has been shown to be a major source of reactive oxygen species (ROS) that may damage mitochondrial DNA and may be a cause of aging (see Sections 14.9 and 14.10).

Complex II: Succinate–Ubiquinone Oxidoreductase

Complex II, better known as succinate dehydrogenase, consists of a 70-kDa subunit that contains FAD covalently bound to a histidine residue, a 30-kDa subunit that contains three iron–sulfur centers, and two small hydrophobic proteins. In the oxidation of succinate to fumarate, two electrons and two protons are transferred to FAD (Figure 14.32). The $FADH_2$ transfers electrons to ubiquinone via FeS centers of complex II in the reactions.

$$\text{Succinate} \rightarrow \text{fumarate} + 2H^+ + 2e^-$$

$$UQ + 2H^+ + 2e \rightarrow UQH_2$$

$$\text{Overall} \quad \text{Succinate} + UQ \rightarrow \text{fumarate} + UQH2$$

$$\Delta E^{0'} = 0.029\ V \qquad \Delta G^{0'} = -5.6\ kJ/mol$$

The amount of free energy liberated in these reactions is insufficient for proton pumping across the membrane so no gain in free energy is accomplished in complex II. Figure 14.32 provides a schematic representation of these events.

Other Mitochondrial Flavoprotein Dehydrogenases

Other mitochondrial dehydrogenases feed electrons into the electron transport chain at the level of ubiquinone. Glycerol 3-phosphate, formed from glycerol released by hydrolysis of triacylglycerols or by reduction of dihydroxyacetone phosphate produced during glycolysis, is oxidized by **glycerol 3-phosphate dehydrogenase** (Figure 14.32).

$$\text{Glycerol 3-phosphate} + FAD \rightarrow \text{dihydroxyacetone phosphate} + FADH_2$$

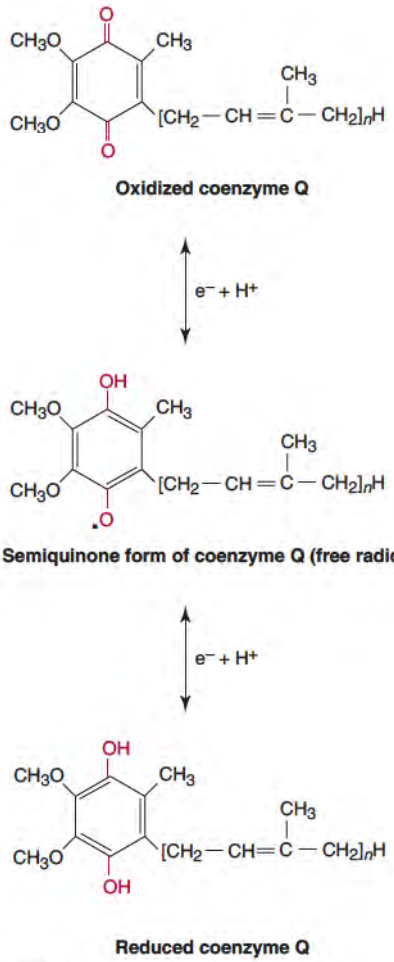

Figure 14.31 Oxidation–reduction of ubiquinone (coenzyme Q). Note that ubiquinone can accept one electron at a time forming an intermediate semiquinone.

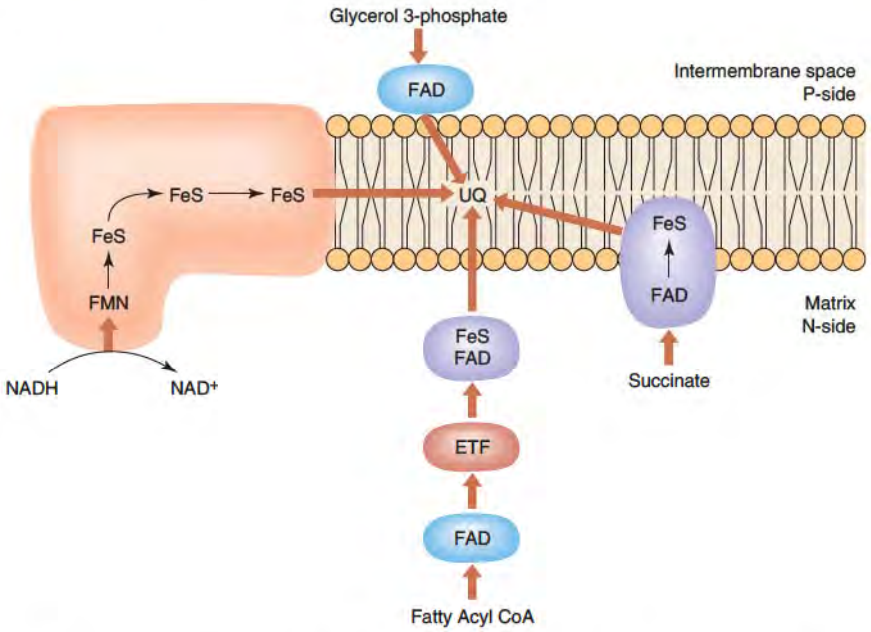

Figure 14.32 Reduction of ubiquinone (UQ) in the mitochondrial inner membrane by the flavoproteins NADH, succinate, glycerol 3-phosphate, and fatty acyl CoA dehydrogenases.

This flavoprotein, a single polypeptide chain, is localized on the outer face of the inner membrane and transfers electrons directly to ubiquinone in the membrane. The importance of glycerol 3-phosphate dehydrogenase in shuttling of reducing equivalents from NADH in the cytosol to the mitochondrial electron transport chain will be discussed in Section14.8 (p. 477).

Acyl-CoA dehydrogenase, a flavoprotein that catalyzes the first step in β-oxidation of fatty acids, transfers electrons from fatty acyl CoA to FAD to form $FADH_2$, which then transfers electrons to **e**lectron **t**ransferring **f**lavoprotein (**ETF**). Electrons are then transferred from ETF to **ETF–ubiquinone oxidoreductase** which transfers electrons directly to ubiquinone in the inner membrane. Figure 14.32 illustrates the reduction of the ubiquinone pool by complex I, complex II, glycerol 3-phosphate dehydrogenase, and ETF–ubiquinone oxidoreductase. Ubiquinol is subsequently oxidized by complex III.

Complex III: Ubiquinol–Cytochrome *c* Oxidoreductase

Complex III, or cytochrome bc_1 complex, catalyzes transfer of two electrons from ubiquinol to cytochrome *c* with translocation of four protons across the membrane. In mammals this enzyme complex consists of 11 subunits of which 3 have prosthetic groups that serve as redox centers. These are **cytochrome *b***, which contains two hemes, b562 and b566; **cytochrome c_1**, which contains one heme group; and the **Rieske iron–sulfur protein**, which contains a 2Fe2S cluster. Resolution of the complete structure of complex III by X-ray crystallography was achieved recently (Figure 14.33). The dimeric complex (250 kDa for each monomer) is pear shaped and has a large domain protruding 75 Å into the mitochondrial matrix and a smaller domain containing the head groups of the Rieske iron–sulfur protein and cytochrome c_1 protruding into the intermembrane space. The transmembrane domain of each monomer of complex III consists of eight α-helices of the hydrophobic protein, cytochrome *b*, plus membrane-anchoring helices of the Rieske iron–sulfur protein, cytochrome c_1, and other subunits of each monomer. Oxidation of ubiquinol occurs at the Q_O site located at the P side of the mitochondrial membrane facing the intermembrane space with the transfer of one electron to the iron–sulfur protein and the second electron to b_L and b_H with the release of two protons to the intermembrane space. The proposed mechanism for the transfer of electrons and protons in complex III, termed the Q cycle, is described in Figure 14.34 and A Closer Look 14.1, p. 568.

Cytochromes

The cytochromes are proteins that contain a heme group tightly bound to the protein (p. 791). Unlike the heme in hemoglobin or myoglobin in which heme iron remains in the Fe^{2+} state during oxygen transport, iron in heme of a cytochrome is alternately oxidized (Fe^{3+}) or reduced (Fe^{2+}) as it functions in the transport of electrons. The cytochromes of mammalian

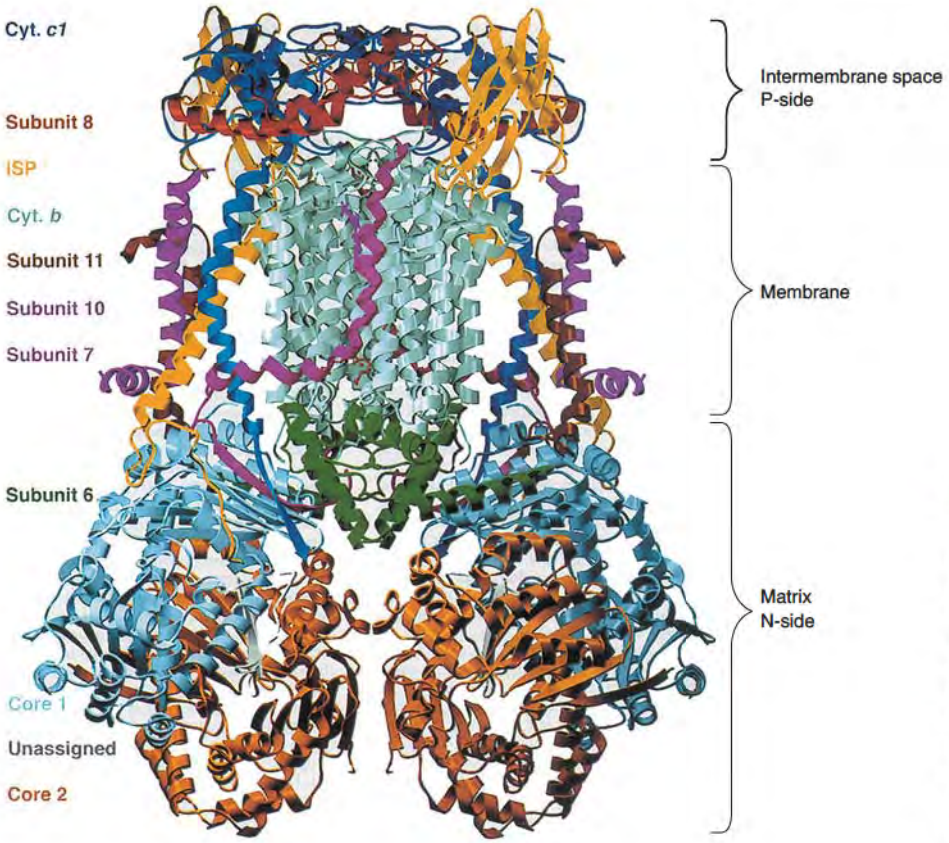

Figure 14.33 Model of the crystal structure of the dimeric cytochrome bc_1 complex. The α-helices of cytochrome *b* (pale green) form the transmembrane domain of the complex. The complex protrudes 75 Å into the matrix and 38 Å into the intermembrane space. Colors identifying the subunits are shown on the left. ISP is iron–sulfur protein.

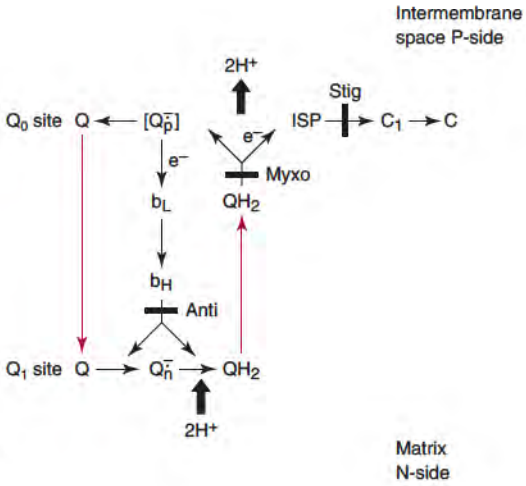

Figure 14.34 The Q cycle. Ubiquinol (QH_2) is oxidized with the transfer of one electron to the iron–sulfur protein, release of two protons to the intermembrane space, and formation of the semiquinone ($Q^{\bullet-}_p$) at the Q_O site, which transfers electrons via hemes b_L and b_H to form a semiquinone ($Q^{\bullet-}_n$) at the Q_i site. A second molecule of QH_2 is oxidized at the Q_O site with release of two protons and transfer of one electron to the iron–sulfur protein and to $Q^{\bullet-}_n$ to form QH_2 with the uptake of two protons from the matrix. Sites of inhibitors myxothiazol (Myxo), stigmatellin (Stig), and antimycin (Anti) are indicated.

mitochondria are designated as *a*, *b*, and *c* on the basis of the α band of their absorption spectrum and the type of heme group attached to the protein (Figure 14.35). The absorption band and standard redox potential depend on the structure of the heme and its environment in the protein. Cytochrome *b* and other ***b*-type cytochromes** contain the same iron–protoporphyrin IX (Figure 14.35) found in hemoglobin and myoglobin; however, these hemes are buried in the membrane and cannot bind O_2. The ***c*-type cytochromes** contain heme *c* that is covalently bound to two cysteine residues of the protein via thioether linkages involving vinyl side chains of protoporphyrin IX. The ***a*-type cytochromes**, contain heme *a*, a modified form of protoporphyrin IX (p. 793) in which a formyl group and an isoprenoid side chain have been added. Two forms of cytochrome *a* are present in cytochrome *c* oxidase, complex IV.

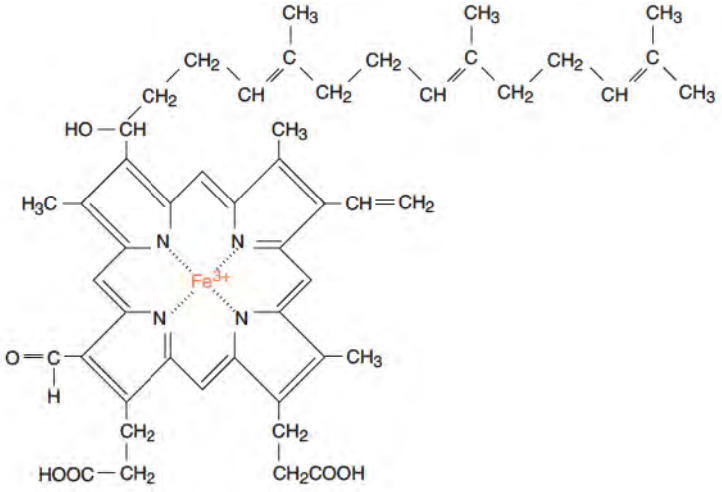
Cytochrome *c* Is a Mobile Electron Carrier

Electrons are transferred through complex III to cytochrome *c*, a globular hydrophilic protein of 13 kDa. The planar heme group is located in the middle of the protein surrounded

A CLOSER LOOK 14.1

The Q Cycle, for Electron Transfer and Proton Pumping in Complex III

Complex III contains two *b*-type hemes, a high-potential b_L (+0.50 V) and a low-potential b_H (0.10 V) plus cytochrome c_1. The transfer of electrons through this complex is best explained by the Q cycle in which four protons are translocated across the membrane for every two electrons transferred from ubiquinol to cytochrome *c* (Figure 14.38). For electron transfer to continue, two separate ubiquinone- or ubiquinol-binding sites are required in the bc_1 complex: a ubiquinol oxidizing site (Q_O) involving the low potential heme *b* (heme b_L) located at the positive (P) side of the membrane, where inhibitors such as myxothiazol and stigmatellin bind; and a ubiquinone-reducing site (Q_i), involving the high-potential heme *b* (heme b_H) located at the negative (N) side of the membrane, where inhibitors such as antimycin bind. Oxidation of ubiquinol at the Q_O site results in the transfer of one electron to the 2Fe2S cluster of the iron–sulfur protein with the release of two protons to the intermembrane space. The iron–sulfur protein then transfers an electron to the heme of cytochrome c_1. The strongly reducing ubisemiquinone anion formed at the Q_O site after the transfer of the first electron from ubiquinol rapidly transfers an electron to cytochrome b_L which then transfers an electron to high-potential heme of cytochrome b_H at the Q_i site. The reduced cytochrome b_H then transfers this electron to ubiquinone at the Q_i site to form a stable ubisemiquinone. To complete the Q cycle, a second molecule of ubiquinol is oxidized at the Q_O site with the release of another two protons and transfer of one electron to the iron–sulfur protein and the second electron to heme b_L. Heme b_L transfers an electron to b_H and eventually to the ubisemiquinone at the Q_i site to form ubiquinol with the uptake of two protons from the matrix. The Q cycle explains how during the oxidation of two ubiquinols at the Q_O site, four protons are released to the intermembrane space, while two protons are taken up from the matrix side to reduce ubiquinone at the Q_i site, a net of two protons released per ubiquinol oxidized.



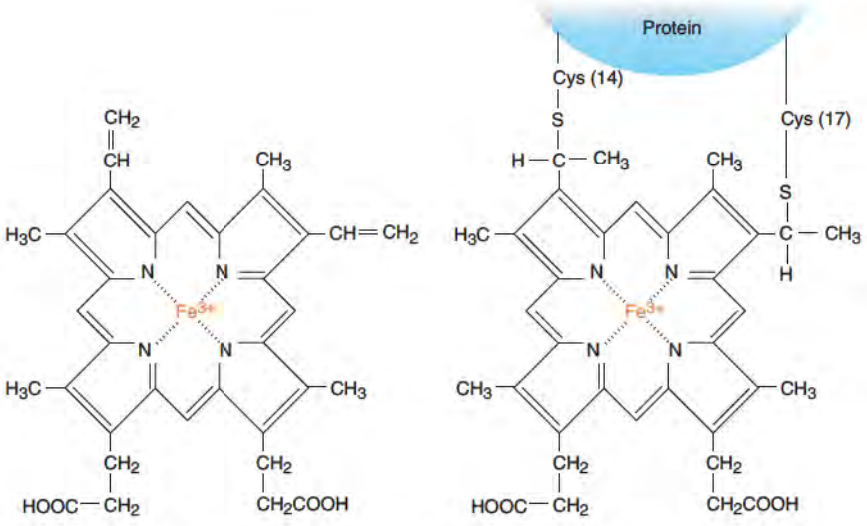


Figure 14.35 **Structures of heme *a*, heme *b*, and heme *c*.**

by hydrophobic residues and covalently bound to two conserved cysteine residues through vinyl ether linkages (Figure 14.35). The heme iron is coordinated to a nitrogen of a histidine and a sulfur atom of a methionine, thus preventing the interaction of the heme with O_2 (Figure 14.36).

Cytochrome *c*, like ubiquinone, is a mobile electron carrier. It is held loosely by electrostatic forces to the outer face of the inner membrane where it binds to cytochrome c_1 of complex III and accepts electrons from it. The reduced cytochrome *c* then moves along the membrane surface to interact with subunit II of cytochrome *c* oxidase through electrostatic linkages and donates electrons to the Cu_A site.

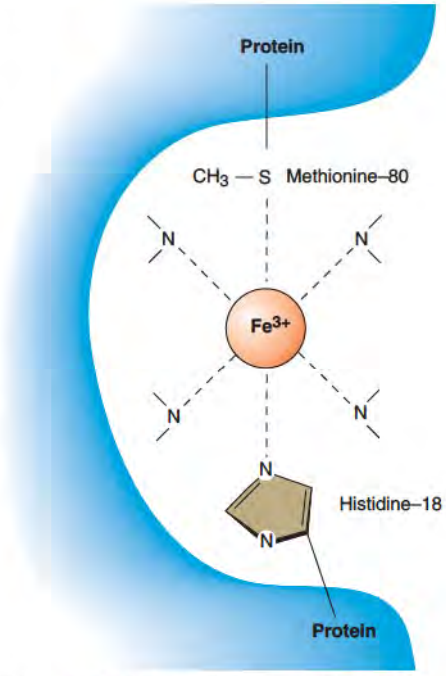

Figure 14.36 Six coordination positions of cytochrome *c*.

Complex IV: Cytochrome *c* Oxidase

Complex IV transfers electrons from cytochrome *c* to O_2, the terminal electron acceptor, to form water coupled to translocation of protons across the membrane. The mammalian complex consists of 13 subunits with a total mass of 200 kDa and contains two cytochromes, ***a*** and a_3, and two copper centers, known as $\mathbf{Cu_A}$ and $\mathbf{Cu_B}$. A simpler cytochrome *c* oxidase containing only three or four subunits, which catalyzes similar electron transfer and proton pumping reactions is present in bacterial membranes. The three subunits are homologous to the three largest subunits of mammalian cytochrome *c* oxidase, which are encoded in mitochondrial DNA (mtDNA). The remaining subunits of complex IV are encoded in nuclear DNA and may be regulatory subunits or function in assembly of the complex.

The crystal structure of a bacterial cytochrome *c* oxidase and complex IV from beef heart mitochondria have been solved (Figure 14.37). Subunit I, the largest, contains twelve transmembrane helices but lacks any significant extramembranous domains. Two heme groups, *a* and a_3, are bound to subunit I with the heme coordinated by nitrogen atoms of conserved histidine residues. The planes of both hemes lie perpendicular to the membrane. Subunit I also contains a copper atom (Cu_B) that with heme a_3 forms a binuclear center involved in transfer of electrons from heme a to O_2 (Figure 14.38). Subunit II has a large domain protruding from the cytosolic face of the inner membrane, where reduced cytochrome *c* binds, and contains two atoms of copper bound through sulfhydryl groups to two cysteine moieties (called Cu_A). Subunit III contains seven transmembrane helices with negligible extramembranous domains but does not have any redox carriers. Subunits II and III are localized on opposite sides of

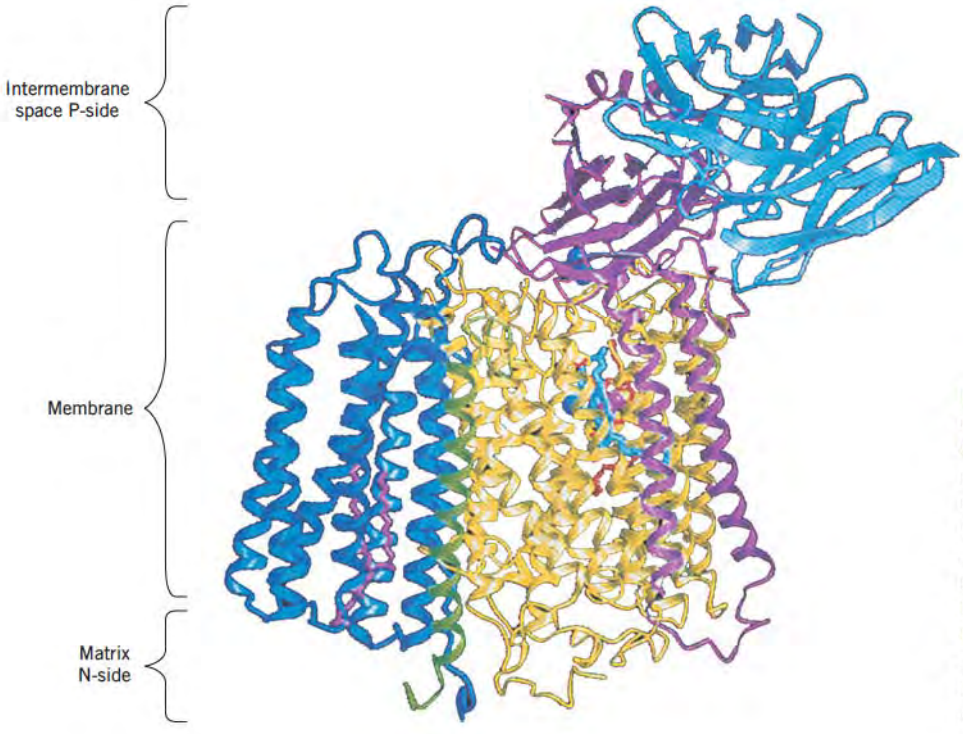

Figure 14.37 Model of crystal structure of cytochrome *c* oxidase from bacterium *Paracoccus denitrificans*. Subunit I (12 transmembrane helices) is yellow, subunit II (two transmembrane helices) is purple, and subunit III (7 transmembrane helices) is blue with an embedded phospholipid in pink. The antibody fragment used to drive crystallization is cyan. Reproduced with permission from Iwata, S., Ostermeier, C., Ludwig, B., Michel, H., et al. *Nature* 376:660, 1995. Figure 14.39 Pathways of electron and proton transfer through cytochrome *c* oxidase. Cytochrome *c* binds on the surface of subunit II and transfers electrons to CuA. Electrons are transferred from CuA to heme *a* and then to the binuclear center (heme a_3 and CuB) where oxygen is reduced to water. Four protons are transferred to the binuclear center for reduction of oxygen and four protons are pumped across the membrane by a different channel.

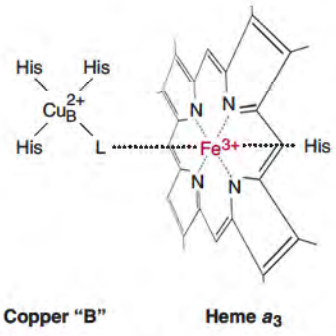

Figure 14.38 Binuclear center of cytochrome *c* oxidase indicating heme *a*3 and CuB. L is an unknown but proposed ligand.

subunit I; the role of subunit III is unclear. Electrons are transferred from reduced cytochrome *c* first to Cu_A, then to heme *a*, and finally to the binuclear center containing Cu_B and heme a_3 where the transfer of four electrons to oxygen occurs (Figure 14.39 and A Closer Look 14.2). The transfer of four electrons to form water results in the uptake of four protons from the matrix to reduce oxygen and the translocation of four protons across the mitochondrial membrane to contribute to the electrochemical gradient (Figure 14.39).

Electron Transport Chain Inhibitors

A dynamic picture of the electron transport chain has developed with increasing knowledge of the detailed chemistry of the different respiratory chain complexes (Figure 14.40). Each complex exists independently in the inner membrane and is freely mobile. Complexes I and II, and the other flavoprotein dehydrogenases, diffuse in the membrane and transfer electrons to the ubiquinone pool in the membrane. Ubiquinol also diffuses freely in the membrane and is oxidized by complex III. Electrons are transferred from complex III to cytochrome *c* which moves along the surface of the membrane to complex IV where

A CLOSER LOOK 14.2

Pathways of Electron Transfer through Complex IV

Electrons are transferred from reduced cytochrome *c* to the Cu_A site on subunit II and then to heme *a* on subunit I of complex IV (Figure 14.43). The Cu_A and heme *a* are localized within 1.5 Å of each other, permitting rapid electron transfer. Electrons are then transferred to the binuclear center consisting of Cu_B and heme a_3 where final transfer of electrons to O_2 occurs. Initially, two electrons are transferred to an O_2 tightly bound to the binuclear center to form a peroxy derivative of oxygen (O_2^{2-}). Two additional electrons are transferred with uptake of four protons from the matrix to form water. Since each of the redox carriers present in complex IV is a one-electron carrier and the reduction of O_2 to water requires four electrons, the reactions catalyzed by complex IV have evolved to prevent release of partially reduced toxic oxygen intermediates such as superoxide, hydrogen peroxide, or hydroxyl radicals (see Section 14.10, p. 583). Each of the intermediates formed in the reduction of O_2 remains tightly bound to the binuclear center and is thus largely prevented from dissociating until water is produced.

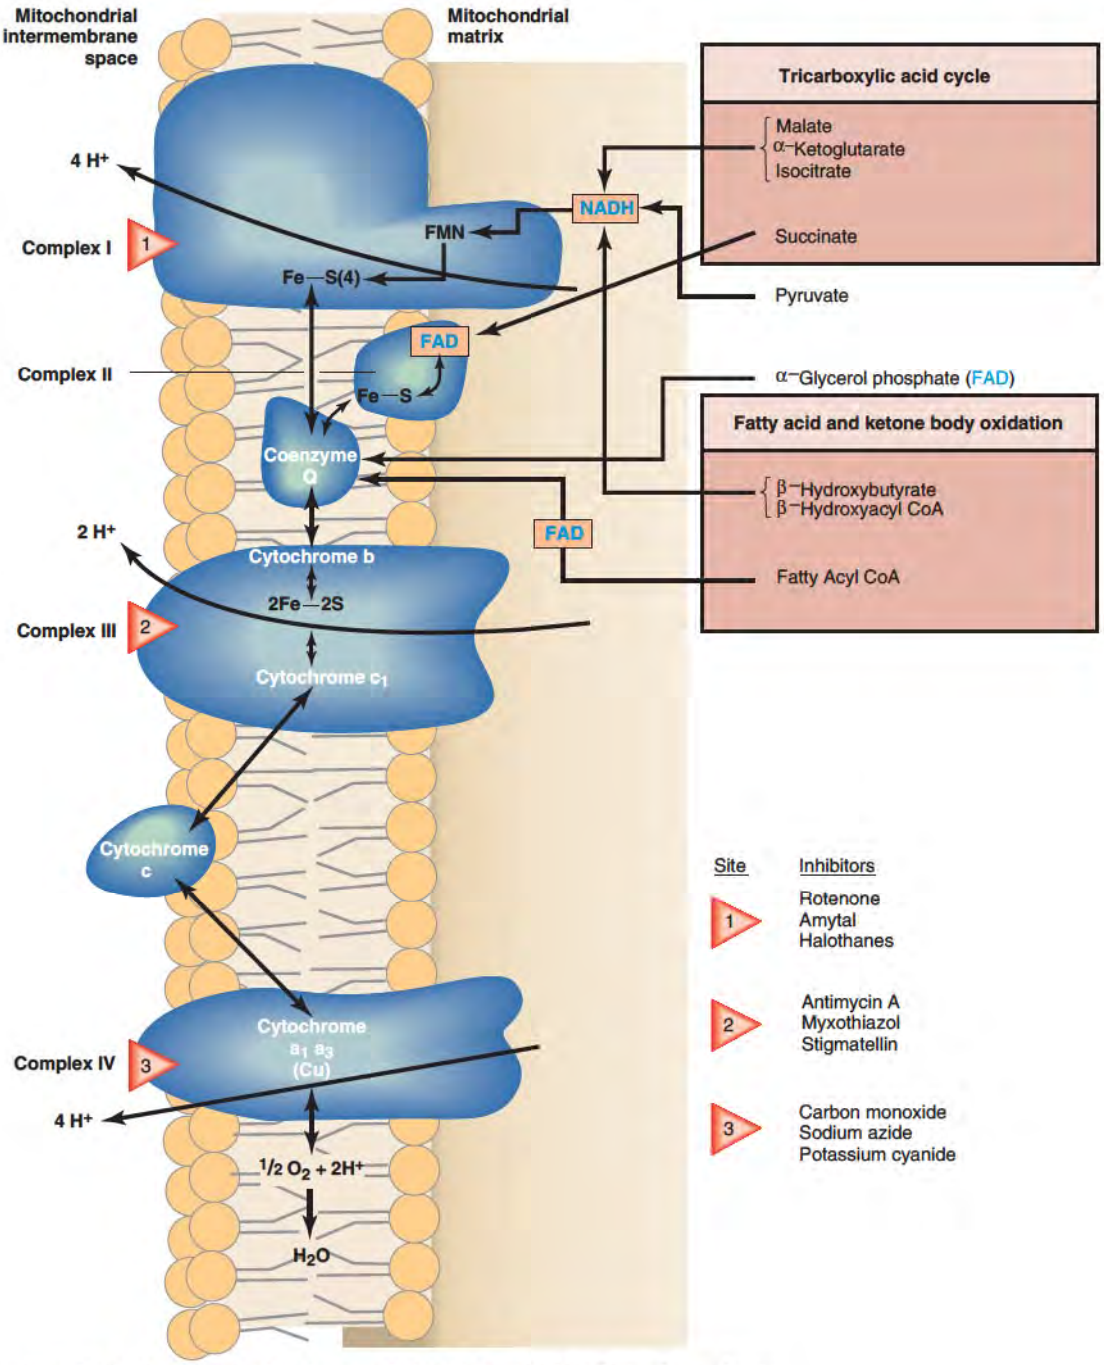

Figure 14.40 Overview of mitochondrial electron transport chain indicating locations of complexes I–IV, ubiquinone (CoQ) and cytochrome *c* in the inner membrane, pathways of electron transfer, and sites of proton pumping. The binding sites for specific inhibitors on the complexes are indicated at complex I (rotenone, amytal, and halothanes), at complex III (antimycin A, myxothiazole, and stigmatellin), and at complex IV (carbon monoxide, sodium azide, and potassium cyanide).

its electrons are transferred to O_2. Currently, it is accepted that the transfer of two electrons from NADH to O_2 results in the translocation of 10 protons across the membrane, 4 each from complexes I and IV and 2 from complex III. The electrochemical gradient, thus formed, provides the potential energy that is used to drive ATP synthesis by the ATP synthase (p. 572).

Figure 14.40 indicates the sites where specific inhibitors bind and block electron flow. Rotenone, a commonly used insecticide, binds stoichiometrically to complex I and prevents the reduction of ubiquinone. Piericidin, Amytal, and other barbiturates including halothanes used in anesthetics also inhibit complex I by preventing the transfer of electrons

CLINICAL CORRELATION 14.3

Cyanide Poisoning

Inhalation of hydrogen cyanide gas or ingestion of potassium cyanide causes a rapid and extensive inhibition of the mitochondrial electron transport chain at the cytochrome oxidase step. Cyanide is one of the most potent and rapidly acting poisons known. It binds to the Fe^{3+} of heme a_3 in cytochrome *c* oxidase, which catalyzes the terminal step of the electron transport chain. Mitochondrial respiration and energy production cease, and cell death occurs rapidly. Death occurs from tissue anoxia, most notably of the central nervous system. An antidote to cyanide poisoning, if the poisoning is diagnosed rapidly, is the administration of various nitrites that convert oxyhemoglobin to methemoglobin by oxidizing Fe^{2+} of hemoglobin to Fe^{3+}. Methemoglobin (Fe^{3+}) competes with cytochrome a_3 (Fe^{3+}) for cyanide by forming a methemoglobin–cyanide complex. Administration of thiosulfate causes the cyanide to react with the enzyme rhodanese, forming the nontoxic thiocyanate. Cytochrome *c* oxidase is also inhibited by carbon monoxide (CO) that binds to the reduced form of heme a_3 and by H_2S.

Holland, M. A., and Kozlowski, L. M. Clinical features and management of cyanide poisoning. *Clin. Pharmacol.* 5:737, 1986.

from the iron–sulfur centers to ubiquinone. Complex II is inhibited by carboxin and thenoyltrifluoroacetone as well as by malonate that acts as a competitive inhibitor with the substrate succinate. Antimycin, an antibiotic, inhibits electron transfer through complex III by binding to the Q_i site and blocking the transfer of electrons from the cytochrome heme b_H to ubiquinone. Other antibiotics, such as myxothiazol and stigmatellin, inhibit electron transfer through complex III by binding to the Q_O site and blocking the transfer of electrons from ubiquinol to the 2Fe2S center of the iron–sulfur protein. Complex IV is inhibited by cyanide (CN^-), azide (N_3^-), H_2S, and carbon monoxide (CO). Cyanide and azide bind tightly to the oxidized form of heme a_3 (Fe^{3+}) and prevent the transfer of electrons from heme *a* to the binuclear center. By contrast, carbon monoxide binds to the reduced form of heme a_3 (Fe^{2+}) competitively with O_2 and prevents electron transfer to O_2. Hence, inhibition of mitochondrial electron transport results in impairment of the energy-generating function of oxidative phosphorylation leading to the death of the organism (Clin. Corr. 14.3).

Figure 14.40 also indicates the three sites where protons are translocated across the mitochondrial membrane during electron transport to contribute to the formation of the electrochemical gradient used for ATP synthesis. Four protons are translocated by electron transfer through complexes I and IV, while two protons are translocated by complex III.

14.7 • OXIDATIVE PHOSPHORYLATION

The energy released during the transfer of electrons to O_2 via the mitochondrial electron transport chain is used to translocate protons across the inner membrane and establish a **proton gradient** (Figure 14.41). This makes the intermembrane space more acidic and the matrix space more alkaline. Simultaneously, the external face of the membrane becomes more positively charged and the matrix face becomes more negatively charged establishing a **charge gradient**, since there is no compensating translocation of a negatively charged ion.

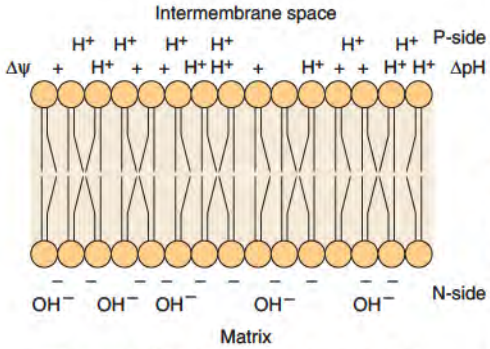

Figure 14.41 The electrochemical gradient consists of a gradient of charges ($\Delta\psi$) and proton concentration (ΔpH) across inner mitochondrial membrane.

During the transfer of two electrons from NADH to O_2, approximately 10 protons are pumped across the membrane to establish the electrochemical gradient (see Figure 14.40). The total free energy derived from the translocation of protons and the charge distribution across the membrane can be calculated by the following equation in which Z is the absolute value of the charge, f is the Faraday constant, and ψ is the membrane potential:

$$\Delta G^{0'} = 2.3RT\Delta\text{pH} + Zf\psi$$

In actively respiring mitochondria, the observed change in pH across the membrane is 0.75−1.0 pH units and that in membrane potential is 0.15−2.0 V. Hence, the $\Delta G^{0'}$ calculated is roughly 200 kJ for the translocation of 10 H^+ across the membrane during transfer of electrons from NADH to O_2. The $\Delta G^{0'}$ can also be calculated from the difference in

standard redox potentials of the redox pair. The calculated $\Delta G^{0'}$ for the redox pairs NADH and O_2 is 219 kJ/mol (Section 14.6), suggesting that the energy of the electron transfer reactions is efficiently captured in the electrochemical potential. The energy stored in the **proton and charge gradient** and the electrochemical gradient, also called the **protonmotive force**, drives the synthesis of ATP by the movement of protons down the electrochemical gradient through the ATP synthase by a mechanism discussed later in this section.

Coupling of ATP Synthesis and Electron Transport

The rate of ATP utilization regulates the rate of ATP synthesis in mitochondria, which in turn regulates the rate of electron transfer. The coupling of ATP synthesis to electron transport is achieved by the electrochemical gradient, as illustrated by the experiment shown in Figure 14.42. The rate of electron transport measured by the rate of O_2 consumption by a suspension of liver mitochondria increases only after addition of an electron donor (succinate in this experiment) and ADP (a phosphate acceptor) plus phosphate (P_i). Conversion of all the added ADP to ATP returns the rate to that observed prior to addition of ADP. Hence, the rate of electron transport, or O_2 uptake, is tightly coupled to ATP synthesis. Chemiosmosis readily explains this relationship, termed respiratory control. When the energy needs of the cell are low, ATP will accumulate and the proton gradient will not be used for ATP synthesis. The magnitude of the proton gradient increases until the energy required to pump protons across the membrane against the existing electrical gradient equals that released during transfer of electrons from NADH to O_2. At this point, electron transport ceases as equilibrium has been attained. In cells using ATP, ADP accumulates leading to stimulation of the ATP synthase. While ATP is synthesized, the magnitude of the proton gradient decreases as protons move through the ATP synthase to provide the energy for ATP synthesis. As a result, the proton back pressure on the electron transport chain will decrease. The increased rate of electron transport through the chain stimulates the oxidation of NADH, resulting in the formation of NAD^+. The increased concentrations of NAD^+ coupled with the increased concentrations of ADP in cells actively using ATP acts to stimulate reactions of the TCA cycle and fatty acid oxidation. In this way, the need for ATP in a cell regulates in a coordinated fashion the rate of electron flow through the electron transport chain and of the reactions of the TCA cycle and fatty acid oxidation.

P/O Ratios for Mitochondrial Electron Transport and Oxidative Phosphorylation

The P/O ratio (phosphate incorporated into ATP to atoms of O_2 utilized) is a measure of the number of ATP molecules formed during the transfer of two electrons through all or part of the electron transport chain. Classically, the P/O ratio had been thought to be a whole number, 3 for transfer of two electrons from NADH linked substrates to O_2, 2 for succinate to O_2, and 1 for reduced cytochrome *c* to O_2. These P/O ratios suggested that one ATP was produced during electron transfer through each of the proton-pumping complexes I, III, and IV. Questions about actual P/O ratios, however, have arisen with recent calculations that 10 protons are pumped across the mitochondrial membrane during the transfer of two electrons from NADH to O_2, whereas the synthesis of one ATP and its transport across the membrane requires four protons. These proton stoichiometries result in a calculated P/O ratio of 2.5. Indeed, recent experimental determinations of the P/O ratio gave values of approximately 2.5 with NADH-linked substrates and 1.5 with succinate.

Effects of Uncouplers and Inhibitors of the Electron Transport–Oxidative Phosphorylation System

The coupling between electron transport and ATP synthesis can be abolished by chemical reagents, or **uncouplers**, such as 2,4-dinitrophenol or carbonylcyanide-p-trifluoromethoxyphenylhydrazone. After addition of an uncoupler to a suspension of tightly coupled liver mitochondria with a low rate of O_2 uptake, a rapid increase in the rate of O_2 consumption is observed (Figure. 14.43*a*). Because electron transport is uncoupled from ATP synthesis, electron transport may continue but without ATP synthesis. Uncouplers are hydrophobic

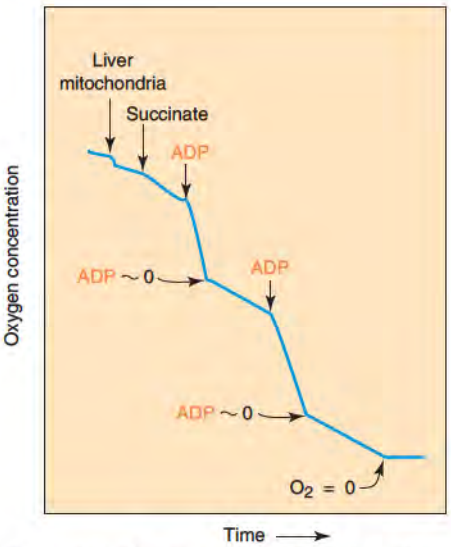

Figure 14.42 Demonstration of coupling of electron transport to oxidative phosphorylation in a suspension of liver mitochondria. In a medium containing Pi, addition of ADP stimulates rate of electron transfer measured as oxygen uptake. This is defined as respiratory control.

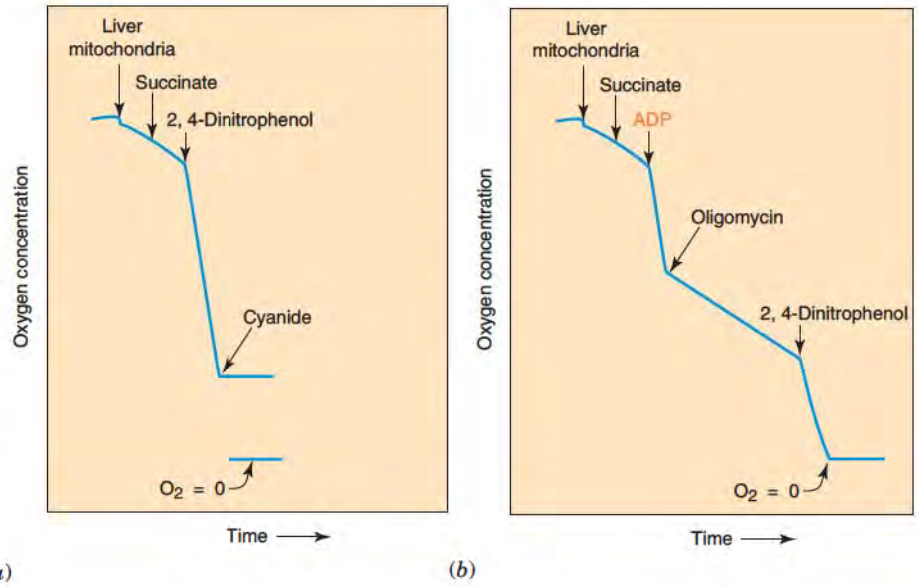

Figure 14.43 Inhibition and uncoupling of oxidative phosphorylation in liver mitochondria. (*a*) Addition of the uncoupler 2,4-dinitrophenol stimulates the rate of oxygen uptake by dissipating the proton gradient. Cyanide addition inhibits oxygen uptake. (*b*) Stimulation of oxygen uptake by ADP is inhibited by oligomycin, which blocks proton movements through F_O of ATP synthase. Addition of the uncoupler, 2,4-dinitrophenol, relieves inhibition by oligomycin and stimulates the rate of oxygen uptake.

weak acids that pick up a proton in the intermembrane space where a higher concentration of protons results from active electron transfer. These protonated uncouplers, being lipophilic, rapidly diffuse into the mitochondrial matrix where they lose their proton, because of the lower concentration of protons there. In this way the proton gradient can be completely dissipated as shown in Figure 14.44 and hence ATP synthesis is abolished.

As illustrated in Figure 14.43*b*, addition of **oligomycin**, an inhibitor of the ATP synthase, to liver mitochondria actively respiring in the presence of ADP results in an

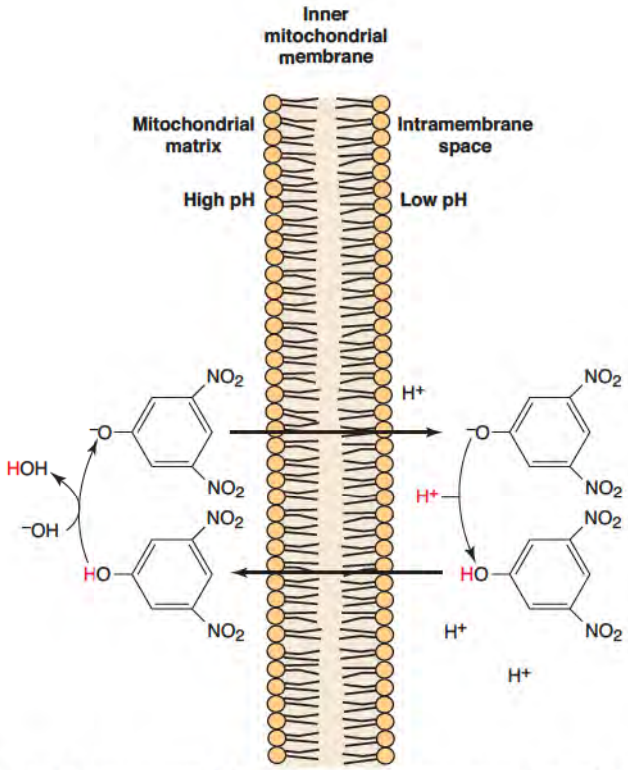

Figure 14.44 Action of the uncoupler, 2,4-dinitrophenol, a proton ionophore which equilibrates pH across the inner mitochondrial membrane. 2,4-Dinitrophenol is a weak acid that picks up a proton from the intermembrane space (P-side of membrane) that has a high proton concentration and carries it across the membrane to the matrix (N-side of membrane) where the proton dissociates due to the low proton concentration there.

inhibition of O_2 uptake. Oligomycin blocks the synthesis of ATP by preventing the movement of protons through the ATP synthase. Since ATP synthesis and electron flow are tightly coupled, the buildup of protons in the intermembrane space almost completely blocks the rate of electron transport as discussed for respiratory control. Subsequent addition of 2,4-dintirophenol that dissipates the proton gradient results in a rapid increase in the rate of O_2 uptake, because electron transport has been uncoupled from ATP synthesis.

ATP Synthase

ATP synthase, or complex V, located in the inner mitochondrial membrane of mammals, yeast, and fungi and in the cytoplasmic membrane of bacteria, catalyzes ATP synthesis using the energy of the proton gradient as protons flow through the ATP synthase. ATP synthase consists of two domains, $\mathbf{F_1}$, a peripheral complex first observed in electron micrographs as small particles bound to the inner mitochondrial membrane (Figure 14.45) and $\mathbf{F_0}$, an integral membrane protein complex. The F_1 domain contains the binding sites for ATP and ADP and catalyzes ATP synthesis (Figure 14.46). The F_0 domain provides a channel for the translocation of protons across the membrane. Removal of F_1 from the mitochondrial inner membrane by gentle agitation leaves an intact electron transport chain capable of electron transfer without formation of a proton gradient, since protons pumped across the membrane during electron transfer flow back into the matrix through the F_0 domain. Adding the F_1 domain back to the stripped membranes permits formation of a proton gradient as F_1 reconstitutes with F_0 and plugs the flow of protons through F_0. The entire ATP synthase can be isolated and when incorporated into artificial membrane vesicles, it will synthesize ATP when an electrochemical gradient is established across the membrane. The ATP synthase is a multicomponent complex of 480–500 kDa (Table 14.6 and Figure 14.46). The F_1 domain consists of five nonidentical subunits (α, β, γ, δ, and ε) with a subunit stoichiometry of α_3, β_3, γ, δ, and ε and a mass of 350–380 kDa. Binding sites for ATP and ADP are present on both α- and β-subunits. The catalytic sites are on the β-subunits, while the function of nucleotides bound to the α-subunits is unknown. The γ-subunit forms the central core of F_1, whereas the δ-subunit may be involved in the attachment of the F_1 domain to the membrane. The F_0 domain of the *E. coli* enzyme consists of three nonidentical hydrophobic subunits termed a, b, and c, which are present in the apparent stoichiometry of a_1, b_2, $c_{9–12}$. The c-subunits each contain an essential charged residue (aspartate-61 in *E. coli*) that is involved in proton pumping. Each c-subunit consists of two trans-membrane α-helices with aspartate residue-61 located in the middle. Mutation of this aspartate to asparagine abolishes proton pumping. Mutations of charged residues have also implicated the a-subunit of F_0 in proton movements, whereas the b-subunits appear to act to attach the F_1 domain to F_0. The F_0 domain found in mitochondria contains subunits homologous to subunits a, b, and c of the *E. coli* enzyme; however, additional subunits are also present.

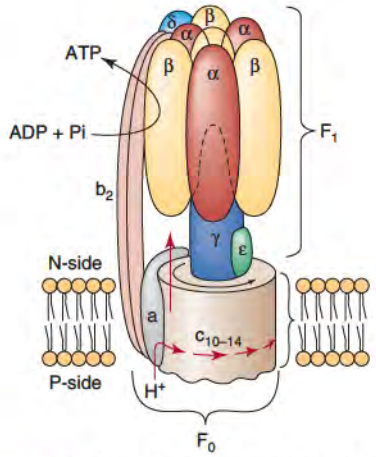

Figure 14.46 Model for mitochondrial F_1F_0–ATP synthase, a rotating molecular motor. ATP synthesis occurs on the β-subunits of F_1, whereas F_0 contains a proton channel. In F_0, the c-subunits in the membrane are attached to the shaft containing the γ and ε of F_1 and constitute a rotor. The two b-subunits of F_0 along with the α- and β-subunits and the δ-subunit constitute a stator (nonmoveable structural element). Protons flow through the a- and c-subunits of F_O causing the rotor to turn resulting in conformational changes in the β-subunits where ATP is synthesized.

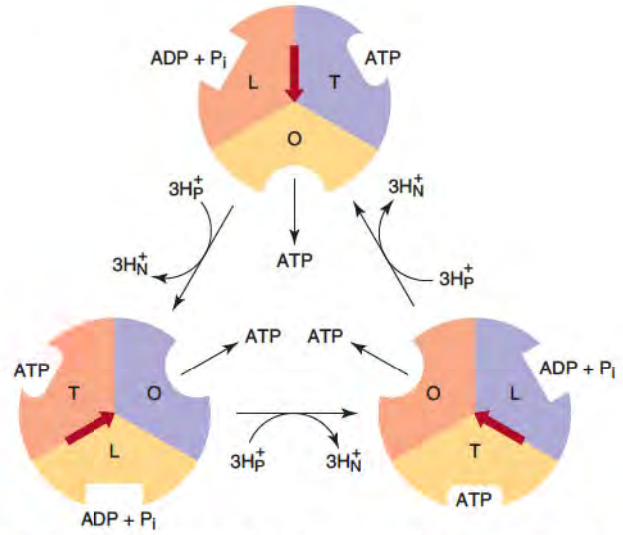

Figure 14.47 The binding change model for ATP synthesis by ATP synthase. Each β-subunit of F_1 has a non-identical adenine nucleotide binding site. At any time, one of these β-subunits is in the T (tight) conformation which binds ATP tightly, a second is in the L (loose) conformation which binds ATP and P_i loosely, and a third is in the O conformation (open) which does not bind nucleotides. The proton gradient causes rotation of the γ-subunit, the central shaft, which comes into contact with each β-subunit in succession producing a cooperative conformation change converting the T site to the O site releasing ATP, the L site to the T site promoting synthesis of ATP, and the O site to the L site binding ADP and P_i.

A CLOSER LOOK 14.3

Synthesis of ATP on F_1

The binding-charge mechanism suggests that the three β-subunits each adopt different conformations that change during catalysis with only one subunit acting as the catalytic site. As depicted in Figure 14.51, one subunit has an open conformation (O) with a low affinity for ligands and is empty. A second subunit has a loose conformation (L) with a low affinity for ligands and is inactive, while the third subunit has a tight conformation (T) that has a high affinity for ligands and is active in catalysis. According to this model, the synthesis of ATP occurs on the β-subunit in the T conformation. During catalysis, ADP and P_i, bind to the β-subunit in the L conformation. The energy provided by passage of protons through F_0 to F_1 results in the following conformational changes: The T site containing ATP changes to the O conformation with the release of ATP, the L site changes to the T conformation with ATP synthesis, and the O site changes to the L conformation binding ADP and P_i. According to this model, the energy released by electron transfer is conserved as a proton gradient that drives conformational changes in the ATP synthase resulting in the binding of substrates, the synthesis of ATP on the enzyme and the release of the product ATP.

Synthesis of ATP on F_1

The mechanism of ATP synthesis by F_1 was derived from isotope exchange experiments, which revealed that in the presence of stoichiometric amounts of ADP, ATP, and inorganic phosphate with isolated F_1, the reaction was essentially in equilibrium having a $\Delta G^{0'}$ close to zero. This exchange reaction

$$\text{Enz:ADP} + P_i \rightleftharpoons \text{Enz:ATP}$$

proceeds readily even in the absence of a proton gradient. The result indicated that the synthesis of ATP by F_1 does not require the input of energy; however, the movement of protons through the ATP synthase was required for release of ATP from their unique binding to the β-subunits of F_1. It was proposed that the energy released during the movement of protons across the membrane causes a conformational change in the ATP synthase, which results in the release of tightly bound ATP from one of the β-subunits, the binding of ADP and Pi to a second β-subunit in a loose conformation, and forcing the third β-subunit into the tight conformation where ATP synthesis occurs (Figure 14.47 and A Closer Look 14.3).

Mechanism of ATP Synthesis

Resolution of the crystal structure of F_1 has provided dramatic visualization of the conformations of the different β-subunits that provide evidence for the binding-change model described in A Closer Look 14.3. In this crystal structure, alternating α- and β-subunits form the knob of F_1 with the single γ-subunit forming a central shaft through the center of F_1 (Figure 14.48*a* and *b*). Each β-subunit had a different conformation depending on the presence of substrate. Thus F_1 crystallized in the presence of ADP and a non-hydrolyzable analog of ATP revealed binding of ATP analogue to one β-subunit, binding of ADP to a second β-subunit, and an empty third β-subunit (Figure 14.48*c*).

The model for ATP synthesis that has developed is that protons flow through the membrane by first binding to conserved acidic amino acid residues in subunit a of F_0. Protons then bind to a conserved amino acid residue present in the c-subunit causing the ring of c-subunits attached to γ- and ε-subunits to rotate. The movement of γ-subunit causes conformational changes in β-subunits as γ-subunit associates sequentially with each β-subunit in turn. The a- and b-subunits of F_0 plus δ-subunit of F_1 form the stator to hold α- and β-subunits in position, while γ- and c-subunits form the moving rotor. (See A Closer Look 14.4, p. 578, for experimental evidence for this proposed mechanism.)

14.8 • MITOCHONDRIAL INNER MEMBRANE CONTAINS SUBSTRATE TRANSPORT SYSTEMS

Whereas the outer membrane presents little or no permeability barrier to substrate or nucleotide molecules of interest in energy metabolism, the inner membrane limits the types of substrates, intermediates, and nucleotides that can diffuse from cytosol into the matrix. Various transport systems have been described in mitochondria (Figure 14.49), some of which have been thoroughly characterized. These transport systems facilitate selective movement of various substrates and intermediates back and forth across the inner mitochondrial membrane. Through these transporters, various substrates can be accumulated in the matrix, since the transporters can move the substrate against a concentration gradient.

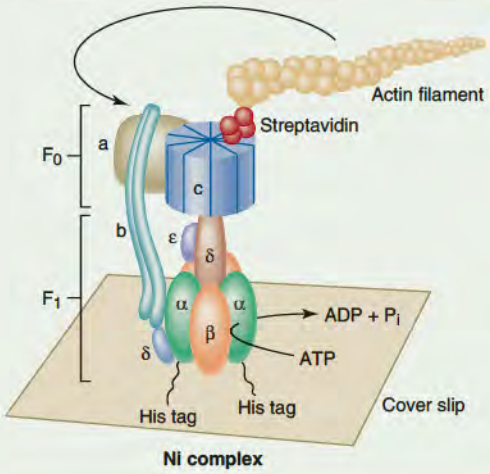
Transport of Adenine Nucleotides and Phosphate

Continued synthesis of ATP in the mitochondrial matrix requires that cytosolic ADP formed during energy-consuming reactions be transported back across the inner membrane into the matrix for conversion to ATP. Similarly, newly synthesized ATP must be transported back

A CLOSER LOOK 14.4

Experimental Evidence for Rotation of the γ- and *c*-Subunits by ATP Synthase

The binding-change model predicts that the γ-subunit should move in one direction during ATP synthesis and in the opposite direction during ATP hydrolysis, such that ATP hydrolysis results in formation of a proton gradient. The rotation of the γ-subunit in a single F_1 subunit was demonstrated by attaching a fluorescent actin polymer to the γ-subunit of an F_1 in which $\alpha_3\beta_3$ subunits were fixed to a microscope slide (see figure). Rotation of the fluorescent γ-subunit was observed on addition of ATP. Similar experiments were performed using the entire F_1/F_0 complex in which the complex of *c*-subunits along with the γ-subunit rotated as indicated by the fluorescent actin attached to one c subunit. Under both experimental conditions, the rotor movement was not continuous but occurred in discrete steps of approximately 120°, which is consistent with stepwise movement of γ-subunit from one β-subunit to another. ATP synthase is the smallest known molecular motor.



F_1 domain is attached to a nickel coated coverslip by histidine residues genetically engineered at the N-terminus of the α-subunits. Biotin, covalently attached to *c*-subunits, binds very tightly to the protein streptavidin that is covalently attached to an actin filament containing a fluorescent probe. Addition of ATP that is hydrolyzed by the ATPase of F_1 causes actin filament to rotate in one direction proving that *c*-subunit of F_0 rotates. Earlier experiments in which an actin filament was attached to γ-subunit provided evidence that γ-subunit can also rotate. Presumably, both γ- and *c*-subunits rotate as a unit. Redrawn from Sambongi, Y., Iko, Y., Tanabe, M., Omote, H., et al. *Science* 286:1722, 1999.

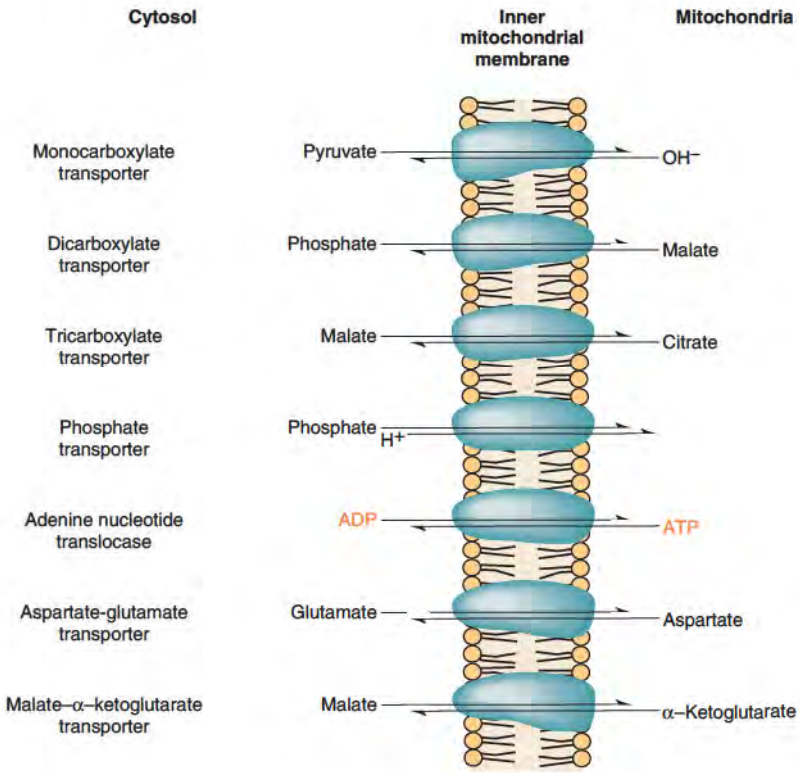


Figure 14.49 **Mitochondrial metabolite transporters.**

across the inner membrane into the cytosol to meet the energy needs of the cell. This exchange of the highly charged hydrophilic adenine nucleotides is catalyzed by a very specific **adenine nucleotide translocase** located in the inner membrane (Figure 14.50). The adenine nucleotide translocase, a homodimer of 30-kDa subunits, catalyzes a 1:1 exchange of ATP for ADP. The presence of one nucleotide-binding site on the transporter suggests that the enzyme alternately faces the matrix or the intermembrane space during the transport process. Newly synthesized ATP is bound to the translocase in the matrix, which then changes its conformation to face the cytosol where the ATP is released in exchange for an ADP. The translocase then changes conformation again to bring the nucleotide-binding site containing ADP back to face the matrix. The translocase favors outward movement of ATP and inward movement of ADP despite observations that both nucleotides bind equally well to the binding site. The explanation for this is that at pH 7, ADP has three negative charges whereas ATP has four. Hence, the exchange of one ATP for one ADP results in net outward movement of one negative charge, which is equivalent to import of one proton. The membrane potential established during electron transfer is positive outside, which would favor outward transport of more negatively charged ATP over that of ADP. The adenine nucleotide translocase is present in high concentrations, up to 14% of total protein, in the inner membrane. Hence, it is unlikely that transport of adenine nucleotides across the inner mitochondrial membrane is ever rate limiting for ATP synthesis.

A second transporter essential for oxidative phosphorylation is the **phosphate transporter**, which transports cytosolic phosphate plus a proton into the matrix (Figure 14.50). This symport also depends on the proton gradient as phosphate and protons are transported in a 1:1 ratio. Transport of ADP and phosphate requires a significant fraction of the energy present in the electrochemical gradient produced during electron transfer. Thus, the protonmotive force provides energy for ATP synthesis by ATP synthase as well as for uptake of the two required substrates.

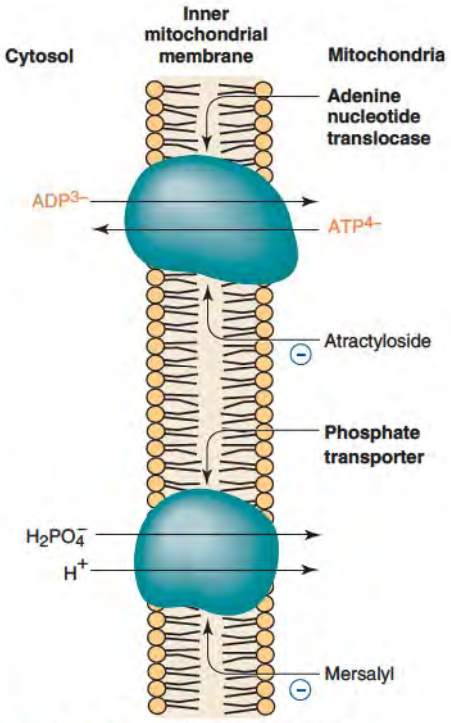

Figure 14.50 The adenine nucleotide translocase and phosphate transporter.

Substrate Shuttles Transport Reducing Equivalents across the Inner Mitochondrial Membrane

The nucleotides involved in cellular oxidation–reduction reactions (e.g., NAD^+, NADH, $NADP^+$, NADPH, FAD, and $FADH_2$) and CoA and its derivatives are not transported across the inner mitochondrial membrane. Thus, to transport reducing equivalents (e.g., protons and electrons) from cytosol to matrix or the reverse, substrate shuttle mechanisms are required.

Two substrate transport shuttles are shown in Figure 14.51. The malate–aspartate shuttle and α-glycerol–phosphate shuttle are employed in various tissues to translocate reducing equivalents from cytosol to matrix for oxidation to yield energy. Their operation requires that appropriate enzymes are localized on either side of the membrane and that appropriate transporters be present in the mitochondrial inner membrane.

In the **glycerol–phosphate shuttle**, two glycerol phosphate dehydrogenases, one in the cytosol and the other on the outer face of the inner mitochondrial membrane, are involved. NADH produced in the cytosol is used to reduce dihydroxyacetone phosphate to glycerol 3-phosphate by the cytosolic isozyme. The glycerol 3-phosphate in turn is oxidized by the mitochondrial isozyme, a flavoprotein, to produce dihydroxyacetone phosphate and $FADH_2$ that is oxidized by the electron transport chain.

The **malate–aspartate shuttle** operates on the same principle. NADH in the cytosol reduces oxaloacetate to malate, which enters mitochondria on the malate/α-ketoglutarate transporter. This malate is readily oxidized by mitochondrial malate dehydrogenase to oxaloacetate and NADH that is then oxidized by the electron transport chain. The oxaloacetate produced is converted to aspartate by mitochondrial aspartate aminotransferase and can then cross the membrane via the aspartate–glutamate transporter where cytosolic aspartate amino transferase converts it to oxaloacetate. The antiport transport of aspartate out of mitochondria in exchange for glutamate is driven by the membrane potential and is therefore irreversible.

Acetyl Units Are Transported as Citrate

The inner mitochondrial membrane does not have a transporter for acetyl CoA, but acetyl groups are transferred from the mitochondria to cytosol, where they are required

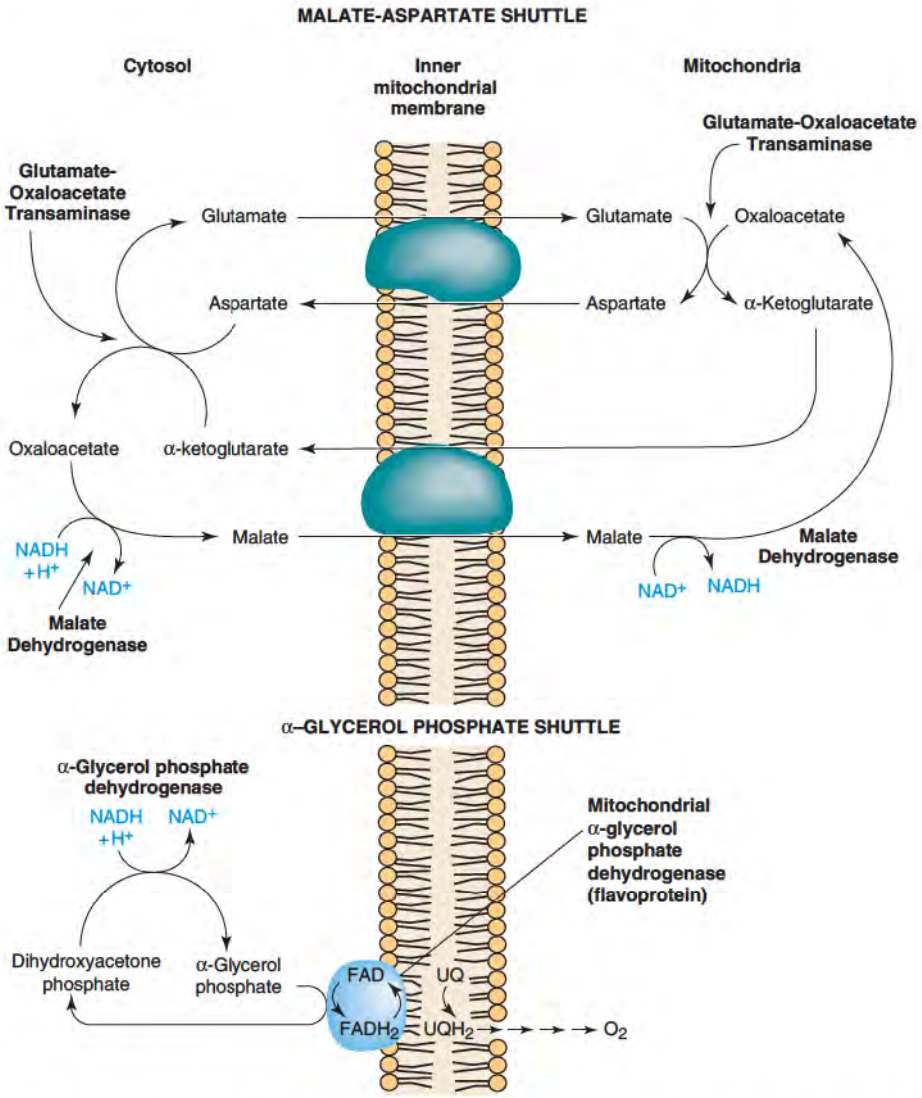

Figure 14.51 Transport shuttles for reducing equivalents.

for fatty acid or sterol biosynthesis (Figure 14.52). Intra-mitochondrial acetyl CoA is converted to citrate by citrate synthase of the TCA cycle. Citrate is then exported to cytosol by a tricarboxylate transporter in exchange for malate. Cytosolic citrate is cleaved to acetyl CoA and oxaloacetate at the expense of an ATP by **ATP-citrate lyase** (p. 684). Substrate shuttle mechanisms are involved in movement of appropriate substrates and

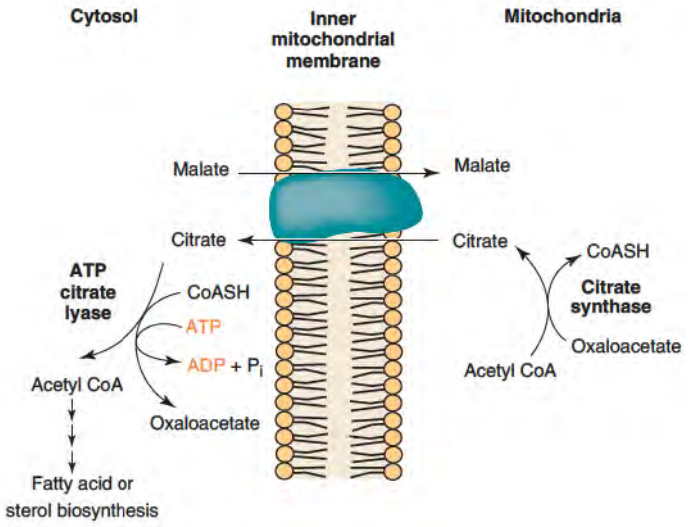

Figure 14.52 Export of citrate generated in mitochondria to cytosol where it serves as a source of acetyl CoA for biosynthesis of fatty acids or sterols.

intermediates in both directions across the inner membrane during periods of active gluconeogenesis (p. 619) and ureagenesis (p. 758) by the liver.

Mitochondria Have a Specific Calcium Transporter

In most mammalian tissues, mitochondria have a transport system for translocating Ca^{2+} across the inner membrane. The distribution/redistribution of cellular Ca^{2+} pools within cells is critical for muscle contraction, neural transmission, secretion, and hormone action. Distinct pools of Ca^{2+} have been detected in endoplasmic reticulum (or sarcoplasmic reticulum), mitochondria, nuclei, and Golgi. Some intracellular Ca^{2+} is bound to nucleotides, metabolites, or membrane ligands, while a portion is free in solution. Cytosolic Ca^{2+} concentration is about 10^{-7} M, whereas the extracellular concentration is at least four orders of magnitude greater. Ca^{2+} entry into mitochondria is by a uniporter in the inner membrane, which uses the energy of the electrochemical gradient (Figure 14.53). Confocal microscopy of living cells has provided convincing evidence that mitochondria take part in regulation of cytosolic Ca^{2+} concentration. Mitochondria are localized in close proximity to endoplasmic reticulum and sarcoplasmic reticulum. The binding of certain hormones to cell membranes results in release of inositol trisphosphate (IP_3) from phosphatidyl inositol, which releases Ca^{2+} from endoplasmic reticulum (p. 16). The resulting transient microdomains of high Ca^{2+} concentrations may be modulated by uptake into nearby mitochondria. In mitochondria, Ca^{2+} regulates the pyruvate dehydrogenase complex as well as isocitrate and α-ketoglutarate dehydrogenases. One consequence of uptake of high concentrations of Ca^{2+} into mitochondria is the opening of a pore on the outer membrane leading to release of cytochrome *c* into cytosol and activation of apoptosis.

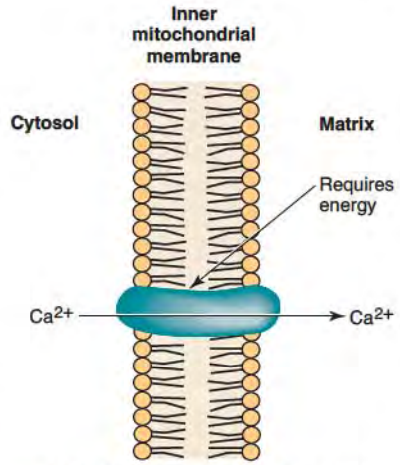

Figure 14.53 Mitochondrial calcium carrier.

Uncoupling Proteins

Brown adipose tissue plays a major role in nonshivering thermogenesis in newborns, in hibernating animals, and in experimental animals in diet-induced thermogenesis. The primary agent involved in cold-induced thermogenesis in brown fat is the uncoupling protein, UCP-1, which is localized exclusively in the inner mitochondrial membrane of brown adipose tissue. UCP-1 carries protons from the mitochondrial matrix and acts to uncouple ATP synthesis from electron transport (Figure 14.54). Thermogenesis results from activation of

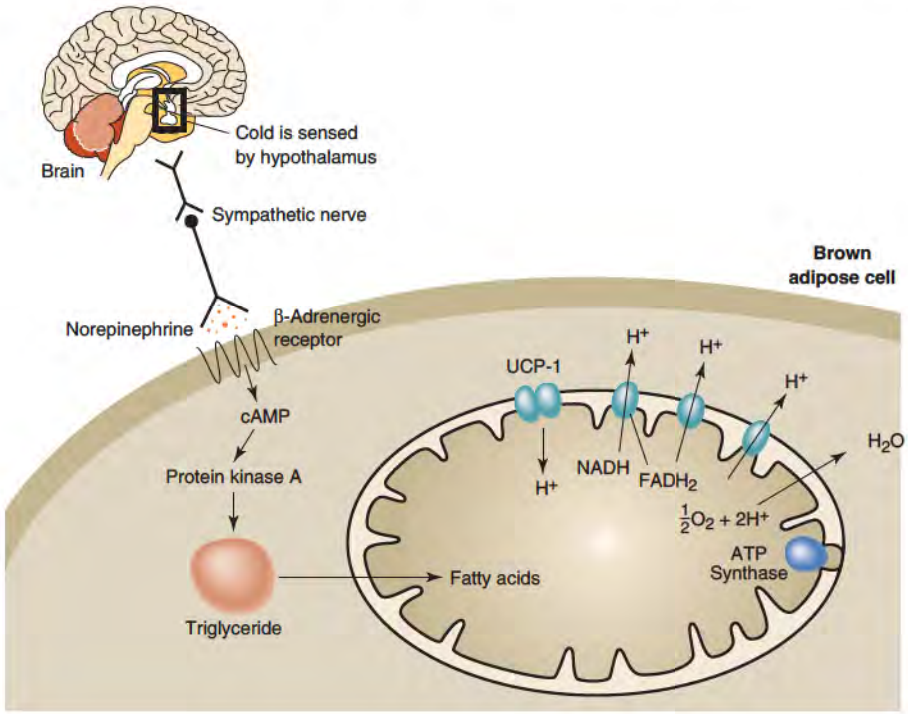

Figure 14.54 Activation of UCP-1 by cold adaptation. Cold stimulates release of norepinephrine from sympathetic nerve cells. The norepinephrine binds to the β-adrenergic receptor resulting in activation of a lipase with production of free fatty acids that activate proton-conducting protein, UCP-1.

sympathetic nerves by the brain responding to cold exposure with the release of norepinephrine that binds to β-adrenergic receptors on cell membranes of brown fat cells. This binding causes release of cAMP and the activation of protein kinase A, which stimulates lipolysis. The production of free fatty acids activates UCP-1, which transports protons back into the matrix (Figure 14.54). The stimulation of proton transport by free fatty acids is believed to result from release of a proton from the carboxyl group of the free fatty acid. UCP-1 is a member of the mitochondrial transporter family that includes the adenine nucleotide translocase and the phosphate transporter but with a specific pore for the transport of protons into the matrix. Chronic cold-induced stimulation of the β-adrenergic receptor by norepinephrine results in increased transcription of the UCP-1 gene, stimulation of mitochondrial biogenesis, and eventual hyperplasia of brown adipose tissue. In large mammals, such as dogs, cats, and primates who do not hibernate, including humans, discrete deposits of brown fat are present at birth, but become sparse during later development.

Four other uncoupling proteins, UCP-2, UCP-3, UCP-4, and UCP-5, with sequences similar to that of UCP-1 have been discovered in tissues other than brown adipose tissue. The presence of uncoupling proteins in tissues such as skeletal muscle has prompted investigations into the possible role of these proteins in regulation of energy expenditure and perhaps obesity. Development of pharmacological agents that affect uncoupling proteins has been suggested as a treatment for obesity. Recently, it has been suggested that uncoupling proteins may act to prevent the formation of reactive oxygen species in mitochondria.

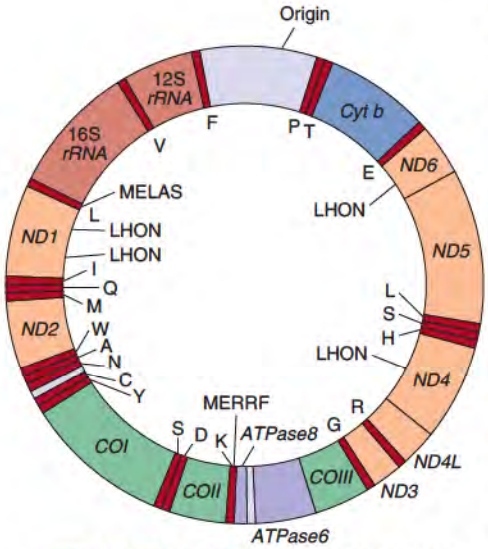

Figure 14.55 Map of genes on mitochondrial DNA. The indicated genes CO1, CO11, and CO111 encode subunits of cytochrome *c* oxidase, ND encode subunits of complex I, and ATPase encode subunits of ATP synthase. The dark red bands indicated by single letters are the genes for tRNAs. LHON indicates location of mutations causing Leber's Hereditary Optic Neuropathy. Mutations in the tRNA for leucine (L) cause MELAS (mitochondrial encephalopathy, lactic acidosis and strokelike activity), and those in the tRNA for lysine (K) cause MERRF (myoclonic epilepsy and ragged red fibers).

14.9 • MITOCHONDRIAL GENES AND DISEASES

Mitochondria contain their own genome, a circular double-stranded DNA that contains structural genes for 13 proteins of the electron transport chain including seven subunits of complex I (NADH:ubiquinone (oxidoreductase), one subunit (cytochrome *b*) of complex III (ubiquinol:cytochrome *c* oxidoreductase), three subunits of complex IV (cytochrome *c* oxidase), and two subunits of complex V (ATP synthase) (Table 14.7). Mitochondrial DNA (mtDNA) also contains genes encoding two ribosomal RNAs (rRNAs) and all the transfer RNAs (tRNAs) required for protein synthesis in mitochondria (Figure 14.55). Mitochondria, however, are not self-replicating organelles as over 90% of all mitochondrial proteins are encoded in nuclear DNA, synthesized in the cytosol, and then imported into mitochondria.

Mitochondrial defects have been implicated in several degenerative diseases of aging including Parkinson and Alzheimer diseases. Several diseases arise from point mutations in mtDNA involving either tRNAs or one of the structural genes. Other diseases arise from deletions of large portions of mtDNA. Generally, these diseases result from decreased activity of the electron transport chain, which leads to the accumulation of pyruvate and fatty acids with resultant lactate acidosis and accumulation of triglycerides. The rate of ATP synthesis is also decreased, resulting in muscle weakness and exercise intolerance. A hallmark of all mitochondrial diseases is their maternal inheritance, because essentially all mitochondria present in a fertilized ovum are derived from the egg. See Clin. Corrs. 14.4, 14.5, and 14.6 for a discussion of diseases resulting from mutations in mtDNA.

TABLE 14.7 • Subunits of Electron Transport Complexes Encoded by Human Mitochondrial DNA

Complex		*Total Number of Subunits*	*Number of Subunits Encoded by Mitochondrial DNA*
I	NADH–ubiquinone oxidoreductase	>40	7
II	Succinate dehydrogenase	4	0
III	Ubiquinol–cytochrome *c* oxidoreductase	11	1
IV	Cytochrome *c* oxidase	13	3
V	ATP synthase	12	2

CLINICAL CORRELATION 14.4

Leber Hereditary Optic Neuropathy (OMIM 535000)

The first mitochondrial disease to be elucidated at the molecular level is maternally inherited Leber hereditary optic neuropathy (LHON), which affects the central nervous system, including the optic nerves, causing sudden-onset blindness in early adulthood due to the death of the optic nerve. In nearly all families, LHON results from single base changes in the mitochondrial genes encoding three subunits of complex I (ND1, ND4, and ND6), which lower activity of NADH: ubiquinone oxidoreductase (complex I).

The severity of mitochondrial diseases depends on the amount of mutated mtDNA present in a given cell or tissue. The presence of hundreds or thousands of mitochondria in each cell allows for considerable variation in the amount of mutant mtDNA in a tissue as a consequence of the random distribution of mutant mtDNA to the daughter cells at cell division. Patients with a lower percentage of mutant mtDNA develop sudden-onset blindness and other symptoms typical of LHON in early adulthood. Patients with a higher percentage of the mutant mtDNA in which a conserved alanine is replaced by a valine in ND6 develop a severe disease characterized by the early onset of generalized movement disorder, impaired speech, and mental retardation.

Chalmers, R. M., and Schapira, A. H. V. Clinical, biochemical and molecular genetic features of Leber hereditary optic neuropathy. *Biochim. Biophys. Acta* 1410:147, 1999.

CLINICAL CORRELATION 14.5

Mitochondrial Myopathies from Mutations in Mitochondrial tRNA Genes

Point mutations in genes encoding mitochondrial tRNAs result in two of the most common mitochondrial diseases characterized by encephalomyopathy. A mutation in the tRNA gene for lysine causes **m**yoclonic **e**pilepsy and **r**agged **r**ed **f**ibers (MERRF) (OMIM 545000). Symptoms include myoclonus and ataxia with generalized seizures and myopathy. The skeletal muscles contain abnormally shaped mitochondria that contain paracrystalline structures giving an appearance of ragged red fibers (see figure) and decreased cytochrome *c* oxidase activity.

Mutation in the tRNA for leucine causes the common **m**itochondrial **e**ncephalopathy, **l**actic **a**cidosis and **s**troke-like activity (MELAS) (OMIM 540000). The skeletal muscles contain ragged red fibers but retain cytochrome *c* oxidase activity. The severity of symptoms varies with the percentage of mutated mtDNAs. Patients with >85% mutated DNA present with the more severe central nervous symptoms, those with 5%–30% mutated DNA often present with maternally inherited diabetes mellitus and deafness.

Example of paracrystalline inclusions in mitochondria from muscles of ocular myopathic patient (×36,000).
Courtesy of Dr. D. N. Landon, Institute of Neurology, University of London.

The biochemical consequence of both of these tRNA mutations is impaired mitochondrial protein synthesis leading to decreased activities of complex I and cytochrome *c* oxidase.

Wallace, D. C. Mitochondrial diseases in man and mouse. *Science* 283:1482, 1999.

Other mutations in mitochondrial genes lead to progressive muscular weakness, retinitis pigmentosa (loss of retinal response), hearing loss, and ataxia (uncoordinated muscular action), plus enlargement and deterioration of heart muscle. The deleterious effects of aging may also result from mutations that accumulate in mtDNA throughout the life of the individual, which are caused by DNA-damaging agents such as oxygen radicals.

14.10 • REACTIVE OXYGEN SPECIES (ROS)

Oxygen is essential to life. Most intracellular oxidations result in transfer of two electrons to appropriate acceptors such as NAD^+ or FAD, which are then oxidized by the electron transport chain. The terminal step in this chain is catalyzed by cytochrome *c* oxidase, which tightly binds O_2 to the binuclear center where stepwise reduction of O_2 occurs without release of intermediates in the oxidation process (see Section 14.6, p. 561). The electronic structure of O_2, however, favors its reduction by addition of one electron at a time leading

CLINICAL CORRELATION 14.6

Exercise Intolerance in Patients with Mutations in Cytochrome *b*

In 1993, a mutation in cytochrome *b* resulting in lowered activity of the cytochrome bc_1 complex was reported in a 25-year old man who presented with exercise intolerance and proximal weakness. The mutation substituted an aspartate residue for a conserved glycine at position 290. Subsequently, other patients with similar symptoms and lowered bc_1 complex activity were shown to have mutations in which glutamate was substituted for a conserved glycine at position 339, and serine for a conserved glycine at position 34. More recently, a patient with severe hypertrophic cardiomyopathy was shown to have a mutation in which a glutamate was substituted for a conserved glycine at position 166. The mutations of glycine to aspartate or glutamate were located in cytochrome *b* close to the Q_O site for ubiquinol oxidation, while the glycine to serine mutation was located near the Q_i site of ubiquinone reduction. All these mutations involved a guanine to adenine transition in the mtDNA suggesting that the mutation may have resulted from oxidative damage. Moreover, in each of the missense mutations a conserved glycine was replaced by a larger charged molecule, which altered the structure of cytochrome *b* resulting in lowered catalytic activity of the bc_1 complex. Nonsense mutations resulting in truncation of cytochrome *b* and mutations involving deletions of 4 to 24 base pairs of mtDNA have been identified. These nonsense and deletion mutations often lead to severe exercise intolerance, lactic acidosis in the resting state and occasionally myoglobinuria. In contrast to the majority of mutations in mtDNA, the mutations identified in the cytochrome *b* gene were not maternally inherited. Moreover, most have only been expressed in muscle tissues suggesting that these are somatic mutations, which occurred during germ-layer differentiation of myogenic stem cells.

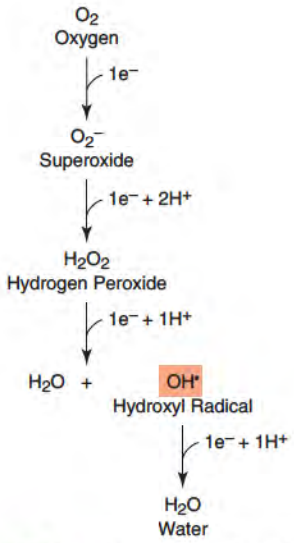

Figure 14.56 One electron steps in reduction of oxygen leading to formation of reactive oxygen species superoxide, hydrogen peroxide, and hydroxyl radical.

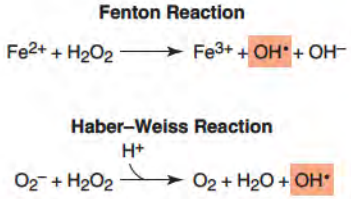

Figure 14.57 The Fenton and Haber–Weiss reactions for formation of toxic hydroxyl radical.

to the generation of oxygen radicals that can cause cellular damage. A radical is a molecule with a highly reactive unpaired electron in an outer orbital, which can initiate chain reactions by removal of an electron from another molecule to complete its own orbital. The stepwise transfer of electrons to O_2 results in the sequential formation of superoxide anions (O_2^-), hydrogen peroxide (H_2O_2), and finally **hydroxyl free radicals (OH·)** (Figure 14.56). The hydroxyl radical is undoubtedly the most dangerous free radical as it is involved in reactions such as lipid peroxidation and generation of other toxic radicals. Hydrogen peroxide itself is not a free radical, but is converted by the Fenton or Haber–Weiss reactions to the hydroxyl radical in the presence of Fe^{2+} or Cu^+, which are prevalent in cells (Figure 14.57).

Production of Reactive Oxygen Species

While oxidative processes in cells generally result in transfer of electrons to O_2 to form water without release of intermediates, a small number of oxygen radicals are inevitably formed due to leakage in electron transfer reactions. The major intracellular source of oxygen radicals is the mitochondrial electron transport chain where superoxide is produced by transfer of one electron to O_2 from the stable semiquinone produced during reduction of ubiquinone by complexes I and II or during oxidation of ubiquinol by complex III (Figure 14.58). Superoxide can also be produced by transfer of an electron from a flavin such as FMN. The reactive oxygen species produced in mitochondria include superoxide, hydrogen peroxide, and hydroxyl radical. Toxic oxygen species are also produced in peroxisomes in which long-chain fatty acids and other compounds are oxidized by transfer of two electrons from $FADH_2$ to O_2 with formation of hydrogen peroxide, which is readily converted to hydroxyl radical (see Figure 14.56). The cytochrome P450 system localized in endoplasmic reticulum can also produce oxygen radicals.

An additional source of ROS in many tissues in the body including neutrophils is the membrane-bound NADPH-dependent oxidase system. Inflammation due to bacterial infection in neutrophils results in the activation of NADPH oxidase which produces superoxide in a process known as the respiratory burst. The conversion of superoxide to hydroxyl radical kills bacteria which are then engulfed by phagocytes (Figure 14.59). In an acute infection, production of oxygen radicals and killing of bacteria are efficient processes; however, in prolonged infections, phagocytes tend to die, releasing toxic oxygen radicals that affect surrounding cells.

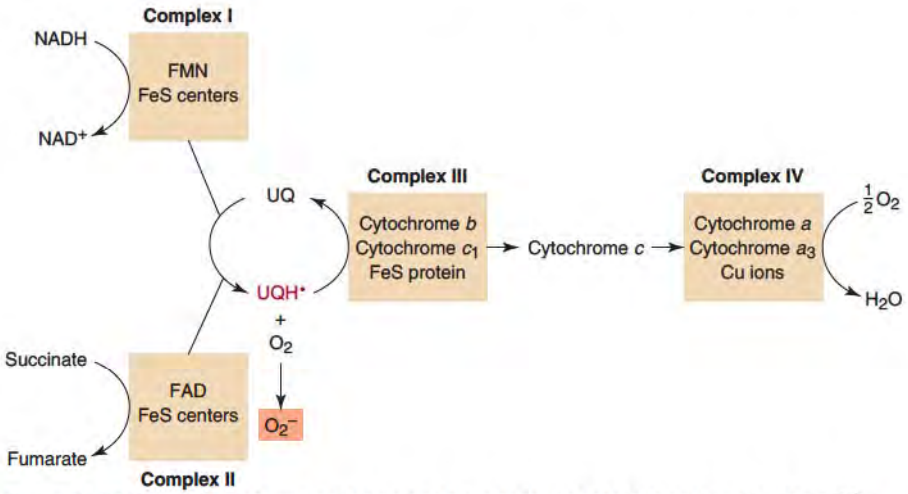

Figure 14.58 Generation of superoxide anions by mitochondrial electron transfer chain. The semiquinone formed during the two electron reduction of ubiquinone by the iron–sulfur centers of both complexes I and II can transfer an electron to oxygen to form the superoxide anion. By contrast, the binuclear center of cytochrome *c* oxidase prevents release of intermediates in the reduction of oxygen.

In addition to its presence in phagocytes, different forms of NADPH oxidase have been reported in many tissues in the body, where they are the major non-mitochondrial source of ROS. The physiological role of these NADPH oxidases in cardiovascular tissues includes cellular processes such as signal transduction, cell proliferation, and apoptosis. Evidence suggests that excess NADPH oxidase can generate ROS contributing to pathological conditions such as atheroslcerosis, hypertension, and other vascular pathologies (Clin. Corr. 14.7).

Cosmic radiation, ingestion of chemicals, and drugs, as well as smog, can lead to formation of reactive oxygen species. Damage from reactive oxygen species often occurs during perfusion of tissues with solutions containing high concentrations of O_2 as happens in patients who have suffered an ischemic episode in which localized O_2 levels are lowered due to blockage of an artery and have then undergone thrombolytic or other procedures to remove the blockage (Clin. Corr. 14.8).

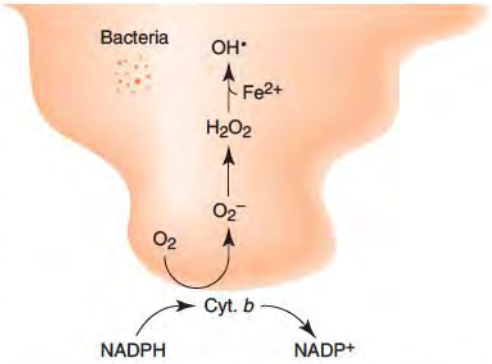

Figure 14.59 Respiratory burst in phagocytes. An electron transfer chain involving a unique cytochrome *b* transfers electrons from NADPH to oxygen with formation of superoxide anion. Superoxide is converted to the hydroxyl radical that kills bacteria subsequently engulfed by phagocytes.

CLINICAL CORRELATION 14.7

NADPH Oxidase (NOX) in Health and Disease

The discovery and characterization of NADPH-dependent oxidase (NOX) in phagocytic cells had suggested that this tissue was the sole location of NOX in the body, where its physiological role was to produce large amounts of superoxide to kill microbes. Elucidation of the biochemical properties of phagocytic NOX also benefited from studies of patients with chronic granulomatous disease, which presents as an inability of affected individuals to combat infection resulting from mutations in NOX, which lead to loss of ability to produce adequate amounts of superoxide. The recent development of more sensitive methods to detect the reactive oxygen species, superoxide and hydrogen peroxide, indicated that NOX was more widely distributed in the body and that furthermore ROS might contribute to physiological processes in non-phagocytic tissues. Subsequently, seven different isoforms of NOX family have been identified in almost all tissues of the body. The role of NOX and superoxide production in nonphagocytic tissues has not been completely resolved as the low levels of these enzymes hinder direct measurements; however, NOX in all tissues is activated by various stimuli and may trigger redox-sensitive signaling pathways that are involved in endothelial activation, cell growth, and apoptosis. Recent studies have revealed the presence of three different isoforms of NOX in cardiovascular tissues; smooth muscle, endothelium, cardiomyocytes, and vascular adventitium. These isoforms of NOX are thought to contribute to maintenance of vascular tone, cell proliferation, angiogenesis, and apoptosis. In addition to the role of NOX in these pathways, the regulatory pathways that maintain vascular tone reflect a complex interplay between ROS and reactive nitrogen species (NO) produced by endothelial nitric oxide synthase.

Despite the beneficial roles of NOX in cell processes, excess ROS generated by NOX may result in numerous pathological conditions including endothelial cell dysfunction that contributes to atherosclerosis, hypertension, congestive heart failure, ischemic reperfusion injury, and the vascular problems associated with diabetes. Continued investigations of the role that NOX plays in normal physiological and in pathological processes will provide insights into the development of therapies needed to combat the chronic diseases that plague humans.

CLINICAL CORRELATION 14.8

Myocardial Reperfusion Injury

The occlusion of a major coronary artery during myocardial infarction results in ischemia or lowered oxygen supply to the affected area leading to damaged cells, the infarct. After an acute myocardial infarction, early reperfusion with appropriate therapy results in reduction of the size of the infarct and a better clinical outcome for the patient. Restoring blood flow to the ischemic tissue, however, may damage the heart in a process termed myocardial reperfusion injury. During reperfusion, the ischemic myocardium is subject to rapid biochemical changes, which may cause further damage to the myocardium. These changes include rapid restoration of electron transfer through the mitochondrial electron transfer chain with the concomitant generation of ROS, which are also generated by xanthine oxidase present in endothelial cells and several hours later by NADPH oxidase located in neutrophils. These increased levels of ROS cause damage to the heart by contributing to intracellular Ca^{2+}overload, rapid restoration of intracellular pH, and inflammation. The increase in intra-mitochondrial Ca^{2+} leads to the opening of the mitochondrial transition pore (MRP), which triggers apoptosis and subsequent cell death. ROS also damage the sarcoplasmic reticulum and cell membrane by lipid peroxidation, induce enzyme denaturation, and cause oxidative damage to DNA. The rapid increase in intracellular ATP levels that occurs when oxygen is introduced during reperfusion due to stimulation of mitochondrial electron transfer combined with the high intracellular levels of Ca^{2+} and restoration of physiologic pH may result in hypercontracture and the resultant death of cardiomyocytes.

The formation of ROS during myocardial reperfusion also results in lowered levels of nitric oxide (NO), an important signaling molecule, thus reducing its protective effects such as neutrophil accumulation, inactivation of superoxide radicals, and improvement of coronary blood flow. During reperfusion of the ischemic heart, the presence of the oxygen radical peroxynitrite ($ONOO^-$) produced from NO and superoxide, has been reported. Peroxynitrite may also contribute to the poor recovery of mechanical function in ischemic hearts.

Myocardial ischemia-reperfusion represents a clinical problem associated with thrombolysis, angioplasty, and coronary bypass surgery. Injuries to the myocardium due to ischemia-reperfusion include cardiac contractile dysfunction, arrhythmias, and irreversible myocyte damage. Ischemia may also arise during surgery especially during transplantation of tissues. Current investigations of possible interventions to prevent reperfusion injury are focused on better understanding of the factors involved in injury especially the opening of the mitochondrial PTP that results in cell death by apoptosis. Clinical trials are currently underway to test new hypotheses to reduce injury from reperfusion. The increased use of invasive procedures in clinical medicine indicates the importance of developing methods to protect against ischemic-reperfusion injury.

Damage Caused by Reactive Oxygen Species

Reactive oxygen species cause damage to all major classes of macromolecules in cells. The phospholipids of plasma and organelle membranes are subject to lipid peroxidation, a free-radical chain reaction initiated by removal of hydrogen from a polyunsaturated fatty acid by hydroxyl radical. The resulting lipid radicals then react with O_2 to form lipid peroxy radicals and lipid peroxide along with malondialdehyde, which is water soluble and can be detected in blood. The effect of lipid peroxidation in humans is exemplified by the brown spots commonly observed on hands of the elderly. These "age" spots contain the pigment lipofuscin, which is probably a mixture of cross-linked lipids and products of lipid peroxidation, which accumulate over the course of a lifetime. One significant consequence of lipid peroxidation is increased membrane permeability leading to an influx of Ca^{2+} and other ions with subsequent swelling of the cell. Similar increases in permeability of organelle membranes may result in maldistribution of ions and cause intracellular damage. For example, accumulation of excessive amounts of Ca^{2+} in mitochondria may trigger apoptosis.

Proline, histidine, arginine, cysteine, and methionine are susceptible to attack by hydroxyl radicals with subsequent fragmentation of proteins, cross-linking, and aggregation. Proteins damaged by oxygen radicals may be targeted for digestion by intracellular proteases.

The most important consequence of oxygen radicals is damage to mitochondrial and nuclear DNA resulting in mutations. The nonspecific binding of ferrous ions (Fe^{2+}) to DNA may result in localized formation of hydroxyl radicals that attack individual bases and cause strand breaks. Mitochondrial DNA is more susceptible to damage, since the electron transport chain is a major source of toxic oxygen radicals. In addition, nuclear DNA is protected from permanent damage by a protective coat of histones as well as by active

and efficient mechanisms for DNA repair. Damage to mtDNA generally results in mutations that affect energy production. The symptoms in effected individuals are manifest in energy requiring processes such as muscle contraction. An example of the consequences of a somatic mutation in the mitochondrial gene for cytochrome *b* that may have been caused by oxygen radicals is presented in Clin. Corr. 14.6, page 584.

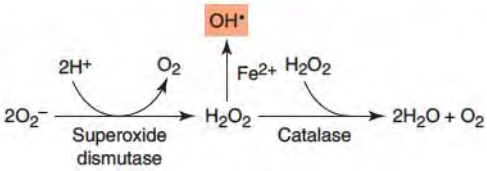

Figure 14.60 Superoxide dismutase and catalase protect cells by removing superoxide and hydrogen peroxide.

Cellular Defenses against Reactive Oxygen Species

Cells that live in an aerobic environment have developed multiple ways to remove reactive oxygen species and thus protect themselves against their deleterious effects. Mammals have three different isozymes of **superoxide dismutase** that catalyze conversion of superoxide to hydrogen peroxide (Figure 14.60). The cytosolic form of superoxide dismutase contains Cu/Zn at its active site, as does the extracellular enzyme; however, the mitochondrial enzyme contains Mn at its active site. Hydrogen peroxide is removed by catalase, a heme-containing enzyme present in highest concentration in peroxisomes and to a lesser extent in mitochondria and cytosol.

Glutathione peroxidase catalyzes reduction of both hydrogen peroxide and lipid peroxides (Figure 14.61). This selenium-containing enzyme uses the sulfhydryl groups of glutathione (GSH) as a hydrogen donor with formation of oxidized or disulfide form of glutathione (GSSG). **Glutathione reductase** converts the disulfide form back to the sulfhydryl form using NADPH produced in the pentose phosphate pathway as an electron donor. The importance of NADPH in maintaining glutathione levels and thus preventing oxidative damage in cells is manifest in the inherited disorder resulting in lowered levels of glucose 6-phosphate dehydrogenase (see Clin. Corr. 16.1, p. 648) in which oxidative stress results in acute hemolytic anemia. Glutathione levels in the liver are critical to prevent hepatic necrosis induced by the common pain killer acetaminophen (sold as Tylenol, Panadol, or Paracetomol) especially in young children.

Protection against reactive oxygen species may also be gained by ingestion of oxygen scavengers such as vitamins C and E and β-carotene. Recent evidence has indicated that substances present in green tea, berries (especially blueberries), and red wine may also protect against oxidative damage by ROS.

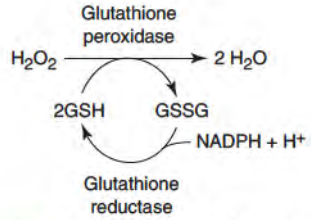

Figure 14.61 Glutathione peroxidase removes hydrogen peroxide as well as lipid peroxides. Electrons are transferred to hydrogen peroxide from the sulfhydryl groups of reduced glutathione (GSH) to form water and oxidized glutathione (GSSG). Glutathione reductase then reduces GSSG to GSH with NADPH as the reducing agent.

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. A bond may be *high energy* for any of the following reasons except
   A. products of its cleavage are more resonance stabilized than the original compound.
   B. the bond is unusually stable, requiring a large energy input to cleave it.
   C. electrostatic repulsion is relieved when the bond is cleaved.
   D. a cleavage product may be unstable, tautomerizing to a more stable form.
   E. the bond may be strained.

2. All of the following tricarboxylic acid cycle intermediates may be added or removed by other metabolic pathways except
   A. citrate.
   B. fumarate.
   C. isocitrate.
   D. α-ketoglutarate.
   E. oxaloacetate.

3. The inner mitochondrial membrane contains a transporter for
   A. NADH.
   B. acetyl CoA.
   C. GTP.
   D. ATP.
   E. NADPH.

4. During the transfer of electrons to O_2 via the mitochondrial electron transport chain,
   A. the energy released is used to translocate protons across the inner membrane.
   B. a proton gradient is generated with the matrix now being more positive than the intermembrane space.
   C. pumping of protons across the membrane occurs each time electrons are moved.
   D. no charge gradient develops because an OH^- moves each time a proton does.
   E. the energy is used directly in the addition of P_i to ADP to form ATP.

5. ATP synthase (also known as complex V) consists of two domains, F_1 and F_o.
   A. F_1 and F_o are both integral membrane protein complexes of the outer membrane.
   B. F_1 domain provides a channel for translocation of protons across the membrane.
   C. F_1 binds ATP but not ADP.
   D. F_1 domain catalyzes the synthesis of ATP.
   E. Only the F_o domain contains more than one subunit.

6. All of the following statements are correct except
   A. reactive oxygen species (oxygen radicals) result when there is a concerted addition of four electrons at a time to O_2.
   B. superoxide anion (O_2^-) and hydroxyl radical (·OH) are two forms of reactive oxygen.
   C. superoxide dismutase is a naturally occurring enzyme that protects against damage by converting O_2^- to H_2O_2.
   D. reactive oxygen species damage phospholipids, proteins, and nucleic acids.
   E. glutathione protects against H_2O_2 by reducing it to water.

Questions 7 and 8: A child presented with severe neurological defects. Blood tests indicated elevated serum levels of lactate, pyruvate, and alanine. Cultures of skin fibroblasts showed deficient activity of the pyruvate–dehydrogenase complex. Further study might indicate which subunit of the complex is defective, although the metabolic effects are essentially the same regardless of which subunit is defective.

7. The active form of pyruvate dehydrogenase is favored by the influence of all of the following on pyruvate dehydrogenase kinase except
   A. low $[Ca^{2+}]$.
   B. low acetyl CoA/CoASH.
   C. high [pyruvate].
   D. low $NADH/NAD^+$.

8. Suppose the specific defect were a mutant pyruvate dehydrogenase (the first catalytic subunit) with poor binding of its prosthetic group. In this type of defect, sometimes greatly increasing the dietary precursor of the prosthetic group is helpful. In this case, increasing which of the following might be helpful?
   A. Lipoic acid
   B. Niacin (for NAD)
   C. Pantothenic acid (for CoA)
   D. Riboflavin (for FAD)
   E. Thiamin (for TPP)

Questions 9 and 10: There are a number of mitochondrial diseases arising from mutations in the mitochondrial genes encoding for mitochondria proteins of mitochondrial tRNAs. Leber Hereditary Optic Neuropathy (LHON) arises from single base changes in the mitochondrial genes encoding three subunits of complex I, diminishing its activity. LHON affects the central nervous system, including the optic nerves, causing sudden-onset blindness in early adulthood.

9. Complex I
   A. transfers electrons directly from NADH to ubiquinone.
   B. can transfer electrons from the $FADH_2$ of succinate dehydrogenase as well as from NADH.
   C. does not contain FeS centers.
   D. transfers electrons coupled to the transport of four protons across the membrane.
   E. is considered a mobile electron carrier because it can travel along the outer face of the inner membrane.

10. An inability to reoxidize NADH because of the defect of complex I would
    A. inhibit isocitrate dehydrogenase and, therefore, inhibit the rate of the TCA cycle.
    B. force the oxaloacetate–malate equilibrium toward oxaloacetate.
    C. promote the α-glycerol phosphate shuttle for transporting reducing equivalents.
    D. cause NADH to freely diffuse from the mitochondria to the cytosol.
    E. force the succinate–fumarate equilibrium toward succinate.

Questions 11 and 12: Cyanide is a potent and rapidly acting poison. It binds to the heme of the cytochrome a_3 in cytochrome oxidase. Death occurs from tissue anoxia, especially in the central nervous system. An antidote to cyanide poisoning, which must be given rapidly, is the administration of a nitrite to convert oxyhemoglobin to methemoglobin. Methemoglobin competes with cytochrome a_3 for cyanide.

11. Cyanide
    A. only minimally inhibits the electron transport chain because cytochrome oxidase is a terminal component of the chain.
    B. inhibits mitochondrial respiration but energy production is unaffected.
    C. also binds the copper of cytochrome oxidase.
    D. binds to Fe^{3+} of cytochrome a_3.
    E. poisoning could also be reversed by increasing O_2 concentration.

12. If cyanide is added to tightly coupled mitochondria that are actively oxidizing succinate,

- **A.** subsequent addition of 2,4-dinitrophenol will cause ATP hydrolysis.
- **B.** subsequent addition of 2,4-dinitrophenol will restore succinate oxidation.
- **C.** electron flow will cease, but ATP synthesis will continue.
- **D.** electron flow will cease, but ATP synthesis can be restored by subsequent addition of 2,4-dinitrophenol.
- **E.** subsequent addition of 2,4-dinitrophenol and the phosphorylation inhibitor, oligomycin, will cause ATP hydrolysis.

Problems

13. For the reaction A $\rightleftharpoons$ B, $\Delta G^{0'} = -29.7$ kJ/mol. At 37°C, $-2.303 RT = -5.94$ kJ/mol. What is the equilibrium ratio of B/A?

14. Using pyruvate, labeled with ^{14}C in its keto group, via the pyruvate dehydrogenase reaction and the TCA cycle, where would the carbon label be at the end of one turn of the TCA cycle? Where would the carbon label be at the end of the second turn of the cycle?

Answers

1. B High energy does not refer to a high energy of formation (bond stability). A *high-energy* bond is so designated because it has a high free energy of hydrolysis. This could arise for reasons A, C, D, or E.

2. C A: Citrate is transported out of the mitochondria to be used as a source of cytoplasmic acetyl CoA. B: Fumarate is produced during phenylalanine and tyrosine degradation. D: α-Ketoglutarate can be formed from glutamate. E: Oxaloacetate is produced by pyruvate carboxylase and is used in gluconeogenesis. Clearly most of the tricarboxylic acid cycle intermediates play multiple roles in the body.

3. D ATP and ADP are transported in opposite directions. A and B: Reducing equivalents from NADH are shuttled across the membrane, as is the acetyl group of acetyl CoA, but NADH and acetyl CoA cannot cross. C: Of the nucleotides, only ATP and ADP are transported. E: Like NADH, NADPH does not cross the membrane.

4. A This is the direct utilization of the energy. B: Movement of protons is from the matrix to the intermembrane space so the latter becomes more positive. C: Only certain electron transfers have sufficient energy to pump electrons. D: No negative ion is transported with the proton so a charge gradient develops. E: The energy is required to release ATP from the subunit, not for the actual synthesis.

5. D This is correct. A: Both are associated with the inner mitochondrial membrane. B: This is the role of the F_o domain. C: Both bind and ATP synthesis occur. E: Changing conformations of different subunits is important in the actions of both domains.

6. A Four electron transfer to oxygen produces water. Oxygen radicals occur when electrons are added stepwise to O_2. B: H_2O_2 is also included as reactive oxygen because it can produce ·OH. C: The H_2O_2 is then degraded by catalase. D: All of these are subject to oxidation with deleterious effects. E: Glutathione peroxidase catalyzes this reaction.

7. A High Ca^{2+} favors the active dehydrogenase but by activating the phosphatase. B, C, and D: NADH and acetyl CoA activate pyruvate dehydrogenase kinase, thus inactivating pyruvate dehydrogenase. Pyruvate inhibits the kinase, favoring the active dehydrogenase.

8. E TPP is the cofactor for the first reaction which decarboxylate pyruvate. A and C: These are cofactors for the dihydrolipoyl transacetylase. B and D: These are cofactors for the dihydrolipoyl dehydrogenase.

9. D This contributes to the protonmotive force required for the synthesis of ATP. A and C: The transfer is not direct but proceeds through FMN and the FeS centers. B: Electrons are transferred from NADH to FMN linked to one of the subunits of complex I, but complex I cannot react with succinate dehydrogenase. E: This is cytochrome *c*.

10. A This is the key regulatory enzyme of the TCA cycle. B: Malate is the reduced form so it would be favored. C: The cytosolic enzyme uses NADH and transports reducing equivalents into the mitochondria. The mitochondrial enzyme is FAD linked. D: NADH does not cross the membrane. E: This reaction is $FADH_2$ linked.

11. D This is why methemoglobin is an effective antidote since it also has an Fe^{3+}. B: Respiration and energy production are coupled so inhibiting one inhibits the other as well. C: Copper is an important part of cytochrome oxidase but cyanide does not bind it. E: The problem is inability to react with O_2, not a lack of O_2.

12. A Cyanide inhibits electron transport at site III, blocking electron flow throughout the system. In coupled mitochondria, ATP synthesis ceases too. Addition of an uncoupler permits the mitochondrial ATPase (which is normally driven in the synthetic direction) to operate, and it catalyzes the favorable ATP hydrolysis reaction unless it is inhibited by a phosphorylation inhibitor such as oligomycin.

13. $\Delta G^{0'} = -RT \ln K = -2.303 RT \log K$. Substitution gives the $\log K = 5$. K then is 100,000 so the B/A = 100,000/1.

14. The labeled keto carbon of pyruvate becomes the labeled carboxyl carbon of acetyl CoA. After condensation with oxaloacetate, the first carboxyl group of citrate is labeled. This label is retained through subsequent reactions to succinate. However, succinate is a symmetrical compound to the enzyme so, in effect, both carboxyl groups of succinate are labeled. This means that the oxaloacetate regenerated is labeled in both carboxyl groups at the end of one turn (actually, half the molecules are labeled in one carboxyl and half in the other but this can't be distinguished experimentally). Note that CO_2 is not labeled. In the second turn, the same carboxyl labeled acetyl CoA is added but this time to labeled oxaloacetate. Both carboxyl groups of the oxaloacetate are released as CO_2 so it will be labeled, as will the regenerated oxaloacetate.

Key Concepts

- Glucose is metabolized by all mammalian cells to form ATP. Anaerobic (absence of oxygen) glycolysis produces two molecules each of lactate and ATP from one molecule of glucose. Aerobic glycolysis (presence of oxygen) produces two molecules each of NADH and pyruvate. NADH must be reoxidized for glycolysis to continue.
- Glycolysis is regulated at three steps. 6-Phosphofructo-1-kinase catalyzes the committed step of glycolysis and is regulated both negatively and positively by allosteric effectors.
- Gluconeogenesis, the formation of glucose from non-carbohydrate substrates, is required to maintain blood glucose and involves those glycolytic enzymes that catalyze reversible reactions. The reactions of glycolysis that are irreversible are bypassed by specific reactions of gluconeogenesis. Some amino acids are glucogenic but fatty acids with an even number of carbons are not.
- Gluconeogenesis is inhibited by insulin and stimulated by glucagon, mediated by regulation of the phosphorylation states of regulatory enzymes. Long-term stimulatory effects of glucagon and inhibitory effects of insulin on gluconeogenesis are mediated by induction and repression of key enzymes of the glycolytic/gluconeogenic pathways.
- When glucose is plentiful, liver and skeletal muscle synthesize and store glycogen. Skeletal muscle utilizes stored glycogen for the synthesis of ATP during exercise and liver releases glucose

from glycogen when blood glucose levels are low. Muscle does not release free glucose.
- Glycogen synthase exists in a phosphorylated form that is dependent for activity on the presence of glucose 6-phosphate, a positive allosteric effector, and a nonphosphorylated form that is independent of glucose 6-phosphate.
- Glycogen phosphorylase, a key enzyme in degradation of glycogen, is activated by AMP and inhibited by glucose and ATP, and is also activated by a signaling cascade involving protein kinases.
- Glycogen storage diseases are caused by inherited defects in enzymes involved in glycogen degradation.

15.1 • INTRODUCTION

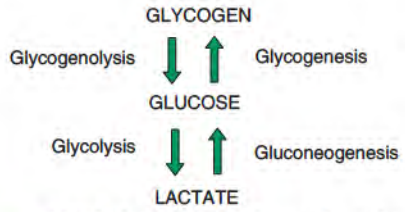

Figure 15.1 Relationship of glucose to major pathways of carbohydrate metabolism.

The major pathways of carbohydrate metabolism begin or end with glucose (Figure 15.1). This chapter describes the utilization of glucose as a source of energy, formation of glucose from non-carbohydrate precursors, storage of glucose in the form of glycogen, and release of glucose from glycogen. An understanding of the pathways and their regulation is necessary because of the important role played by glucose in the body. Glucose is the major form in which carbohydrate absorbed from the intestinal tract is presented to the cells of the body. It is the only fuel used to any significant extent by some specialized cells, and the major fuel of the brain. Therefore, blood glucose must be maintained at a level sufficient to meet these needs at all times. Several tissues of the body have evolved a coordinated working relationship that assures a continuous supply of this essential substrate for these cells and brain. On the other hand, glucose is toxic and can cause tissue damage when its concentration is not controlled within narrow limits. This occurs in diabetes and is a contributing factor to the development of atherosclerosis, hypertension, small-vessel disease, kidney disease, and blindness.

The discussion begins with glycolysis, a pathway used by all body cells to extract part of the chemical energy inherent in the glucose molecule. This pathway also converts glucose to pyruvate and sets the stage for complete oxidation of glucose to CO_2 and H_2O. Gluconeogenesis, the *de novo* synthesis of glucose, is conveniently discussed after glycolysis because it involves many of the same enzymes used in glycolysis, although the reactions being catalyzed are in the reverse direction. In contrast to glycolysis, which produces ATP, gluconeogenesis requires ATP and is therefore an energy-requiring process. Thus, some enzyme-catalyzed steps have to be different between glycolysis and gluconeogenesis. How regulation is exerted at key enzymes will be stressed throughout the chapter. This will be particularly true for glycogen synthesis (glycogenesis) and degradation (glycogenolysis). Many cells store glycogen for their own later needs. The liver is less selfish, storing glycogen mostly for maintenance of blood glucose to ensure that other tissues, especially the brain, have an adequate supply. Regulation of the synthesis and degradation of glycogen is a model for our understanding of how hormones work and how metabolic pathways are regulated. These topics contribute to our understanding of the diabetic condition, starvation, and how tissues of the body respond to stress, severe trauma and injury.

The chemistry and nomenclature of carbohydrates is presented in the Appendix.

15.2 • GLYCOLYSIS

Glycolysis Occurs in All Human Cells

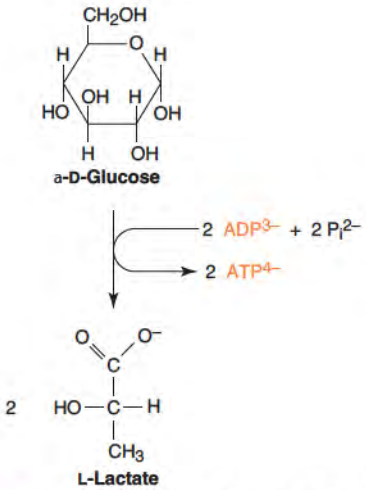

Figure 15.2 Overall balanced equation for the sum of reactions of glycolysis.

The Embden–Meyerhof, or glycolytic, pathway represents an ancient process, possessed by all cells of the human body, in which anaerobic degradation of glucose to lactate occurs with release of energy as ATP. This is an example of *anaerobic fermentation,* a term used for metabolic pathways that organisms use to extract chemical energy from high-energy fuels in the absence of oxygen. For many tissues, glycolysis is only an emergency energy-yielding pathway, capable of producing 2 mol of ATP from 1 mol of glucose in the absence of oxygen (Figure 15.2). When oxygen supply to a tissue is shut off, ATP levels can still be maintained by glycolysis for at least a short period. Many examples could be given, but the capacity to use glycolysis as a source of energy is particularly important during natural birth of human babies. With the exception of the brain, circulation of blood decreases to most parts of the body of the baby during delivery. The brain is not normally deprived of oxygen during

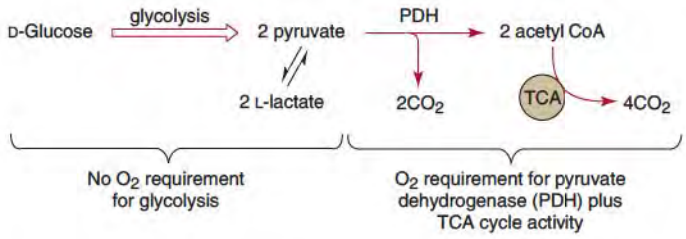

Figure 15.3 Glycolysis is a preparatory pathway for aerobic metabolism of glucose. PDH refers to the pyruvate dehydrogenase complex, TCA to the tricarboxylic acid cycle.

delivery, but other tissues have to depend on glycolysis for their supply of ATP until a normal oxygen supply is available. This conserves oxygen for use by the brain, illustrating one of many mechanisms that have evolved to assure survival of brain tissue in times of stress. Oxygen is not necessary for glycolysis; in fact, oxygen can indirectly suppress glycolysis by the Pasteur effect, which is considered later (p. 609). Nevertheless, glycolysis does occur in cells with an abundant supply of molecular oxygen. Provided cells also contain mitochondria, the end product of glycolysis in the presence of oxygen is pyruvate rather than lactate. Pyruvate is then completely oxidized to CO_2 and H_2O by the pyruvate dehydrogenase complex and enzymes of the TCA cycle housed within the mitochondria (Figure 15.3). Glycolysis therefore sets the stage for aerobic oxidation of carbohydrate. The overall process of glycolysis and mitochondrial oxidation of pyruvate to CO_2 and H_2O has the following sum equation:

$$\text{D-Glucose}(C_6H_{12}O_6) + 6O_2 + 32\ ADP^{3-} + 32\ P_i^{2-} \rightarrow 6CO_2 + 6H_2O + 32\ ATP^{4-} + 32OH^-$$

Much more ATP is produced in complete oxidation of glucose to CO_2 and H_2O (32 ATP/glucose) than is produced in the conversion of glucose to lactate (2 ATP/glucose). This has important consequences to be considered in detail later. The importance of glycolysis as a preparatory pathway is best exemplified by the brain that has an absolute need for glucose. Pyruvate produced by glycolysis is oxidized to CO_2 in mitochondria. An adult human brain uses approximately 120 g of glucose each day to meet its need for ATP. In contrast, glycolysis with lactate as the end product is the major mechanism of ATP production in some other tissues. Red blood cells lack mitochondria and therefore cannot convert pyruvate to CO_2. The cornea, lens, and regions of the retina have a limited blood supply, and also lack mitochondria (because mitochondria would absorb and scatter light), and depend on glycolysis as the major mechanism for ATP production. Kidney medulla, testis, leukocytes, and white muscle fibers have relatively few mitochondria and are therefore almost totally dependent on glycolysis as a source of ATP. Tissues dependent primarily on glycolysis for ATP production consume about 40 g of glucose per day in a normal adult.

Starch is the storage form of glucose in plants and contains α-1,4-glycosidic linkages and α-1,6-glycosidic branches. Glycogen is the storage form of glucose in animal tissues and contains the same type of glycosidic linkages and branches. Exogenous glycogen refers to the glycogen we obtain from animal products; endogenous glycogen is that synthesized and stored in our tissues. Exogenous starch or glycogen is hydrolyzed to glucose in the intestinal tract, whereas stored glycogen endogenous to our tissues is converted to glucose or glucose 6-phosphate by enzymes within the cells. Disaccharides such as milk sugar (lactose) and grocery store sugar (sucrose) are important sources of glucose in our diet. Their hydrolysis by enzymes of the brush border of the intestinal tract is discussed on page 1050. Although glucose can be a source of energy for cells of the intestinal tract, these cells do not depend on glucose to any great extent; most of their energy requirement is met by glutamine catabolism (p. 756). Most of the glucose is absorbed by the cells of the intestinal tract into the portal vein blood and then the general circulation for use by other tissues. Liver is the first major tissue to have an opportunity to remove glucose from the portal vein blood. When blood glucose is high, the liver removes glucose for glycogenesis and glycolysis. When blood glucose is low, the liver supplies the blood with glucose by glycogenolysis and gluconeogenesis. The liver is also the first organ exposed to the blood arriving from the pancreas and therefore experiences the highest concentrations of glucagon and insulin. The effects of these important hormonal regulators of blood glucose levels will be discussed later.

(*n*) Formation of glucuronides (drug and bilirubin detoxification by conjugation) by the glucuronic acid pathway.

Glucose Is Metabolized Differently in Various Cells

Glucose is metabolized mainly by glycolysis in red blood cells (Figure 15.4A). Transport through the plasma membrane is catalyzed by GLUT1 (glucose transporter 1; p. 489). Since these cells lack mitochondria, the end product of glycolysis is lactic acid, which is released into the blood. Glucose used by the pentose phosphate pathway in red blood cells provides NADPH to keep glutathione in the reduced state, which has an important role in the destruction of organic peroxides and H_2O_2 (see Figure 14.61, p. 587). Peroxides cause irreversible damage to membranes, DNA, and other cellular components and must be removed to prevent cell damage and death.

The brain takes up glucose by facilitated transport in an insulin-independent manner by GLUT3 (glucose transporter 3) (Figure 15.4B). Glycolysis yields pyruvate, which is subsequently oxidized to CO_2 and H_2O by the pyruvate dehydrogenase complex and the TCA cycle. The pentose phosphate pathway is active in these cells, generating part of the NADPH needed for reductive synthesis and the maintenance of glutathione in the reduced state.

Muscle and heart cells readily utilize glucose (Figure 15.4C). Insulin stimulates transport of glucose into these cells by way of GLUT4 (glucose transporter 4). In the absence of insulin, GLUT4 exists in intracellular vesicles where it cannot facilitate glucose transport (Figure 15.5). Binding of insulin to its receptor on the plasma membrane initiates a signaling cascade that promotes translocation and fusion of GLUT4-containing vesicles with the plasma membrane, thereby placing GLUT4 where it can facilitate glucose transport. Glucose taken into muscle and heart cells can be utilized by glycolysis to give pyruvate, which is used by the pyruvate dehydrogenase complex and the TCA cycle to provide ATP. Muscle and heart synthesize significant quantities of glycogen, an important fuel that these tissues store for later use.

As in muscle, the uptake of glucose by adipose tissue is dependent upon and stimulated by insulin (Figures 15.4D and 15.5). Pyruvate, as in other cells, is generated by glycolysis and is oxidized by the pyruvate dehydrogenase complex to give acetyl CoA, which is used primarily for *de novo* fatty acid synthesis. Glycolysis also provides carbon for the synthesis of

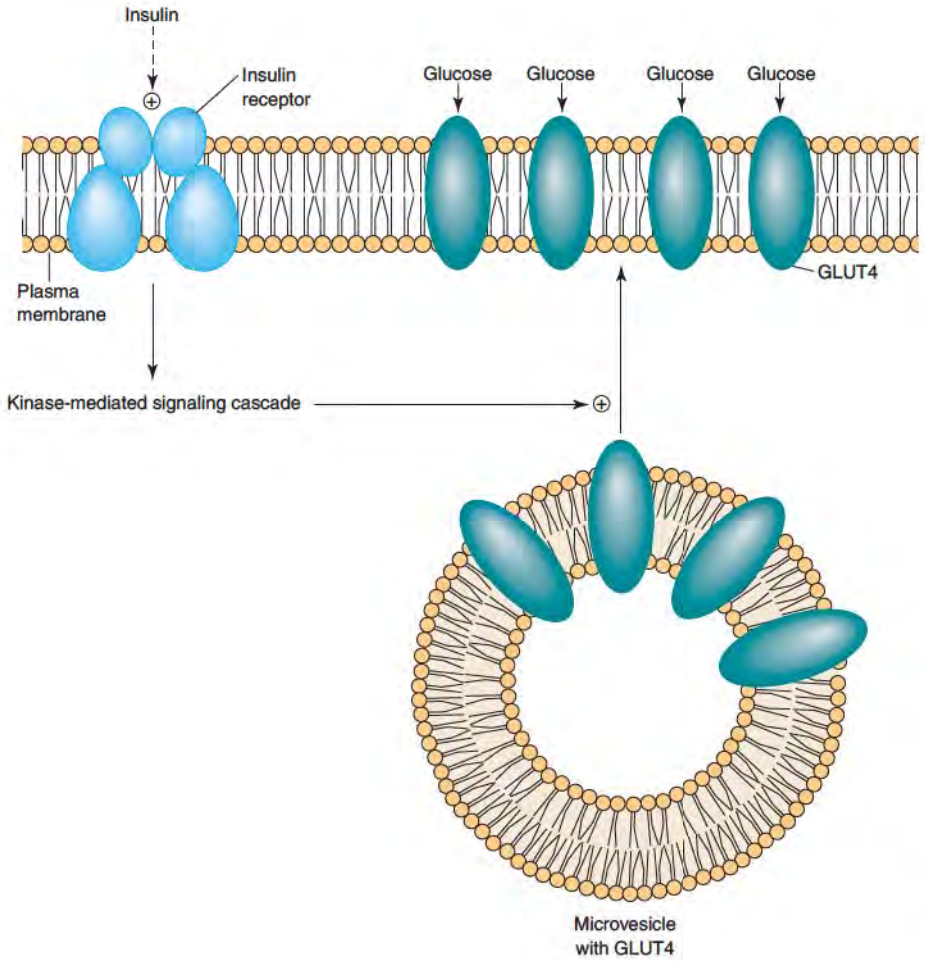

Figure 15.5 Insulin stimulates glucose uptake by adipose tissue and muscle by increasing the number of glucose transporters (GLUT4) in the plasma membrane.

glycerol 3-phosphate (not shown) required for synthesis of triacylglycerol (p. 687). Adipose tissue can carry out glycogenesis and glycogenolysis, but its capacity for these pro-cesses is very limited relative to that of muscle, heart, and liver.

Liver has the greatest number of ways to utilize glucose (Figure 15.4E, p. 594). Uptake of glucose occurs independently of insulin by means of GLUT2, a low-affinity, high-capacity glucose transporter. Glucose is used by the pentose phosphate pathway for the production of NADPH, which is needed for reductive synthesis (*de novo* synthesis of fatty acids and cholesterol), maintenance of reduced glutathione, and numerous reactions catalyzed by endoplasmic reticulum enzyme systems. A vital function of the pentose phosphate pathway is the provision of ribose phosphate for the synthesis of the sugar moiety of nucleotides such as ATP and those in DNA and RNA. Storage of glucose as glycogen is a particularly important feature of the liver. Glucose is also used in the glucuronic acid pathway, which is important in drug and bilirubin detoxification (pp. 654 and 797). The liver carries out glycolysis, the pyruvate produced being used as a source of acetyl CoA for complete oxidation by the tricarboxylic acid cycle and for fatty acid synthesis. Glycolysis also provides the carbon for the synthesis of the glycerol moiety of triacylglycerol, which is synthesized by the liver during production of very low-density lipoproteins (VLDL) (p. 724). The liver also converts three-carbon precursors (lactate, pyruvate, glycerol, and alanine) into glucose by the process of gluconeogenesis to meet the needs of other cells and the brain.

15.3 • GLYCOLYSIS PATHWAY

Glucose is combustible and burns in a test tube to yield heat and light, but of course, no ATP. Cells use about 30 steps to take glucose to CO_2 and H_2O, a seemingly inefficient process, since it can be done in a single step in a test tube. However, side reactions and some of the actual steps used by the cell to oxidize glucose to CO_2 and H_2O lead to the conservation of a significant amount of energy as ATP. In other words, cells produce ATP by the controlled "burning" of glucose, of which glycolysis represents only the first few steps, shown in Figure 15.6.

Glycolysis Occurs in Three Stages

Glycolysis has three major stages.

Priming stage (Figure 15.6*a*)

$$\text{D-Glucose} + 2\ \text{ATP}^{4-} \rightarrow \text{D-fructose 1,6-bisphosphate}^{4-} + 2\ \text{ADP}^{3-} + 2\ \text{H}^+$$

Splitting stage (Figure 15.6*b*)

$$\text{D-Fructose 1,6-bisphosphate}^{4-} \rightarrow 2\ \text{D-glyceraldehyde 3-phosphate}^{2-}$$

Oxidoreduction-phosphorylation stage (Figure 15.6*c*)

$$2\ \text{D-Glyceraldehyde 3-phosphate}^{2-} + 4\ \text{ADP}^{3-} + 2\ \text{P}_i^{2-} + 2\ \text{H}^+ \rightarrow 2\ \text{L-lactate}^- + 4\ \text{ATP}^{4-} + 2\ \text{H}_2\text{O}$$

Sum:

$$\text{D-Glucose} + 2\ \text{ADP}^{3-} + 2\ \text{P}_i^{2-} \rightarrow 2\ \text{L-lactate}^- + 2\ \text{ATP}^{4-} + 2\ \text{H}_2\text{O}$$

The priming stage involves input of two molecules of ATP to convert glucose into fructose 1,6-bisphosphate. ATP is "invested" rather than lost in this stage because it is subsequently regained plus more from later steps. The splitting stage "splits" fructose 1,6-bisphosphate into two molecules of glyceraldehyde 3-phosphate. In the oxidoreduction-phosphorylation stage two molecules of glyceraldehyde 3-phosphate are converted into two molecules of lactate with the production of four molecules of ATP. The overall process therefore generates two molecules of lactate and two molecules of ATP from one molecule of glucose.

Stage One: Priming of Glucose

Although the hexokinase reaction (Figure 15.6*a*) consumes ATP, it gets glycolysis off to a good start by trapping glucose as glucose 6-phosphate (G6P) within the cytosol where all the glycolytic enzymes are located. Phosphate esters are charged and hydrophilic and

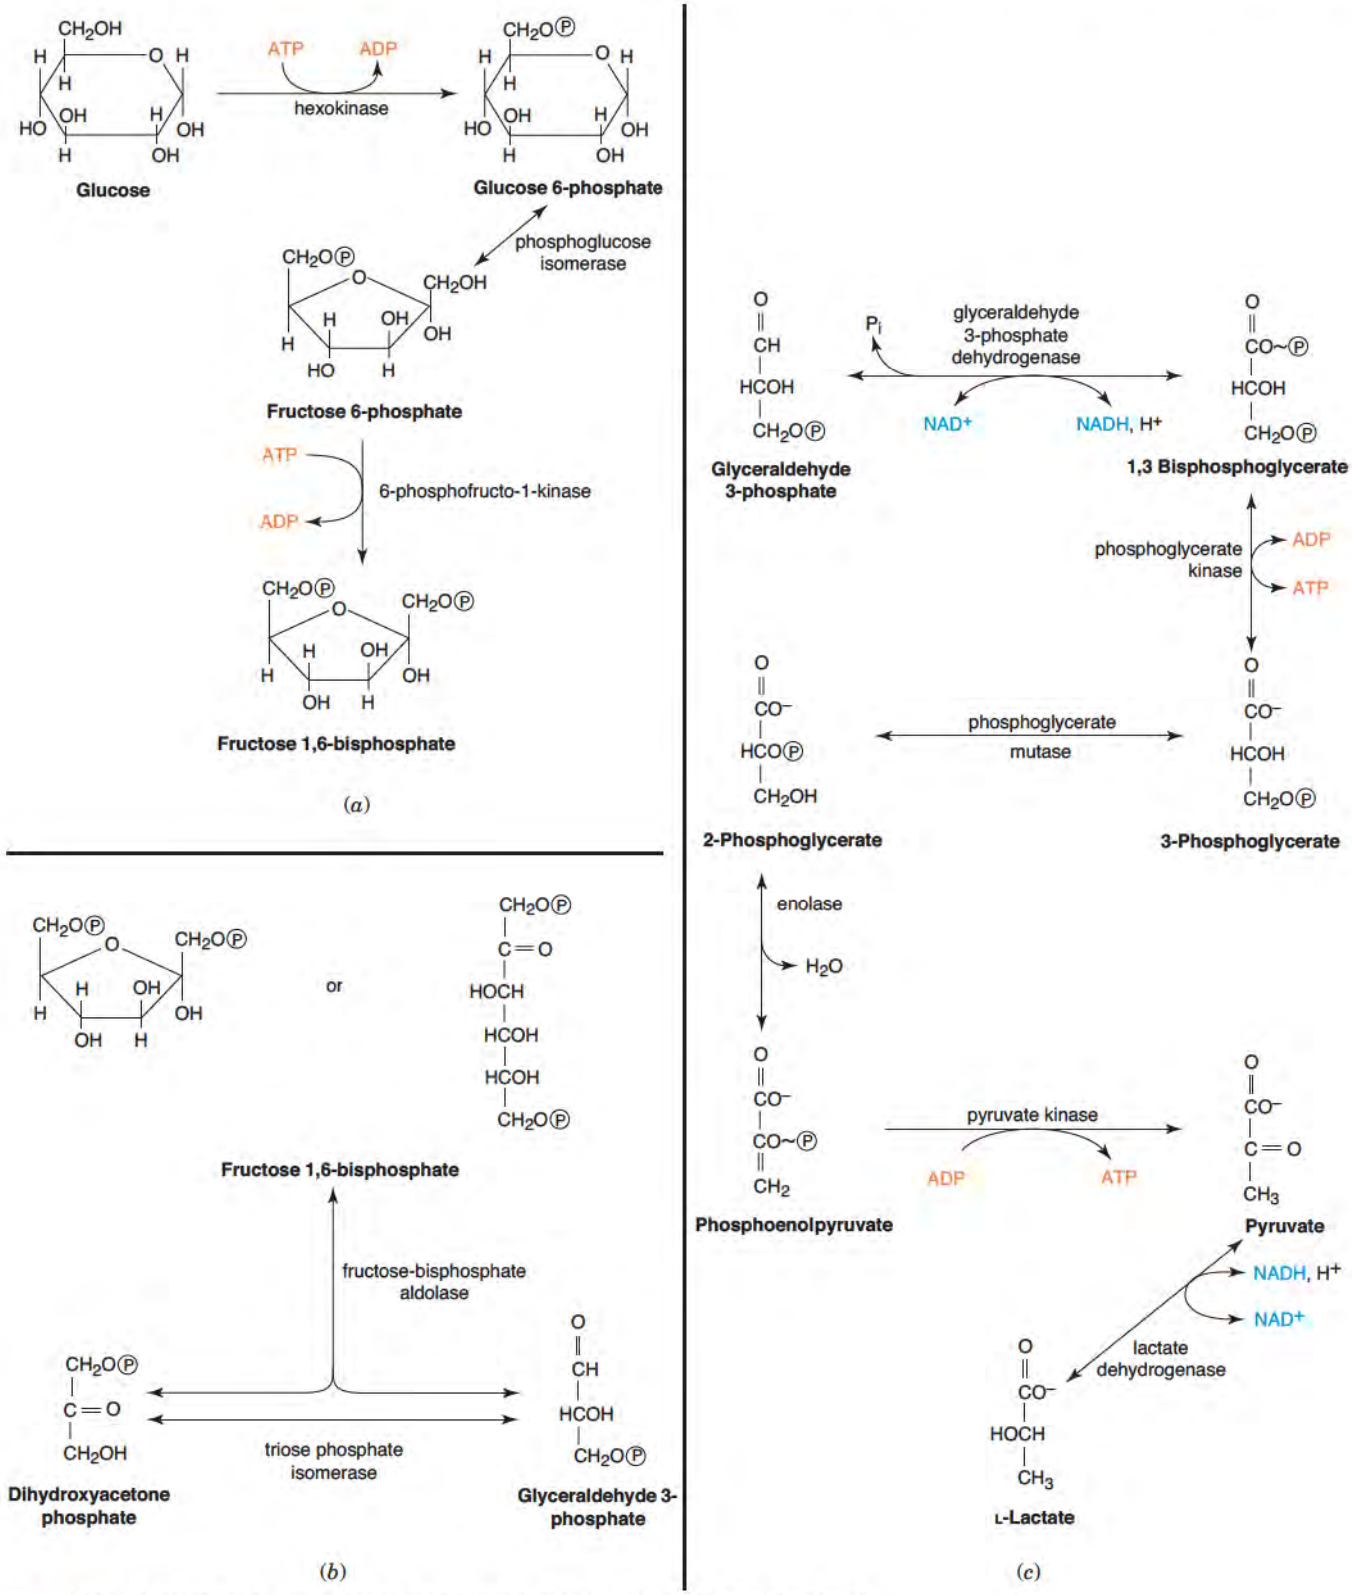

Figure 15.6 The glycolytic pathway, divided into three stages. The symbol P refers to phosphoryl group PO_3^{2-}; ~ indicates a high-energy phosphate bond. (*a*) Priming stage. (*b*) Splitting stage. (*c*) Oxidoreduction–phosphorylation stage.

therefore cannot cross cell membranes. The phosphorylation of glucose by ATP is a thermodynamically favorable, irreversible under cellular conditions, reaction. The reverse reaction cannot be used to synthesize ATP.

The next reaction catalyzed by phosphoglucose isomerase is readily reversible and is not subject to regulation.

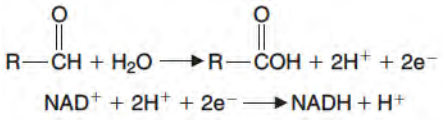
6-Phosphofructo-1-kinase (or phosphofructokinase-1) catalyzes the ATP-dependent phosphorylation of fructose 6-phosphate (F6P) to fructose 1,6-bisphosphate (FBP). This enzyme is subject to regulation by several effectors and is often considered the key regulatory enzyme of glycolysis. The reaction is irreversible and uses the second ATP needed to "prime" glucose.

Stage Two: Splitting of a Phosphorylated Intermediate

Fructose 1,6-bisphosphate aldolase cleaves fructose 1,6-bisphosphate into a molecule each of dihydroxyacetone phosphate (DHAP) and glyceraldehyde 3-phosphate (GAP) (Figure 15.6*b*). This is a reversible reaction, corresponding to an aldol cleavage in one direction and an aldol condensation in the other. Triose phosphate isomerase catalyzes reversible interconversion of DHAP and GAP. With the transformation of DHAP into GAP, one molecule of glucose is converted into two molecules of GAP.

Stage Three: Oxidoreduction Reactions and ATP Synthesis

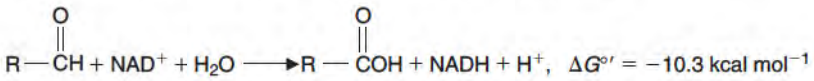
The reaction catalyzed by glyceraldehyde 3-phosphate dehydrogenase (Figure 15.6*c*) is of interest because of what is accomplished. An aldehyde (glyceraldehyde 3-phosphate) is oxidized to a carboxylic acid with the reduction of NAD^+ to NADH. The acid produced is 1,3-bisphosphoglycerate, a mixed anhydride of a carboxylic acid and phosphoric acid, which has a large negative free energy of hydrolysis, enabling it to participate in a subsequent reaction that forms ATP. The overall reaction can be visualized as the coupling of a very favorable exergonic reaction with an unfavorable endergonic reaction. The exergonic reaction is the one in which an aldehyde is oxidized to a carboxylic acid, which is then coupled with an endergonic half-reaction in which NAD^+ is reduced to NADH.



$$R{-}\overset{\overset{O}{\|}}{C}H + H_2O \longrightarrow R{-}\overset{\overset{O}{\|}}{C}OH + 2H^+ + 2e^-$$

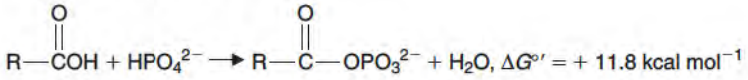
$$NAD^+ + 2H^+ + 2e^- \longrightarrow NADH + H^+$$

The overall reaction (sum of the half-reactions) is quite exergonic.



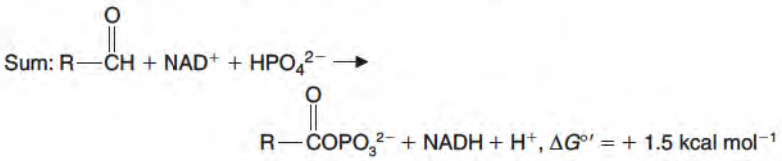
$$R{-}\overset{\overset{O}{\|}}{C}H + NAD^+ + H_2O \longrightarrow R{-}\overset{\overset{O}{\|}}{C}OH + NADH + H^+, \quad \Delta G^{\circ\prime} = -10.3 \text{ kcal mol}^{-1}$$

A second endergonic component of the reaction is formation of a mixed anhydride between the carboxylic acid and phosphoric acid.



$$R{-}\overset{\overset{O}{\|}}{C}OH + HPO_4^{2-} \longrightarrow R{-}\overset{\overset{O}{\|}}{C}{-}OPO_3^{2-} + H_2O, \Delta G^{\circ\prime} = +11.8 \text{ kcal mol}^{-1}$$

The overall reaction involves coupling of the endergonic and exergonic components with an overall standard free-energy change of +6.3 kJ/mol (+1.5 kcal/mol).



$$\text{Sum: } R{-}\overset{\overset{O}{\|}}{C}H + NAD^+ + HPO_4^{2-} \longrightarrow R{-}\overset{\overset{O}{\|}}{C}OPO_3^{2-} + NADH + H^+, \Delta G^{\circ\prime} = +1.5 \text{ kcal mol}^{-1}$$

This reaction is freely reversible in cells. The catalytic mechanism involves glyceraldehyde 3-phosphate reacting with a sulfhydryl group of a cysteine residue to generate a thiohemiacetal (Figure 15.7). An internal oxidation–reduction reaction occurs in which bound NAD^+ is reduced to NADH and the thiohemiacetal is oxidized to a high-energy thiol ester. The thiol ester reacts with P_i to form the mixed anhydride and regenerate the free sulfhydryl group. The mixed anhydride dissociates from the enzyme and exogenous

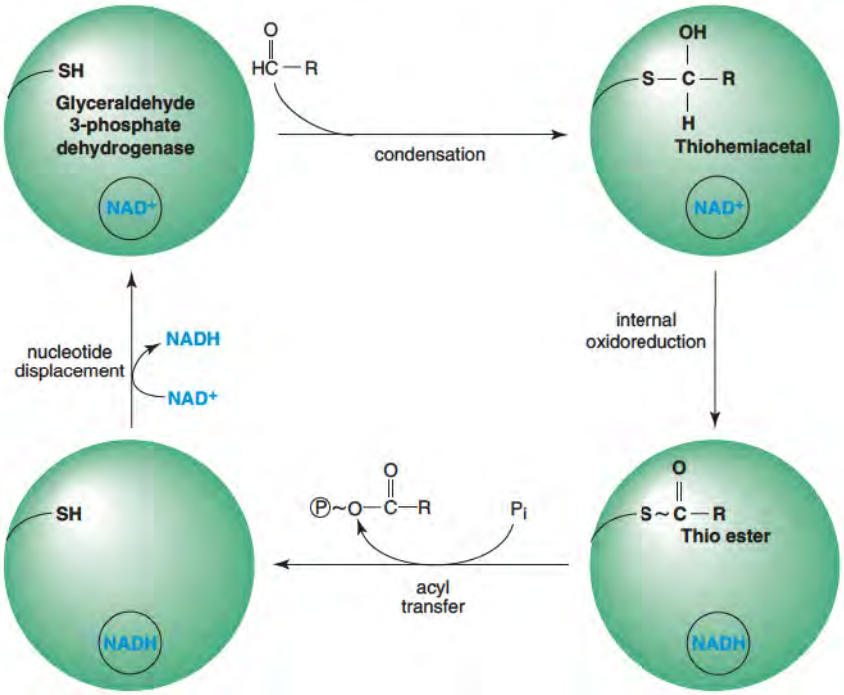


Figure 15.7 Catalytic mechanism of glyceraldehyde 3-phosphate dehydrogenase. Large circle represents enzyme; small circle binding site for NAD^+; RCOH, the aldehyde group of glyceraldehyde 3-phosphate; -SH, the sulfhydryl group of the cysteine residue located at the enzyme's active site; and ~, high-energy bonds in the thio ester and the mixed anhydride.

NAD^+ replaces the bound NADH. It should be noted that a free carboxylic acid group (–COOH) is not generated from the aldehyde group (–CHO) during the reaction. Instead, the enzyme generates a carboxyl group in the form of a high-energy thiol ester, which is converted by reaction with P_i into a mixed anhydride of carboxylic and phosphoric acids.

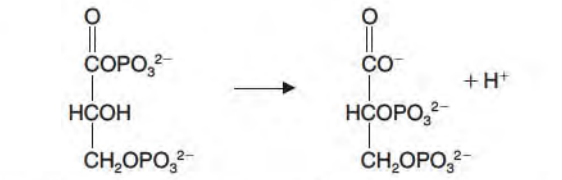
This reaction catalyzed by glyceraldehyde 3-phosphate dehydrogenase requires NAD^+ and produces NADH. Since the cytosol has only a limited amount of NAD^+, continuous glycolytic activity can occur only if NADH is oxidized back to NAD^+; otherwise glycolysis will stop for want of NAD^+. The options that cells have for regeneration of NAD^+ from NADH are described in a later section (p. 601).

In the next reaction phosphoglycerate kinase produces ATP from the high-energy compound 1,3-bisphosphoglycerate (Figure 15.6*c*, p. 597). This is the first site of ATP production in glycolysis. Since two ATP molecules were invested for each glucose molecule in the priming stage, and since two molecules of 1,3-bisphosphoglycerate are produced from each glucose, all of the "invested" ATP is recovered in this step. The glyceraldehyde 3-phosphate dehydrogenase-phosphoglycerate kinase system is an example of substrate-level phosphorylation in which a substrate participates in an enzyme-catalyzed reaction that yields ATP or GTP. Substrate-level phosphorylation stands in contrast to oxidative phosphorylation catalyzed by the mitochondrial electron transfer chain and ATP synthase (p. 572). Note that the combination of glyceraldehyde 3-phosphate dehydrogenase and phosphoglycerate kinase accomplishes the coupling of an oxidation (an aldehyde is oxidized to a carboxylic acid) to a phosphorylation (a mixed anhydride of a carboxylic acid and phosphoric acid is formed) without the involvement of a membrane system.

Phosphoglycerate mutase converts 3-phosphoglycerate to 2-phosphoglycerate. This is a freely reversible reaction in which 2,3-bisphosphoglycerate is an obligatory intermediate at the active site.

$$\text{E-phosphate} + \text{3-phosphoglycerate} \rightleftharpoons \text{E} + \text{2,3-bisphosphoglycerate}$$
$$\text{E} + \text{2,3-bisphosphoglycerate} \rightleftharpoons \text{E-phosphate} + \text{2-phosphoglycerate}$$
$$\text{Sum:}\quad \text{3-phosphoglycerate} \rightleftharpoons \text{2-phosphoglycerate}$$

Involvement of 2,3-bisphosphoglycerate in this reaction creates an absolute requirement for catalytic amounts of this compound in cells. This can be appreciated by noting that E-P cannot be generated without 2,3-bisphosphoglycerate and likewise that 2,3-bisphosphoglycerate cannot be generated without E-P. Cells solve this problem by synthesizing 2,3-bisphosphoglycerate from 1,3-bisphosphoglycerate with a 2,3-bisphosphoglycerate mutase.



This enzyme is bifunctional, serving as mutase for the formation of 2,3-bisphosphoglycerate and also as a phosphatase that hydrolyzes 2,3-bisphosphoglycerate to 3-phosphoglycerate and P_i. All cells contain the minute quantities of 2,3-bisphosphoglycerate necessary to produce the phosphorylated form (E-P) of newly synthesized phosphoglycerate mutase. In striking contrast to other cells of the body, red blood cells contain very high concentrations of 2, 3-bisphosphoglycerate, which functions as an important negative allosteric regulator of the binding of oxygen to hemoglobin (p. 365). In contrast to the extremely small amounts of glucose used for 2,3-bisphosphoglycerate in other cells, from 15% to 25% of glucose converted to lactate in red blood cells goes by way of the *BPG shunt* for the synthesis of 2,3-bisphosphoglycerate (Figure 15.8). It should be noted that the BPG shunt bypasses the PGK step. Therefore, no net production of ATP occurs when glucose is converted to lactate via the BPG shunt. 2,3-Bisphosphoglycerate is also hydrolyzed in red blood cells by multiple inositol polyphosphate phosphatases (MIP phosphatase) (Figure 15.8). By converting 2,3-BPG to 2-phosphoglycerate rather than 3-phosphglycerate, MIP phosphatase expands the BPG shunt to by-pass the reaction catalyzed by phosphoglycerate mutase. Exceptional sensitivity of MIP phosphatase to changes in pH suggest that the activity of this enzyme may set the concentration of 2,3-BPG, the most important allosteric effector of hemoglobin, in physiological and pathological conditions that affect the intracellular pH of red blood cells (A Closer Look 15.1).

Enolase eliminates water from 2-phosphoglycerate to form phosphoenolpyruvate (PEP) in the next reaction (see Figure 15.6*c*, p. 597). This reaction generates a high-energy phosphate from one of markedly lower energy level. $\Delta G^{0\prime}$ for the hydrolysis of phosphoenolpyruvate is −61.9 kJ/mol (−14.8 kcal/mol), while that for 2-phosphoglycerate is −17.6 kJ/mol (−4.2 kcal/mol). Pyruvate kinase (Figure 15.6*c*) accomplishes another substrate-level phosphorylation. This reaction is not reversible under intracellular conditions.

The last step of glycolysis is a freely reversible oxidoreduction reaction catalyzed by lactate dehydrogenase (Figure 15.6*c*). Pyruvate is reduced to give L-lactate and NADH is oxidized to NAD^+. The forward direction of this reaction is the only reaction of the body by which L-lactate can be produced. The reverse direction of this reaction is the only reaction of the body by which L-lactate can be utilized. Lactate dehydrogenase is therefore responsible for both the production and the utilization of L-lactate.

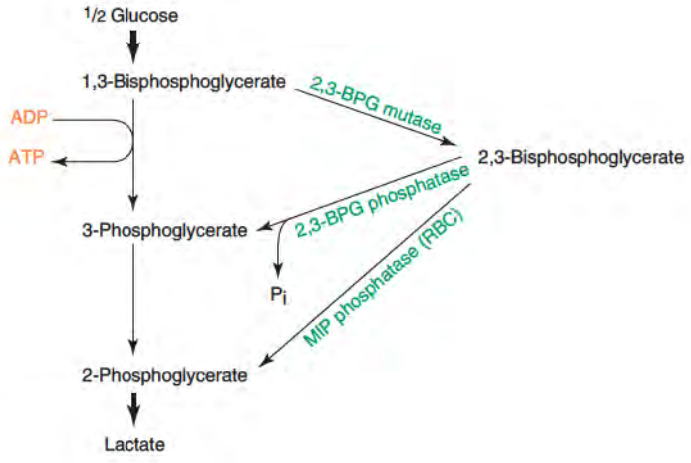


Figure 15.8 The reactions of the 2,3-bisphosphoglycerate (2,3-BPG) shunt are catalyzed by the bifunctional enzyme, 2,3-BPG mutase/phosphatase. 2,3-BPG is also hydrolyzed to 2-phoshoglycerate by multiple inositol polyphosphate phosphatase (MIP phosphatase), so named because multiple inositol polyphosphate was identified before 2,3-BPG to be a substrate for this enzyme.

A CLOSER LOOK 15.1

2,3-Bisphosphoglycerate and High Altitude

Delivery of oxygen to tissues depends on regulation of hemoglobin by allosteric effectors, the most important being 2,3-bisphosphoglycerate, which promotes oxygen release by binding to deoxyhemoglobin. Supply of oxygen to tissues in a variety of conditions is dependent upon regulation of the 2,3-bisphosphoglycerate concentration in red blood cells. Relatively small changes in blood pH and the opposite sensitivities of 6-phosphofructo-1-kinase and MIP phosphatase to pH changes appear to be most important factors. For example, in patients with metabolic acidosis, DPG levels are dramatically reduced in RBCs, most likely because a decrease in pH reduces 6-phosphofructo-1-kinase activity and increases MIP phosphatase activity. Conversely, in response to high altitude or anemia due to blood loss, DPG levels are dramatically increased in RBCs in these situations because an increase in pH increases 6-phosphofructo-1-kinase activity and decreases MIP phosphatase activity. Alkalosis is induced by blood loss and high altitude because hyperventilation due to hypoxia in these situations blows off CO_2 which lowers the blood H^+ concentration by forcing the reaction catalyzed by carbonic anhydrase to the left.

$$CO_2 + H_2O \leftrightarrows H_2CO_3 \leftrightarrows H^+ + HCO_3^-$$

Dephosphorylation of 2,3-bisphosphoglycerate by MIPP expands the regulatory capacity of the Rapoport-Lubering glycolytic shunt. *Proc. Natl. Acad. Sci. USA* 105: 998, 2008.

ATP Yield and Balanced Equation for Anaerobic Glycolysis

Conversion of one molecule of glucose to two molecules of lactate results in the net formation of two molecules of ATP. Two molecules of ATP are used in the priming stage, but subsequent steps yield four molecules of ATP so that the overall net yield is two molecules of ATP.

$$\text{D-Glucose} + 2\ ADP^{3-} + 2\ P_i^{2-} \rightarrow 2\ \text{L-lactate}^- + 2\ ATP^{4-} + 2\ H_2O$$

Cells have only a limited amount of ADP and P_i. Flux through glycolysis is dependent on an adequate supply of these substrates. If the ATP is not utilized for performance of work, glycolysis stops for want of ADP and/or P_i. Consequently, the ATP generated has to be used in normal work-related processes for glycolysis to occur. Use of ATP for any work-related process is represented simply by

$$ATP^{4-} + H_2O \rightarrow ADP^{3-} + P_i^{2-} + H^+ + \text{“work”}$$

When the quantities are doubled and added to the previous equation for glycolysis, excluding the work accomplished since this is necessary for ATP turnover, the overall balanced equation becomes

$$\text{D-Glucose} \rightarrow 2\ \text{L-lactate}^- + 2\ H^+$$

This shows that anaerobic glycolysis generates acid that can create major problems for the body (described later in Clin. Corr. 15.5, p. 611) since intracellular pH must be maintained near neutrality for optimum enzyme activity.

NADH Generated by Glycolysis Has to Be Oxidized Back to NAD^+: Role of Lactate Dehydrogenase and Substrate Shuttles

Anaerobic Glycolysis

NADH and NAD^+ do not appear in the balanced sum equation for anaerobic glycolysis because the generation of NADH and its utilization are coupled (balanced) in the pathway (see Figure 15.6*c*). Two molecules of NADH are generated by glyceraldehyde 3-phosphate dehydrogenase and two are utilized by lactate dehydrogenase. NAD^+ is available in only limited amounts and must be regenerated for glycolysis to continue unabated. The two reactions involved are

$$\text{D-Glyceraldehyde 3-phosphate} + NAD^+ + P_i \rightarrow \text{1,3-bisphospho-D-glycerate} + NADH + H^+$$

$$\text{Pyruvate} + NADH + H^+ \rightarrow \text{L-lactate} + NAD^+$$

The sum reaction is

D-Glyceraldehyde 3-phosphate + pyruvate + P_i → 1,3-bisphosphoglycerate + L-lactate

Perfect coupling of reducing equivalents by these reactions occurs under anaerobic conditions or in cells that lack mitochondria.

Mitochondrial Oxidation of NADH Produced by Glycolysis

When oxygen and mitochondria are present, the reducing equivalents of NADH generated by glyceraldehyde 3-phosphate dehydrogenase are shuttled into the mitochondria for oxidation, leaving pyruvate rather than lactate as the end product of glycolysis. The mitochondrial inner membrane is not permeable to NADH (p. 577) but the malate–aspartate shuttle and the glycerol–phosphate shuttle (see Figure 14.51, p. 580) transport reducing equivalents into the mitochondrial matrix space (p. 560). Liver makes greater use of the malate–aspartate shuttle, but some muscle cells are more dependent on the glycerol–phosphate shuttle. The shuttle systems move reducing equivalents from the cytosol into the mitochondria but will not shuttle reducing equivalents from the mitochondria into the cytosol. The sum of all reactions of the malate–aspartate shuttle reactions is simply

$$NADH_{cytosol} + H^+_{cytosol} + NAD^+_{mito} \rightarrow NAD^+_{cytosol} + NADH_{mito} + H^+_{mito}$$

The glycerol phosphate shuttle produces $FADH_2$ within the mitochondrial inner membrane (see Figure 14.40, p. 571). The active site of the mitochondrial glycerol 3-phosphate dehydrogenase is exposed on the cytosolic surface of the mitochondrial inner membrane. The sum of all reactions of the glycerol phosphate shuttle is

$$NADH_{cytosol} + H^+_{cytosol} + FAD_{inner\ membrane} \rightarrow NAD^+_{cytosol} + FADH_{2\ inner\ membrane}$$

The mitochondrial NADH formed by the malate–aspartate shuttle activity can be used by the mitochondrial electron transport chain for the production of 2.5 molecules of ATP by oxidative phosphorylation.

$$NADH_{mito} + H^+ + 0.5\ O_2 + 2.5\ ADP + 2.5\ P_i \rightarrow NAD^+_{mito} + 2.5\ ATP + H_2O$$

In contrast, the $FADH_2$ formed by the glycerol phosphate shuttle yields only 1.5 molecules of ATP.

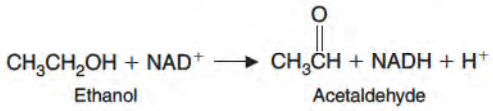
$$FADH_{2\ inner\ membrane} + 0.5\ O_2 + 1.5\ ADP + 1.5\ P_i \rightarrow FAD_{inner\ membrane} + 1.5\ ATP + H_2O$$

Thus, the ATP yield from the oxidation of the NADH generated by glycolysis is 3 or 5, depending on the substrate shuttle used for its oxidation.

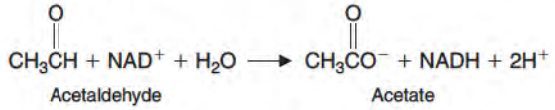
Shuttles Are Important in Other Oxidoreduction Pathways

Alcohol Oxidation

Alcohol (i.e., ethanol) is oxidized to acetaldehyde with production of NADH by alcohol dehydrogenase.



This enzyme is located almost exclusively in the cytosol of hepatocytes. Acetaldehyde traverses the mitochondrial inner membrane for oxidation by an aldehyde dehydrogenase in the mitochondrial matrix space.



The NADH generated by the last step can be used directly by the mitochondrial electron transfer chain. However, the NADH generated by cytosolic alcohol dehydrogenase is oxidized back to NAD^+ by one of the substrate shuttles (see Figure 14.51, p. 580).

Thus, the capacity to oxidize alcohol is dependent on the ability of the liver to transport reducing equivalents from the cytosol into the mitochondria by these shuttle systems.

Glucuronide Formation

Water-soluble glucuronides of bilirubin and various drugs (p. 431) are eliminated in the urine and bile. For glucuronide formation, UDP-glucose (see p. 654 for structure) is oxidized to UDP-glucuronic acid (see p. 655 for structure) by

$$\text{UDP-D-glucose} + 2\ NAD^+ + H_2O \rightarrow \text{UDP-D-glucuronic acid} + 2\ NADH + 2\ H^+$$

Primarily in liver, this "activated" glucuronic acid is transferred to a nonpolar, acceptor molecule, such as bilirubin or a compound (R-OH) foreign to the body.

$$\text{UDP-D-glucuronic acid} + \text{R-OH} \rightarrow \text{R-O-glucuronic acid} + \text{UDP}$$

NADH generated by the first reaction is reoxidized by the substrate shuttles. Since ethanol oxidation and drug conjugation occurs in the liver, the two occurring together may overwhelm the capacity of the substrate shuttles. This explains the advice not to mix the intake of pharmacologically active compounds with alcohol (see Clin. Corr. 15.1).

Sulfhydryl Reagents and Fluoride Inhibit Glycolysis

Glyceraldehyde 3-phosphate dehydrogenase is inhibited by sulfhydryl reagents because of the catalytically important cysteine residue at its active site. During a catalytic cycle the sulfhydryl group reacts with glyceraldehyde 3-phosphate to form a thiohemiacetal (see Figure 15.7, p. 599). Sulfhydryl reagents, which are often mercury-containing compounds or alkylating compounds such as iodoacetate, prevent formation of the thiohemiacetal (Figure 15.9).

Fluoride is a potent inhibitor of enolase. Mg^{2+} and P_i form an ionic complex with fluoride that inhibits enolase by interfering with the binding of its substrate (Mg^{2+} 2-phosphoglycerate^{2-}).

Hyperglycemia Inhibits Glycolysis

Glyceraldehyde 3-phosphate dehydrogenase is vulnerable to inhibition in cells exposed to high glucose levels. This is because hyperglycemia promotes overproduction of reactive oxygen species which activate poly(ADP-ribose) polymerase (PARP). In a reaction that

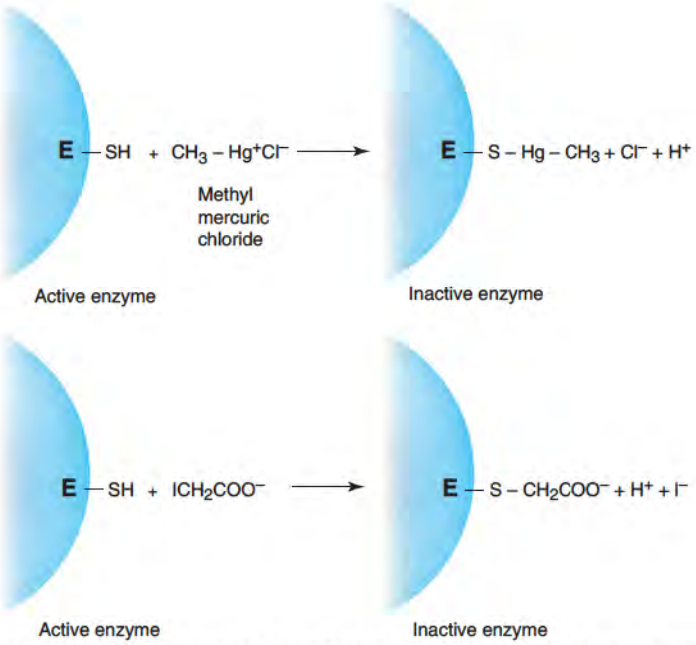


Figure 15.9 Mechanism for inactivation of glyceraldehyde 3-phosphate dehydrogenase by sulfhydryl reagents.

CLINICAL CORRELATION 15.1

Alcohol and Barbiturates

Acute alcohol intoxication increases sensitivity to the general depressant effects of barbiturates. Barbiturates and alcohol interact with the γ-aminobutyrate (GABA) activated chloride channel. Activation of this channel inhibits neuronal firing, which may explain the depressant effects of both compounds. This combination is very dangerous and normal prescription doses of barbiturates are potentially lethal when taken with ethanol. Furthermore, ethanol inhibits the metabolism of barbiturates, thereby prolonging the time barbiturates remain effective in the body. Hydroxylation of barbiturates by the NADPH-dependent cytochrome P^{450} system of the endoplasmic reticulum of the liver is inhibited by ethanol. This decreases formation of water-soluble derivatives of the barbiturates for elimination by the kidneys and bile. Blood levels of barbiturates remain high and cause increased CNS depression.

Surprisingly, the sober alcoholic is less sensitive to barbiturates. Chronic ethanol consumption apparently causes adaptive changes in the sensitivity to barbiturates (cross-tolerance) and induces cytochrome P450 of liver endoplasmic reticulum involved in drug hydroxylation reactions. Consequently, the sober alcoholic can metabolize barbiturates more rapidly. This sets up the following scenario: A sober alcoholic has trouble falling asleep, even after taking several sleeping pills, because his liver has increased capacity to hydroxylate the barbiturate contained in the pills. In frustration he consumes more pills and then alcohol. Sleep results, but may be followed by respiratory depression and death because the alcoholic, although less sensitive to barbiturates when sober, remains sensitive to the synergistic effect of alcohol.

A CLOSER LOOK 15.2

Glyceraldehyde 3-Phosphate Dehydrogenase and Hyperglycemia

When blood glucose levels are elevated, cells of the body that are unable to restrict the uptake of glucose are vulnerable to damage from too much intracellular glucose. The most susceptible cells are found in the retina, kidney, and neurons of peripheral nerves, early sites of damage in diabetes. Overproduction of the superoxide radical ($O_2^{-}\cdot$) by mitochondria is the primary cause of the damage, at least in part because of inactivation of glyceraldehyde 3-phophate dehydrogenase, an enzyme required for glycolysis. Oxidation of the overload of glucose in these cells results in excessive reduction of the mitochondrial electron transport chain. Transfer of a single electron from one of the overloaded carriers of the electron transport chain to oxygen produces the superoxide radical. The superoxide radical activates poly(ADP-ribose) polymerase, a DNA repair enzyme that ADP-ribosylates free sulfhydryl groups of many enzymes including the active site cysteine residue of glyceraldehyde 3-phosphate dehydrogenase. Partial inhibition of glycolysis by this mechanism may contribute to the damage induced by hyperglycemia in susceptible cells.

Brownlee, M. Banting Lecture 2004. The pathology of diabetic complications: A unifying mechanism. *Diabetes* 54: 1615, 2005.

uses NAD^+ as substrate and produces nicotinamide, PARP catalyzes the poly(ADP-ribosyl)ation of cysteine residues of a number of proteins including the active site cysteine of glyceraldehyde 3-phosphate dehydrogenase (A Closer Look 15.2).

Arsenate Prevents Net Synthesis of ATP without Inhibiting Glycolysis

Pentavalent arsenic or arsenate prevents net synthesis of ATP by causing arsenolysis in the glyceraldehyde 3-phosphate dehydrogenase reaction (Figure 15.10). The structure of arsenate resembles that of P_i (also pentavalent) and readily substitutes for P_i in enzyme-catalyzed reactions. The mixed anhydride of arsenic acid and the carboxyl group of 3-phosphoglycerate is formed by glyceraldehyde 3-phosphate dehydrogenase. 1-Arsenato 3-phosphoglycerate is unstable, and undergoes spontaneous hydrolysis to 3-phosphoglycerate and inorganic arsenate. As a consequence, glycolysis continues unabated in the presence of arsenate, but 1,3-bisphosphoglycerate is not formed. ATP is therefore not synthesized by phosphoglycerate kinase. Thus net ATP synthesis does not occur when glycolysis takes place in the presence of arsenate, the ATP invested in the priming stage being balanced by the ATP generated in the pyruvate kinase step. Arsenolysis also interferes with ATP formation by oxidative phosphorylation, hence the toxicity of arsenate (Clin. Corr. 15.2).

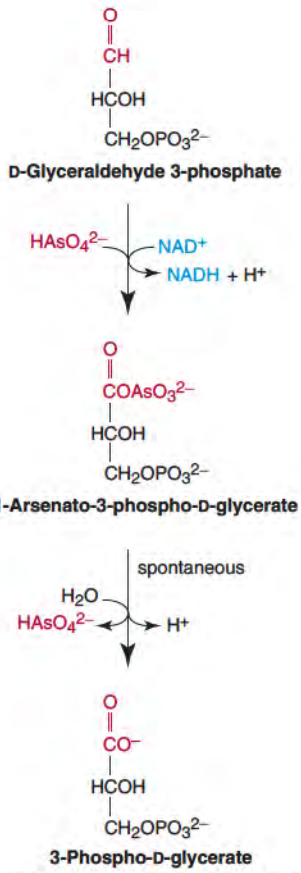

Figure 15.10 Arsenate uncouples oxidation from phosphorylation at the glyceraldehyde 3-phosphate dehydrogenase reaction.

15.4 • REGULATION OF GLYCOLYSIS

As in other complex pathways that involve multiple steps, flux through glycolysis is determined by the activities of several enzymes rather than a single *rate-limiting* enzyme. Quantitative information about the relative contribution of an enzyme to flux through a pathway under a particular set of conditions is best determined from the *control strength* for the enzyme. The effect that a small inhibition of the activity of an enzyme has upon flux through a pathway is used to determine an enzyme's control strength according to the equation

$$\text{Control Strength} = \frac{\text{Change in flux}}{\text{Change in enzyme activity}}$$

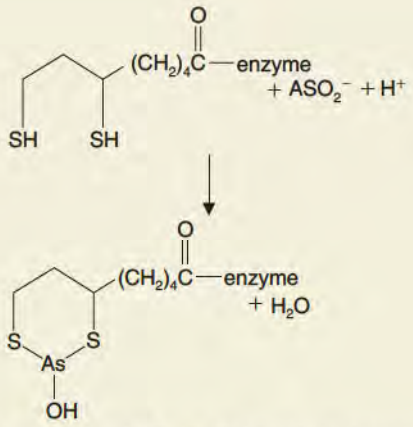
For the purpose of illustration, assume that inhibition of a particular enzyme by 10% has no effect on flux. The control strength of the enzyme is then zero (0 divided by 10). Now assume that inhibition of an enzyme by 10% results in 10% inhibition of flux. The control strength would be 1.0 (10 divided by 10), which means that flux is entirely dependent on the activity of the enzyme under these conditions. Now assume that inhibition of an enzyme by 10% results in only 5% inhibition of flux through the pathway. The control

CLINICAL CORRELATION 15.2

Arsenic Poisoning

Most forms of arsenic are toxic, the trivalent form (arsenite as AsO_2^-) being much more toxic than the pentavalent form (arsenate or $HAsO_4^{2-}$). Less ATP is produced whenever arsenate substitutes for P_i in biological reactions. Arsenate competes for P_i binding sites on enzymes, resulting in the formation of arsenate esters that are unstable. Arsenite works by a different mechanism, involving formation of a stable complex with enzyme bound lipoic acid (See illustration to right.).

For the most part arsenic poisoning is explained by inhibition of enzymes that require lipoic acid as a coenzyme. These include pyruvate dehydrogenase, α-ketoglutarate dehydrogenase, and branched-chain α-keto acid dehydrogenase. Chronic arsenic poisoning from well water contaminated with arsenical pesticides or through the efforts of a murderer is best diagnosed by determining the concentration of arsenic in the hair or fingernails of the victim. About 0.5 mg of arsenic is present in 1 kg of hair from a normal individual. The hair of a person chronically exposed to arsenic could have 100 times as much.



Hindmarsh, J. T., and McCurdy, R. F. Clinical and environmental aspects of arsenic toxicity. *CRC Crit. Rev. Clin. Lab.* Sci. 23: 315, 1986; and Mudur, G. Half of Bangladesh population at risk of arsenic poisoning. *British Medical Journal* 320: 822, 2000.

strength is now 0.5 (5 divided by 10), which means that half of control of flux is determined by this enzyme. The rest of the control is exerted by one or more other steps, since the control strength of steps of a linear pathway must sum to 1.0 by definition.

With the caveat that regulation of flux through glycolysis is dependent on the tissue and the nutritional and hormonal state, the enzymes of glycolysis with the greatest control strength are hexokinase, 6-phosphofructo-1-kinase, and pyruvate kinase (Figure 15.11). These enzymes are regulated by allosteric effectors and/or covalent modification.

A nonregulatory enzyme most likely catalyzes a *near-equilibrium reaction*, whereas a regulatory enzyme most likely catalyzes a *nonequilibrium reaction*. The activity of a nonregulatory enzyme readily brings its substrates and products to equilibrium concentrations. A regulatory enzyme is not active enough to equilibrate its substrates and products. Whether an enzyme-catalyzed reaction is near equilibrium or nonequilibrium can be determined by comparing the established equilibrium constant for the reaction with the mass-action ratio as it exists within a cell. The equilibrium constant for the reaction A + B → C + D is defined as

$$K_{eq} = \frac{[C][D]}{[A][B]}$$

where the brackets indicate the concentrations at equilibrium. The mass-action ratio is calculated in a similar manner, except that the steady-state (ss) concentrations of reactants and products within the cell are used.

$$\text{Mass-action ratio} = \frac{[C]_{ss}[D]_{ss}}{[A]_{ss}[B]_{ss}}$$

If the mass-action ratio is approximately equal to K_{eq}, the enzyme is said to catalyze a near-equilibrium reaction and is not considered likely to be regulated. When the mass-action ratio is considerably different from the K_{eq}, the enzyme is said to catalyze a nonequilibrium reaction and is usually regulated. Comparison of mass-action ratios and equilibrium constants for enzymes of glycolysis in liver indicates that many enzymes catalyze equilibrium reactions. The reactions of glucokinase (liver isoenzyme of hexokinase), 6-phosphofructo-1-kinase, and pyruvate kinase in liver are far from equilibrium, suggesting that they are likely sites for regulation.

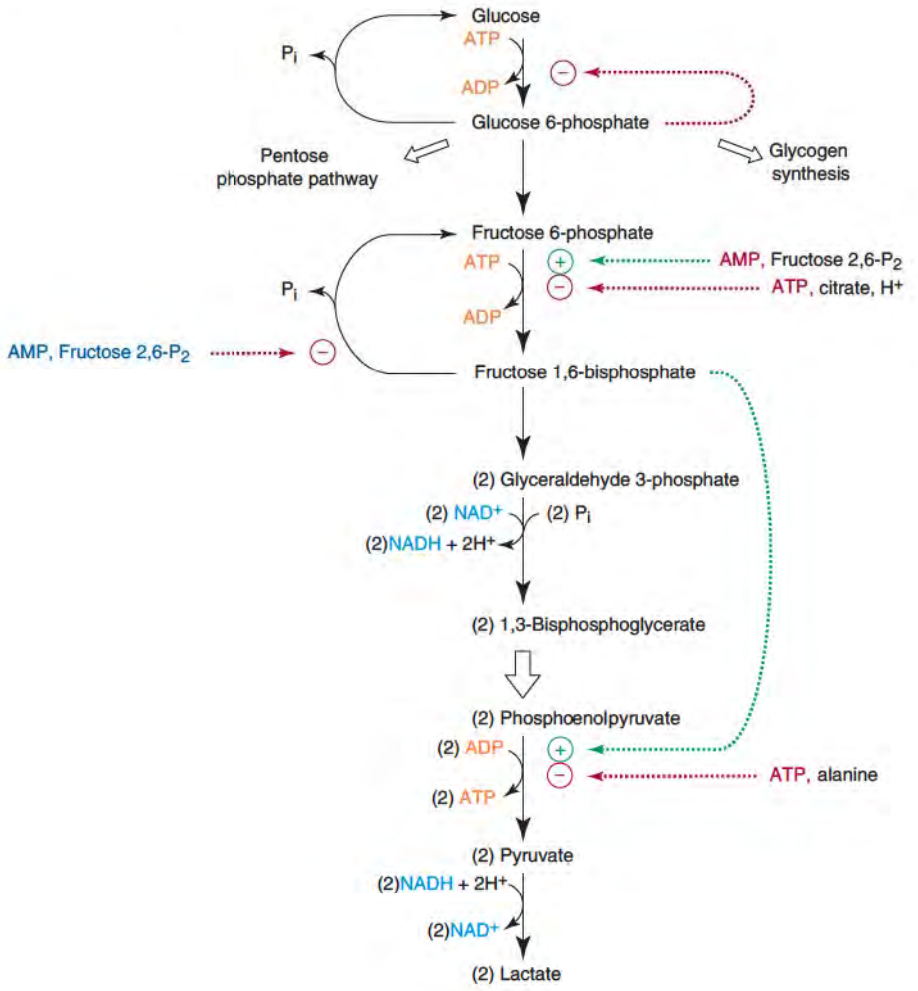


Figure 15.11 Important regulatory features of glycolysis. Because of tissue differences in isoenzyme expression, not all tissues of the body have all of the regulatory mechanisms shown here.

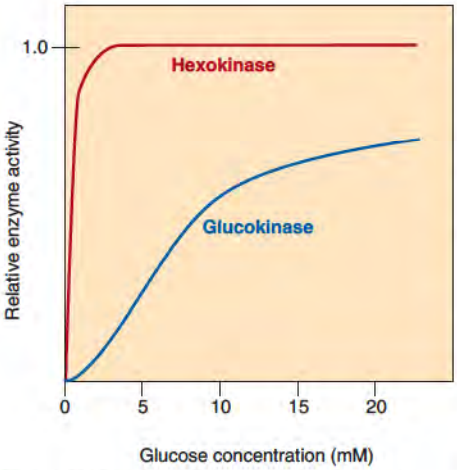

Figure 15.12 Comparison of the substrate saturation curves for hexokinase and glucokinase.

Hexokinase and Glucokinase Have Different Properties

Four different isoenzymes of hexokinase (I, II, III, and IV) are expressed in a tissue-specific manner in the body. The hexokinase isoenzymes found in most tissues (I, II, and III) have a low K_m for glucose (< 0.1 mM) relative to its concentration in blood (~ 5 mM) and are strongly inhibited by the product glucose 6-phosphate (G6P). The latter is important as it prevents hexokinase from tying up all of the inorganic phosphate of a cell in the form of phosphorylated hexoses (Clin. Corr. 15.3). Although the hexokinase reaction is not at equilibrium because of the inhibition imposed by G6P, the level at which hexokinase is expressed in cells can have a major impact on the rate of glycolysis in cells (A Closer Look 15.3).

Liver parenchymal cells and β cells of pancreas are unique in that they contain hexokinase isoenzyme IV, usually called glucokinase, which has strikingly different kinetic properties. Glucokinase catalyzes ATP-dependent phosphorylation of glucose like other hexokinases, but its $S_{0.5}$ (substrate concentration that gives enzyme activity of one half maximum velocity) for glucose is considerably higher than the K_m for glucose of the other hexokinases (Figure 15.12). Furthermore, glucokinase is much less sensitive to product inhibition by G6P, and its glucose saturation curve is sigmoidal, which is indicative of cooperativity (p. 414). Because the Michaelis–Menten equation does not apply (p. 400), its kinetics are described by a $S_{0.5}$ value (concentration of substrate required to produce a rate one half of V_{max}) rather than a K_m value for glucose. Although not sensitive to inhibition by physiological concentrations of G6P, glucokinase is indirectly regulated by fructose 6-phosphate, which is just one step removed and in equilibrium with G6P. A special glucokinase inhibitory protein (GK-RP), which is located in the nucleus of liver cells, is responsible for this effect (Figure 15.13). GK-RP sequesters glucokinase as an inactive complex in the nucleus. Fructose 6-phosphate promotes binding of glucokinase to the regulatory protein,

CLINICAL CORRELATION 15.3

Fructose Intolerance (OMIM 229600)

Patients with hereditary fructose intolerance are deficient in the liver enzyme (aldolase B) that splits fructose 1-phosphate into dihydroxyacetone phosphate and glyceraldehyde. Three isoenzymes (A, B, and C) are expressed in mammals. Aldolase B is present in the largest amounts in liver. It acts on both fructose 1-phosphate and fructose 1,6-bisphosphate, but it has much greater affinity (lower *Km*) for fructose 1,6-bisphosphate. Consumption of fructose by an individual with an aldolase B deficiency results in accumulation of fructose 1-phosphate and depletion of P_i and ATP in the liver. The reactions involved are those of fructokinase and the enzymes of oxidative phosphorylation.

$$\text{Fructose} + \text{ATP} \rightarrow \text{fructose 1-phosphate} + \text{ADP}$$
$$\text{ADP} + P_i + \text{energy provided by electron transport chain'} \rightarrow \text{ATP}$$
$$\text{Net: } P_i + \text{fructose} \rightarrow \text{fructose 1-phosphate}$$

Tying up P_i as fructose 1-phosphate makes it impossible for liver mitochondria to generate ATP by oxidative phosphorylation. The ATP levels fall precipitously, making it impossible for the liver to carry out its normal functions. Cell damage results largely because of inability to maintain normal ion gradients by the ATP-dependent pumps. The cells swell and undergo osmotic lysis.

Although patients with fructose intolerance are particularly sensitive to fructose, humans in general have a limited capacity to handle this sugar. The capacity of the normal liver to phosphorylate fructose greatly exceeds its capacity to split fructose 1-phosphate. This means that fructose use by the liver is poorly controlled and that excessive fructose could deplete the liver of P_i and ATP. Fructose was tried briefly in hospitals as a substitute for glucose in patients being maintained by parenteral nutrition. The rationale was that fructose would be a better source of calories than glucose because its utilization is relatively independent of the insulin status of a patient. Delivery of large amounts of fructose by intravenous feeding was soon found to result in severe liver damage. Similar attempts have been made to substitute sorbitol and xylitol for glucose, but they also tend to deplete the liver of ATP and, like fructose, should not be used for parenteral nutrition.

Steinmann, B., Gitzelmann, R., and Van den Berghe, G. Disorders of fructose metabolism. In Scriver, C. R., Beaudet, A. L., Sly, W. S., and Valle, D. (Eds.), *The Metabolic and Molecular Bases of Inherited Disease,* 8th ed.. New York: McGraw Hill, 2001, p. 1489; Ali, M., Rellos, P., and Cox T.M. Hereditary fructose intolerance. *J. Med. Genetics* 35: 353, 1998; and Wong, D. Hereditary fructose intolerance. *Mol. Gen. Metab.* 85: 165, 2005.

A CLOSER LOOK 15.3

Hexokinase II and Cancer

As a rule, rapidly growing cancers metabolize glucose faster than normal cells, at least in part because overexpression of hexokinase II gives cancer cells greater enzymatic capacity for glucose phosphorylation. On top of this, tight binding of hexokinase II to the mitochondrial outer membrane provides the enzyme with first dibs for the ATP produced by oxidative phosphorylation. The exceptional capacity that cancer cells have for glucose metabolism is used to detect cancer by positron emission tomography (PET). ^{18}F-labeled 2-deoxyglucose is administered to individuals suspected of having cancer. Large amounts of ^{18}F-2-deoxyglucose-6-P accumulate in cancer cells that rapidly metabolize glucose. The absence of a hydroxyl group in the 2 position of the 2-deoxyglucose moiety prevents further metabolism of ^{18}F-2-deoxyglucose-6-P.

Mathupala, S. P., Ko, Y. H., and Pedersen, P. L. Hexokinase II: Cancer's double-edged sword acting as both facilitator and gatekeeper of malignancy when bound to mitochondria. *Oncogene* 25: 4777, 2006.

thereby inhibiting glucokinase. Fructose 6-phosphate in effect promotes translocation of glucokinase from the cytosol to the nucleus where glucokinase is completely inhibited by the inhibitory protein. This inhibitory effect of fructose 6-phosphate on glucokinase can be completely overcome by a large increase in glucose concentration. Glucose triggers dissociation of glucokinase from the regulatory protein, thereby promoting translocation of glucokinase from the nucleus to the cytosol. These special regulatory features of glucokinase (high $S_{0.5}$ for glucose, cooperativity with respect to glucose concentration, and glucose-stimulated translocation from the nucleus to the cytosol) contribute to the capacity of the liver to "buffer" blood glucose levels. Because GLUT2, the glucose transporter of liver cells, brings about rapid equilibration of glucose across the plasma membrane, the cellular concentration of glucose is the same as that in the blood. Since the $S_{0.5}$ of glucokinase for glucose (~ 7 mM) is greater than normal blood glucose concentrations (~ 5 mM) and glucose promotes translocation of glucokinase from the nucleus, any increase in portal blood glucose above normal leads to a dramatic increase in the rate of glucose phosphorylation by glucokinase in the liver (see Figures 15.12 and 15.13). Likewise, any decrease in glucose

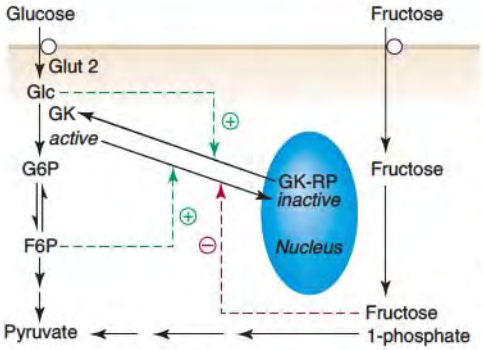

Figure 15.13 Glucokinase activity is regulated by translocation of the enzyme between the cytoplasm and the nucleus. Glucose increases glucokinase (GK) activity by promoting translocation of the enzyme to the cytoplasm. Fructose 6-phosphate decreases GK by stimulating translocation into the nucleus. Fructose 1-phosphate increases GK by inhibiting translocation into the nucleus. Binding of GK to regulatory protein (RP) in the nucleus completely inhibits GK activity.

concentration has the opposite effect. Thus, liver uses glucose at a significant rate only when blood glucose levels are greatly elevated and decrease its use of glucose when blood glucose levels are low. This buffering effect on blood glucose levels would not occur if glucokinase had the low K_m characteristic of other hexokinases, as it would then be completely saturated at physiological concentrations of glucose. On the other hand, a low K_m form of hexokinase is a good choice for tissues such as the brain in that it allows phosphorylation of glucose even when blood and tissue glucose concentrations are dangerously low.

The glucokinase reaction is not at equilibrium under normal intracellular conditions because of the rate restriction imposed by the high $S_{0.5}$ and inhibition by the regulatory protein. Another factor in opposition to the activity of glucokinase is glucose 6-phosphatase which like glucokinase has a high K_m (3 mM) for glucose 6-phosphate relative to its intracellular concentration (~ 0.2 mM). Thus, flux through this step is almost directly proportional to the intracellular concentration of glucose 6-phosphate. As shown in Figure 15.14, the combined action of glucokinase and glucose 6-phosphatase constitutes a futile cycle; that is, the sum of their reactions is hydrolysis of ATP to give ADP and P_i without the performance of any work. When blood glucose concentrations are about 5 mM, the activity of glucokinase is almost exactly balanced by the opposing activity of glucose 6-phosphatase. The result is that no net flux occurs in either direction. This futile cycling is wasteful of ATP but, combined with the process of gluconeogenesis (p. 619), contributes significantly to the "buffering" action of the liver on blood glucose levels. It also provides a mechanism for preventing glucokinase from tying up all of the P_i of the liver.

Fructose, a component of fruits, honey, vegetables, and high-fructose corn syrup used in popular carbonated beverages, promotes hepatic glucose utilization by an indirect mechanism. It is converted in liver to fructose 1-phosphate (Clin. Corr. 15.3, p. 607), which promotes dissociation of glucokinase from its regulatory protein (see Figure 15.13) and therefore translocation out of the nucleus. This action, which is capable of overriding the inhibition of glucokinase normally imposed by fructose 6-phosphate, may be a factor in the adverse effects sometimes associated with excessive dietary fructose consumption, e.g., increased hepatic carbohydrate utilization, lipogenesis, and hypertriacylglycerolemia.

Glucokinase is also an inducible enzyme. Induction and repression of synthesis of an enzyme are slow processes, usually requiring several hours before significant changes occur. Insulin promotes transcription of the glucokinase gene. An increase in blood glucose levels signals an increase in insulin release from the β cells of the pancreas, which promotes transcription and increases the amount of liver glucokinase enzyme protein. Thus, a person who has consumed a large carbohydrate-rich meal will have greater amounts of glucokinase than one who has not. The liver with glucokinase induced contributes more to the lowering of elevated blood glucose levels. The absence of insulin makes the liver of patients with diabetes mellitus deficient in glucokinase, in spite of high blood glucose levels, and decreases the ability of the liver to "buffer" blood glucose (Clin. Corr. 15.4). Defects in the gene-encoding glucokinase that alter its $S_{0.5}$ and/or V_{max} cause maturity-onset diabetes of the young (MODY), a form of type 2 diabetes mellitus.

6-Phosphofructo-1-kinase Is a Regulatory Enzyme of Glycolysis

6-Phosphofructo-1-kinase is an important regulatory site of glycolysis. It catalyzes the first committed step of glycolysis because the reaction catalyzed by phosphoglucose isomerase is reversible and cells make use of glucose 6-phosphate in the pentose phosphate pathway and

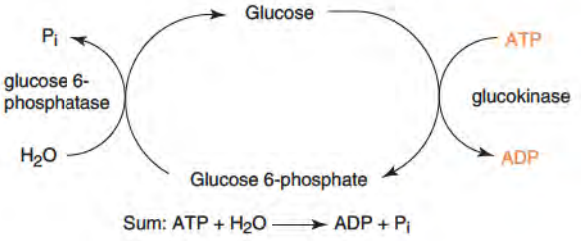

Figure 15.14 Phosphorylation of glucose followed by dephosphorylation constitutes a futile cycle in parenchymal cells of the liver.

CLINICAL CORRELATION 15.4

Diabetes Mellitus

Diabetes mellitus is a chronic disease characterized by derangements in carbohydrate, fat, and protein metabolism. Two major types are recognized clinically: type 1 (see Clin. Corr. 21.8, p. 868) and type 2 (see Clin. Corr. 21.6, p. 866).

In patients without fasting hyperglycemia, the oral glucose tolerance test can be used for diagnosis. It consists of determining the blood glucose level in the fasting state and at intervals of 30–60 min for 2 h or more after consuming a 100-g carbohydrate load. In normal individuals, blood glucose returns to normal levels within 2 h after ingestion of the carbohydrate. In diabetics, blood glucose reaches a higher level and remains elevated for longer periods of time, depending on the severity of the disease. However, many factors may contribute to an abnormal glucose tolerance test. The patient must have consumed a high carbohydrate diet for the preceding 3 days, presumably to allow for induction of enzymes of glucose-utilizing pathways, for example, glucokinase, fatty acid synthase, and acetyl-CoA carboxylase. Almost any infection (even a cold) and less well-defined stress, (presumably by effects on the sympathetic nervous system) can result in transient abnormalities of the glucose tolerance test. Because of these problems, fasting hyperglycemia (> 126 mg/dl) should probably be the *sine qua non* for the diagnosis of diabetes. Glucose uptake by insulin-sensitive tissues, that is, muscle and adipose, is decreased in the diabetic state. The diabetic patient either lacks insulin or has developed *insulin resistance* in these tissues. Resistance to insulin results from abnormality of the insulin receptor or in subsequent steps that mediate the metabolic effects of insulin. Liver parenchymal cells do not require insulin for glucose uptake. Without insulin, however, the liver has diminished capacity to remove glucose from the blood. This is explained in part by decreased glucokinase activity and the loss of insulin's action on key enzymes of glycogenesis and the glycolytic pathway.

Taylor, S. I. Insulin action, insulin resistance, and type 2 diabetes mellitus. In Scriver, C. R., Beaudet, A. L., Sly, W. S., and Valle, D. (Eds.), *The Metabolic and Molecular Bases of Inherited Disease*, 8th ed. New York: McGraw Hill, 2001, p. 1433; American Diabetes Association web site www.diabetes.org/home.jsp.

for glycogen synthesis. Citrate, ATP, and hydrogen ions (low pH) are the important negative allosteric effectors whereas AMP and fructose 2,6-bisphosphate are important positive allosteric effectors (see Figure 15.11, p. 606). These compounds signal the need for different rates of glycolysis in response to changes in (a) energy state of the cell (ATP and AMP), (b) internal environment of the cell (hydrogen ions), (c) availability of alternate fuels such as fatty acids and ketone bodies (citrate), and (d) the insulin/glucagon ratio in the blood (fructose 2,6-bisphosphate).

Regulation of 6-Phosphofructo-1-kinase by ATP and AMP

The Pasteur effect refers to the inhibition of glucose utilization and lactate accumulation that occurs when respiration (oxygen consumption) is initiated in anaerobic cells. It is readily understandable on a thermodynamic basis since complete oxidation of glucose to CO_2 and H_2O yields much more ATP than anaerobic glycolysis.

$$\text{Glycolysis} \quad \text{D-Glucose} + 2\ ADP^{3-} + 2\ P_i^{2-} \rightarrow 2\ \text{L-lactate}^- + 2\ ATP^{4-}$$

$$\text{Complete Oxidation} \quad \text{D-Glucose} + 6\ O_2 + 32\ ADP^{3-} + 32\ P_i^{2-} + 32\ H^+ \rightarrow 6\ CO_2 + 6\ H_2O + 32\ ATP^{4-}$$

Cells use ATP to provide the energy necessary for their inherent work processes. Since so much more ATP is produced from glucose in the presence of oxygen, much less glucose has to be consumed to meet the energy need. The Pasteur effect occurs in part because of ATP inhibition of glycolysis at the level of 6-phosphofructo-1-kinase. This can be readily rationalized since ATP is an inhibitor of 6-phosphofructo-1-kinase, and much more ATP is generated in the presence of oxygen than in its absence. Since 6-phosphofructo-1-kinase is severely inhibited at concentrations of ATP (2.5–6 mM) normally present in cells, the relatively small change in ATP concentration that occurs with oxygen versus without oxygen cannot account for large changes in flux through 6-phosphofructo-1-kinase. However, much greater changes occur in the concentration of AMP, a positive allosteric effector of 6-phosphofructo-1-kinase (see Figure 15.11, p. 606). The steady-state concentration of AMP when oxygen is introduced falls dramatically, decreasing 6-phosphofructo-1-kinase activity, suppressing glycolysis, and accounting in large part for the Pasteur effect. Levels of AMP automatically fall when ATP levels rise because the sum of adenine nucleotides in a cell, that is, ATP + ADP + AMP, is nearly constant under most physiological conditions and the amount of

ATP is always much greater than the amount of AMP. Furthermore, adenine nucleotides are maintained in equilibrium in the cytosol by adenylate kinase, which catalyzes the readily reversible reaction of 2ADP → ATP + AMP. The equilibrium constant (K'_{eq}) for this reaction is given by

$$K'_{eq} = \frac{[ATP][AMP]}{[ADP]^2}$$

Since this reaction operates near equilibrium under intracellular conditions, the concentration of AMP is given by

$$[AMP] = \frac{K'_{eq}[ADP]^2}{[ATP]}$$

Because intracellular [ATP] >> [ADP >> [AMP], a small decrease in [ATP] causes a substantially greater percentage increase in [ADP], and since [AMP] is related to the square of [ADP], an even greater percentage increase in [AMP]. Because of this relationship, a small decrease in [ATP] leads to a greater percentage increase in [AMP] than in the percentage decrease in [ATP]. This makes the [AMP] an excellent signal of the energy status of the cell and an important allosteric regulator of 6-phosphofructo-1-kinase activity. The effectiveness of 6-phosphofructo-1-kinase is influenced by [AMP] in yet another way. Fructose 1,6-bisphosphatase catalyzes an irreversible reaction that opposes the reaction of 6-phosphofructo-1-kinase.

$$\text{Fructose 1,6-bisphosphate} + H_2O \rightarrow \text{fructose 6-phosphate} + P_i$$

Fructose 1,6-bisphosphatase sits "cheek by jowl" with 6-phosphofructo-1-kinase in the cytosol of many cells. Together they catalyze a futile cycle (ATP + H_2O → ADP + P_i + "heat") and are therefore capable of decreasing each others "effectiveness." However, AMP inhibits fructose 1,6-bisphosphatase, which is opposite to the effect that AMP has on 6-phosphofructo-1-kinase. Thus, a small decrease in [ATP] triggers a large percentage increase in [AMP], which in turn signals a large increase in net conversion of fructose 6-phosphate into fructose 1,6-bisphosphate because of its effects on these two enzymes. This increases glycolytic flux by increasing the amount of fructose 1,6-bisphosphate available for the splitting stage.

The decrease in lactate that occurs due to the Pasteur effect is readily explained by decreased glycolytic flux. In addition, lactate dehydrogenase loses the competition with the substrate shuttle systems for NADH and the competition with the pyruvate dehydrogenase complex for pyruvate.

Regulation of 6-Phosphofructo-1-kinase by Intracellular pH

It would make sense if lactate, as the end product of glycolysis, would inhibit the most important regulatory enzyme of glycolysis. However, it is hydrogen ions rather than lactate that inhibit 6-phosphofructo-1-kinase (see Figure 15.11, p. 606). As shown in Figure 15.15, anaerobic glycolysis generates lactic acid, and the cell must dispose of it as such or suffer the negative consequences of acidification. This explains why excessive glycolysis lowers blood pH and leads to an emergency medical situation known as lactic acidosis (Clin. Corr.15.5). Plasma membranes contain a symport for lactate and hydrogen ions that allows transfer of lactic acid into the bloodstream. This defense mechanism prevents pH from getting so low that lactic-acid-producing tissues become pickled (Clin. Corr. 15.6). Transport of lactic acid out of a cell requires that blood be available to carry it away. When blood flow is inadequate, for example, in the heart during an attack of angina pectoris or in skeletal muscle during heavy exercise, hydrogen ions cannot escape from cells fast enough. Yet, the need for ATP, manifested by an increase in [AMP], may partially override inhibition of 6-phosphofructo-1-kinase by hydrogen ions. Unabated accumulation of hydrogen ions then causes pain, which, in the case of skeletal muscle, can be relieved by simply terminating the exercise. In the heart, rest or pharmacologic agents that increase blood flow or decrease the need for ATP within myocytes may be effective (Clin. Corr. 15.7).

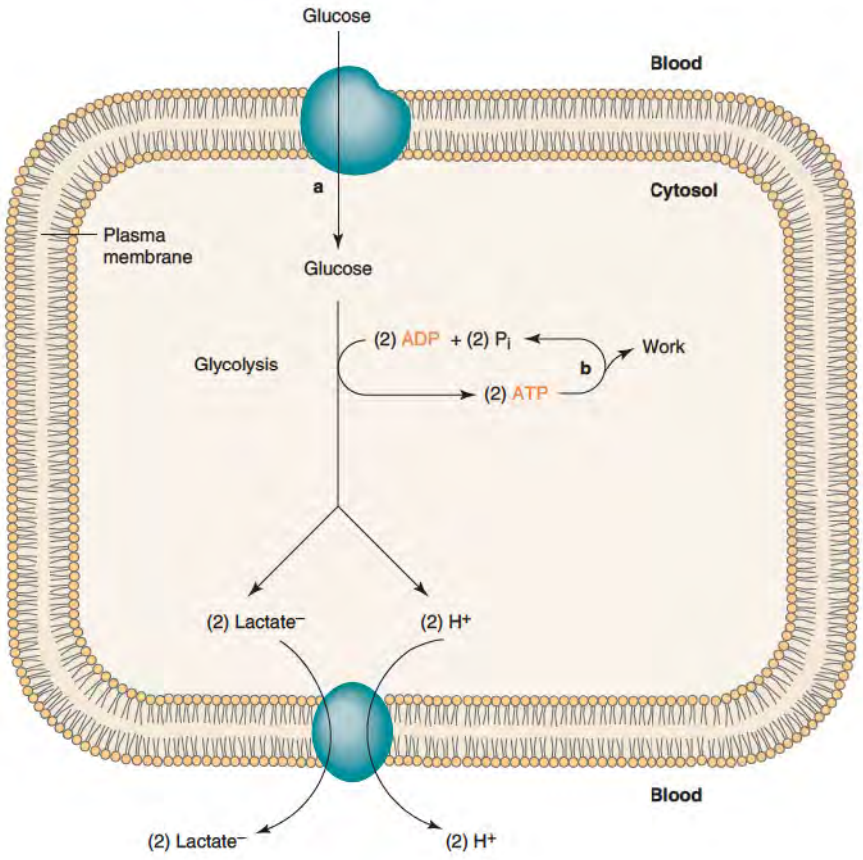

Figure 15.15 Unless lactate formed by glycolysis is transported out of the cell, the intracellular pH will decrease by the accumulation of intracellular lactic acid (equivalent to lactate$^-$ plus H^+ because lactic acid ionizes at intracellular pH). The low pH decreases 6-phosphofructo-1-kinase activity so that further lactic acid production by glycolysis is inhibited. (*a*) Glucose transport into the cell. (*b*) All work performances that convert ATP back to ADP and P_i. (*c*) lactate-H^+ symport (actual stoichiometry of one lactate$^-$ and one H^+ transported by the symport).

CLINICAL CORRELATION 15.5

Lactic Acidosis

This is characterized by elevated blood lactate levels, usually greater than 5 mM, with decreased blood pH and bicarbonate concentrations (see Clin. Corr. 1.2, p. 11). Lactic acidosis is the most frequent form of metabolic acidosis and can be the consequence of overproduction of lactate, underutilization of lactate, or both. Lactate production is normally balanced by lactate utilization so that lactate is usually not present in the blood at concentrations greater than 1.2 mM. All tissues can produce lactate by anaerobic glycolysis, but most tissues do not produce large quantities since they are well supplied with oxygen and mitochondria. However, all tissues respond with an increase in lactate generation when oxygenation is inadequate. A decrease in ATP because of less oxidative phosphorylation increases the activity of 6-phosphofructo-1-kinase. Thus, tissues have to rely on anaerobic glycolysis for ATP production under such conditions and overproduce lactic acid. A good example is muscle exercise, which can deplete the tissue of oxygen and cause an overproduction of lactic acid. Tissue hypoxia occurs, however, in all forms of shock, during convulsions, and in diseases involving circulatory and pulmonary failure.

The major fate of lactate in the body is either complete combustion to CO_2 and H_2O or conversion back to glucose by the process of gluconeogenesis. Both require oxygen. Decreased oxygen availability, therefore, increases lactate production and decreases lactate utilization. The latter can also be decreased by liver diseases, ethanol, and a number of other drugs. Phenformin, a drug that was once used to treat the hyperglycemia of type 2 diabetes, was well documented to induce lactic acidosis as a consequence of inhibition of complex I of the mitochondrial electron transport chain. Thiamin deficiency, common in poorly nourished alcoholics, causes lactic acidosis as a consequence of loss of activity of the pyruvate dehydrogenase complex. Thiamin should be administered immediately to patients with severe lactic acidosis.

Bicarbonate is usually administered in an attempt to control the acidosis associated with lactic acid accumulation. The key to successful treatment, however, is to find and eliminate the cause of the overproduction and/or underutilization of lactic acid and most often involves the restoration of circulation of oxygenated blood.

CLINICAL CORRELATION 15.6

Pickled Pigs and Malignant Hyperthermia (OMIM 145600)

In malignant hyperthermia, a variety of agents, especially the general anesthetic halothane, produces a dramatic rise in body temperature, metabolic and respiratory acidosis, hyperkalemia, and muscle rigidity. This dominantly inherited abnormality occurs in about 1 in 15,000 children and 1 in 50,000–100,000 adults. Death may result the first time a susceptible person is anesthetized. Onset occurs within minutes of drug exposure, and the hyperthermia must be recognized immediately. Packing the patient in ice is effective and should be accompanied by measures to combat acidosis. The drug dantrolene is also effective.

A phenomenon similar to malignant hyperthermia occurs in pigs; it is called porcine stress syndrome. The pigs respond poorly to stress. This genetic disease usually manifests itself as the pig is being shipped to market. On exposure to halothane, susceptible pigs have the same response as that observed in humans with malignant hyperthermia. The meat of pigs that have died from the disease is pale, watery, and of very low pH (i.e., nearly pickled).

In response to halothane, the skeletal muscles of affected individuals become rigid and generate heat and lactic acid. The sarcoplasmic reticulum has an abnormal ryanodine receptor, a Ca^{2+} release channel that is important in excitation–contraction coupling. Because of a defect in this protein, the anesthetic triggers inappropriate release of Ca^{2+} from the sarcoplasmic reticulum and uncontrolled stimulation of heat-producing processes, including myosin ATPase, glycogenolysis, glycolysis, and cyclic uptake and release of Ca^{2+} by mitochondria and sarcoplasmic reticulum. Muscle cells become irreversibly damaged from the excessive heat production, lactic acidosis, and ATP loss.

Regulation of 6-Phosphofructo-1-kinase by Citrate

Many tissues prefer to use fatty acids and ketone bodies as oxidizable fuels in place of glucose. Most such tissues can use glucose but prefer to oxidize fatty acids and ketone bodies. This helps preserve glucose for tissues, such as brain, that are absolutely dependent on it. Oxidation of both fatty acids and ketone bodies elevates levels of cytosolic citrate, which inhibits 6-phosphofructo-1-kinase (see Figure 15.11, p. 606) and decreases glucose utilization.

Hormonal Control of 6-Phosphofructo-1-kinase by cAMP and Fructose 2,6-bisphosphate

Fructose 2,6-bisphosphate (Figure 15.16), like AMP, is a positive allosteric effector of 6-phosphofructo-1-kinase and is a negative allosteric effector of fructose 1,6-bisphosphatase (see Figure 15.11, p. 806). Indeed, without its presence, glycolysis could not occur in liver because 6-phosphofructo-1-kinase would have insufficient activity and fructose 1,6-bisphosphatase would be too active for net conversion of fructose 6-phosphate to fructose 1,6-bisphosphate.

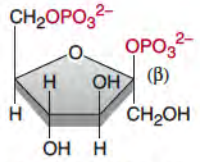

Figure 15.16 Structure of fructose 2,6-bisphosphate.

Binding of glucagon to its membrane receptor activates adenylate cyclase (an intrinsic membrane protein) activity through the action of a stimulatory G protein (G_s; a peripheral membrane protein). The (+) symbol indicates activation.

CLINICAL CORRELATION 15.7

Angina Pectoris and Myocardial Infarction

Chest pain associated with reversible myocardial ischemia is termed angina pectoris (literally, strangling pain in the chest). The pain results from an imbalance between demand for and supply of blood flow to cardiac muscles and is most commonly caused by narrowing of the coronary arteries. The patient experiences a heavy squeezing pressure or ache substernally, often radiating to either the shoulder and arm, or occasionally to the jaw or neck. Attacks occur with exertion, last from 1 to 15 min, and are relieved by rest or by death. The coronary arteries involved are obstructed by atherosclerosis (i.e., lined with fatty deposits) or less commonly narrowed by spasm. Infarction occurs if the ischemia persists long enough to cause severe damage (necrosis) to the heart muscle. Commonly, a blood clot forms at the site of narrowing and completely obstructs the vessel. In infarction, tissue death occurs and the pain is longer lasting and often more severe.

Nitroglycerin and other nitrates are frequently prescribed to relieve the pain. They can be used prophylactically, enabling patients to participate in activities that would otherwise precipitate an attack. Nitroglycerin may work in part by causing dilation of the coronary arteries, improving oxygen delivery, and washing out lactic acid. Probably more important is the effect on the peripheral circulation. Breakdown of nitroglycerin produces nitric oxide (NO) (p. 447) that relaxes smooth muscle, causing venodilation throughout the body. This reduces arterial pressure and allows blood to accumulate in the veins. The result is decreased return of blood to the heart, and reduced volume of blood to be pumped, which reduces the energy requirement. The heart also empties itself against less pressure, which further spares energy. The overall effect is a lowering of the oxygen requirement of the heart, bringing it in line with the oxygen supply via the diseased coronary arteries. Other useful agents are calcium channel blockers, which are coronary vasodilators and β-adrenergic blockers. The β-blockers prevent the increase in myocardial oxygen consumption induced by sympathetic nervous system stimulation of the heart, as occurs with physical exertion.

The coronary artery bypass operation is used in severe cases of angina that cannot be controlled by medication. In this operation, veins are removed from the leg and interposed between the aorta and coronary arteries so as to bypass the portion affected by atherosclerosis and provide the affected tissue with a greater blood supply. Remarkable relief from angina can be achieved by this operation, with the patient being able to return to normal productive life in some cases.

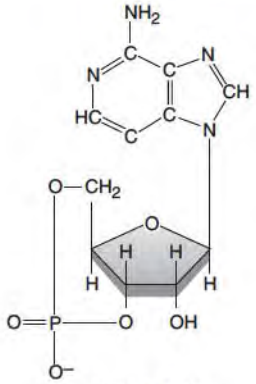
Figure 15.17 summarizes the role of fructose-2, 6-bisphosphate in hormonal control of hepatic glycolysis. The mechanism uses cAMP (Figure 15.18) as the *second messenger* of hormone action. Glucagon is released from the α cells of pancreas and circulates in blood until it encounters glucagon receptors on the outer surface of liver plasma membrane (see p. 615 for more details). Binding of glucagon to its receptor triggers stimulation of adenylate cyclase through the second messenger cyclic AMP (cAMP), which results in a decrease in fructose 2,6-bisphosphate. This makes 6-phosphofructo-1-kinase less effective and fructose 1,6-bisphosphatase more effective, thereby severely restricting flux from fructose 6-phosphate to fructose 1,6-bisphosphate in glycolysis.

Fructose 2,6-bisphosphate is produced from F6P by the enzyme **6-phosphofructo-2-kinase** (Figure 15.19) as a side product rather than as an intermediate of glycolysis. This makes two phosphofructokinases for us to contend with, one (6-phosphofructo-1-kinase) produces an intermediate (fructose 1,6-bisphosphate) of glycolysis and the other (6-phosphofructo-2-kinase) produces a positive allosteric effector (fructose 2,6-bisphosphate) of the former enzyme. Fructose 2,6-bisphosphatase opposes 6-phosphofructo-2-kinase by converting fructose 2,6-bisphosphate to F6P by simple hydrolysis. These kinase and phosphatase activities that determine the amount of fructose 2,6-bisphosphate reside in the same protein, a bifunctional enzyme named 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase. cAMP



Cyclic AMP

Figure 15.18 **Structure of cAMP.**

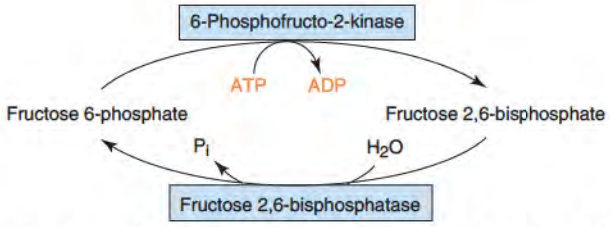


Figure 15.19 **Reactions involved in the formation and degradation of fructose 2,6-bisphosphate.**

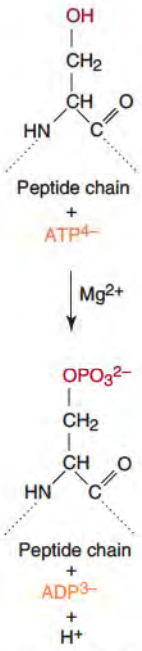

Figure 15.20 Enzymes subject to covalent modification are usually phosphorylated on specific serine residues. Tyrosine and threonine residues are also important sites of covalent modification by phosphorylation.

regulates fructose 2,6-bisphosphate levels in liver by activating the phosphatase and inactivating the kinase moieties of the bifunctional enzyme. This is achieved by cyclic-AMP-mediated activation of **protein kinase A**. Inactive protein kinase A consists of two regulatory and two catalytic subunits. Binding of cAMP to the regulatory subunits causes conformational changes that release and activate the catalytic subunits. The activated catalytic subunits then phosphorylate specific serine residues present in many enzymes (Figure 15.20).

Phosphorylation of an enzyme can conveniently be abbreviated as

$$\boxdot + \text{ATP} \rightarrow \odot\text{-P} + \text{ADP}$$

where ⊡ and ⊙-P are used to indicate dephosphorylated and phosphorylated enzymes, respectively. Phosphorylation causes a change in conformation that affects the active site of the enzyme. The activity of some enzymes is increased whereas that of others is decreased by phosphorylation. Many enzymes are regulated by this type of covalent modification that can be reversed by simply removing the phosphate. Regardless of whether phosphorylation or dephosphorylation activates the enzyme, the active enzyme is called the *a* form and the inactive enzyme the *b* form. Likewise, the action of a protein kinase is always opposed by that of a phosphoprotein phosphatase which catalyzes the reaction of

$$\odot\text{-P} + \text{H}_2\text{O} \rightarrow \boxdot + \text{P}_i$$

Putting these together creates a cyclic control system (Figure 15.21), such that the ratio of phosphorylated to dephosphorylated enzyme depends on the relative activities of the protein kinase and the phosphoprotein phosphatase, both of which are almost invariably also subject to regulation.

The Bifunctional Enzyme 6-Phosphofructo-2-kinase/ Fructose 2,6-bisphosphatase Is Regulated by Phosphorylation

Usually an enzyme subject to phosphorylation is either activated or inactivated as a result of phosphorylation. The bifunctional nature of 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase makes it unique in this regard. A single phosphorylation of liver 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase inactivates the kinase enzyme activity but activates the phosphatase enzyme activity (Figure 15.22). Dephosphorylation has the opposite effects. This provides a very sensitive mechanism for setting the intracellular concentration of fructose 2,6-bisphosphate in liver cells in response to changes in blood levels of glucagon or epinephrine (Figure 15.23). Increased levels of glucagon or epinephrine, acting through plasma membrane glucagon receptors and β-adrenergic receptors, respectively, have the common effect of increasing intracellular levels of cAMP. This activates protein kinase A, which phosphorylates a serine residue of 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase (Figure 15.24), which inhibits the kinase activity and activates its phosphatase activity. The resulting decrease in fructose 2,6-bisphosphate makes 6-phosphofructo-1-kinase less effective and fructose 1,6-bisphosphatase more effective and thereby inhibits glycolysis at the level of the conversion of fructose 6-phosphate to fructose 1,6-bisphosphate. A decrease in glucagon or epinephrine in the blood results in the opposite effect. A phosphoprotein phosphatase removes phosphate from the bifunctional

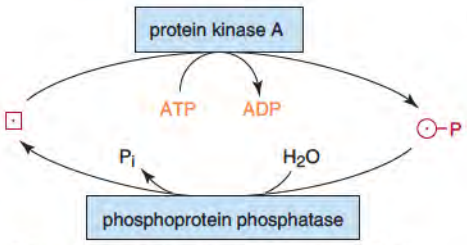

Figure 15.21 General model for regulation of enzymes by phosphorylation-dephosphorylation. The symbols ⊡ and ⊙-P indicate that different conformational and activity states of the enzyme are produced because of phosphorylation-dephosphorylation.

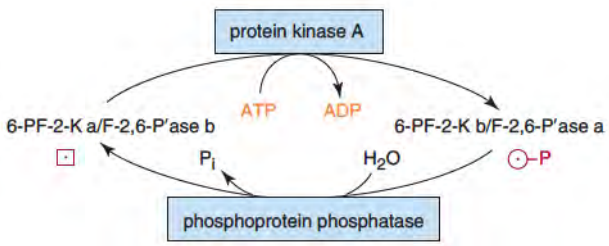

Figure 15.22 Mechanism for covalent modification of 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase. Name of the enzyme is abbreviated as 6-PF-2-K/F-2,6-P'ase. Letters a and b indicate the active and inactive forms of the enzymes, respectively.

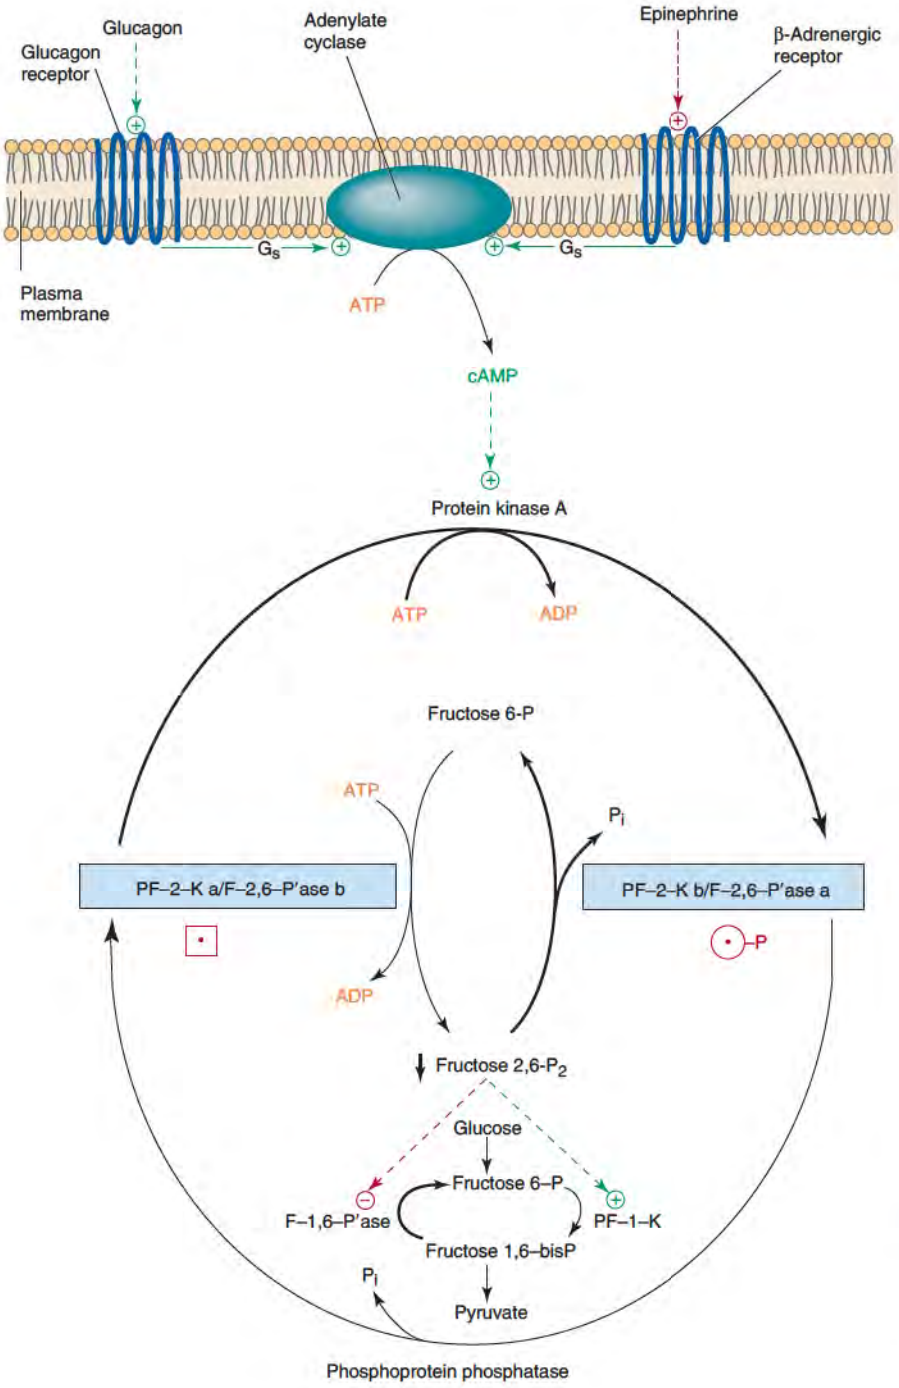

Figure 15.23 Mechanism of glucagon and epinephrine inhibition of hepatic glycolysis by cAMP-mediated decrease in fructose 2,6-bisphosphate.
See legend for Figure 15.19, p. 613. Heavy arrows indicate reactions that predominate in the presence of glucagon. Small arrow before fructose 2,6-bisphosphate indicates a decrease in its concentration.

enzyme to activate the kinase and inactivate the phosphatase. Fructose 2,6-bisphosphate accumulates to a higher steady-state concentration and increases the rate of glycolysis. Thus, glucagon and epinephrine are extracellular signals that stop liver from using glucose, whereas fructose 2,6-bisphosphate is an intracellular signal that promotes glucose utilization by this tissue.

Insulin opposes the actions of glucagon and epinephrine by means of a signaling cascade initiated by activation of the tyrosine kinase activity of its receptor (p. 910). Insulin also activates cAMP phosphodiesterase (lowers cAMP levels), inhibits protein kinase A, and activates phosphoprotein phosphatase, all of which oppose the effects of glucagon and epinephrine (Figure 15.25). Insulin therefore acts to stimulate the rate of glycolysis.

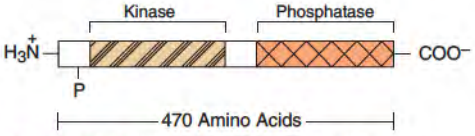

Figure 15.24 Schematic diagram of the primary structure of the liver isoenzyme of 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase. H_3N^+ and COO^- designate the N-terminal and C-terminal ends, respectively. Domain with kinase activity is located in the N-terminal half; domain with phosphatase activity in the C-terminal half. The letter P indicates the site (serine 32) phosphorylated by protein kinase A.

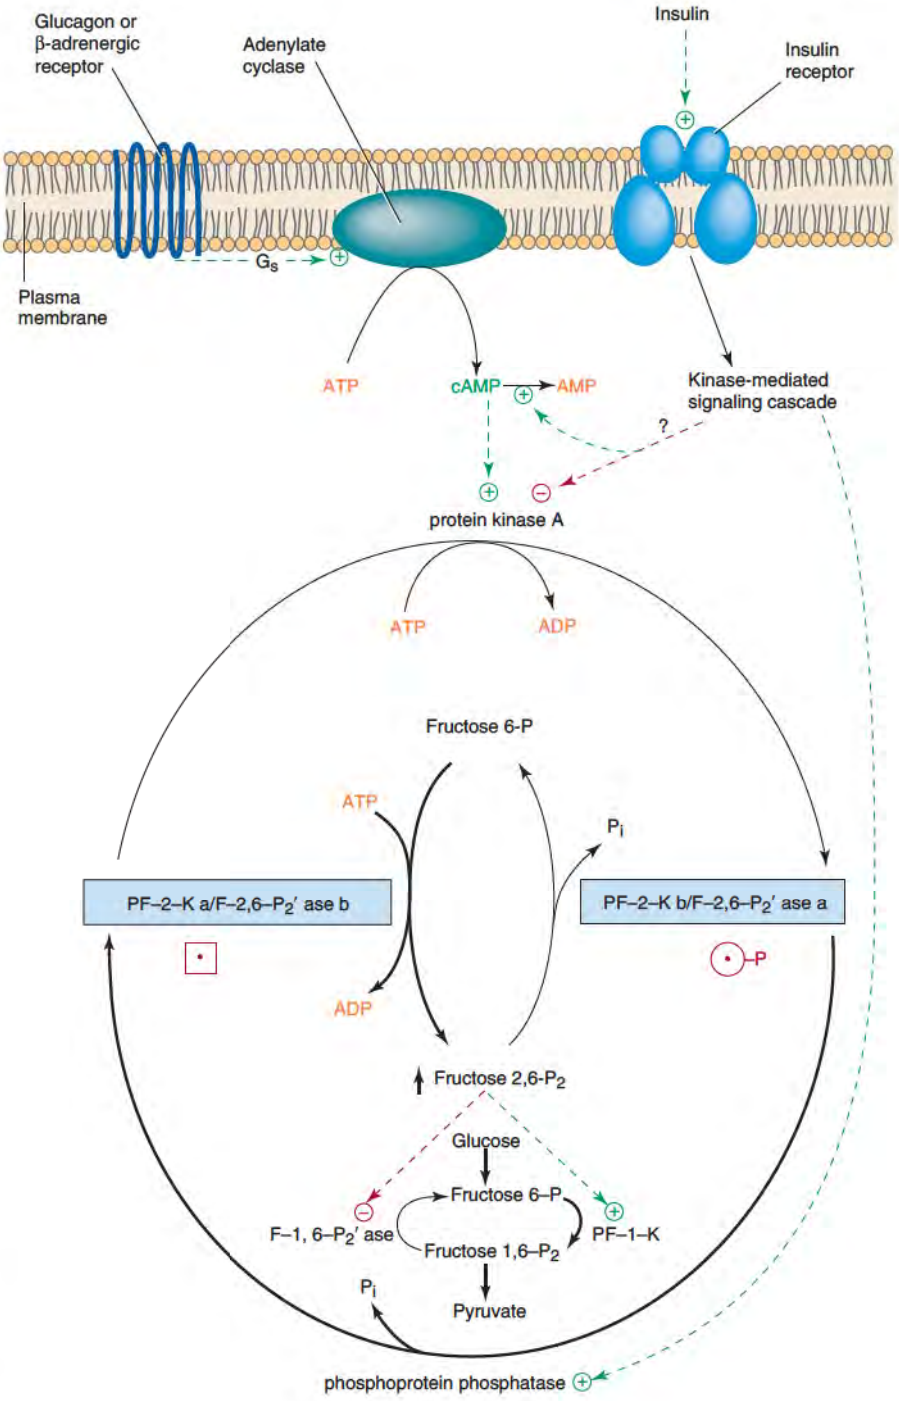

Figure 15.25 Mechanism for accelerated rates of hepatic glycolysis when the concentration of glucagon and epinephrine are low and that of insulin is high in the blood. See legends to Figures 15.17, p. 612, and 15.23, p. 615. The insulin receptor is an intrinsic protein of the plasma membrane. Small arrow before fructose 2,6-bisphosphate indicates an increase in concentration. cAMP is converted to AMP by cAMP phosphodiesterase.

Heart Contains a Different Isoenzyme of 6-Phosphofructo-2-kinase/Fructose 2,6-bisphosphate

An increase in blood level of epinephrine has a markedly different effect on glycolysis in heart than in liver. Although glycolysis is inhibited in liver to conserve glucose for use by other tissues, epinephrine stimulates glycolysis in heart to meet the increased need for ATP caused by an epinephrine-signaled increase in workload. As in liver, epinephrine acts on the heart by way of a β-adrenergic receptor on the plasma membrane, promoting formation of cAMP (Figure 15.26). This results in activation of protein kinase A that then phosphorylates 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase. However, in contrast to what

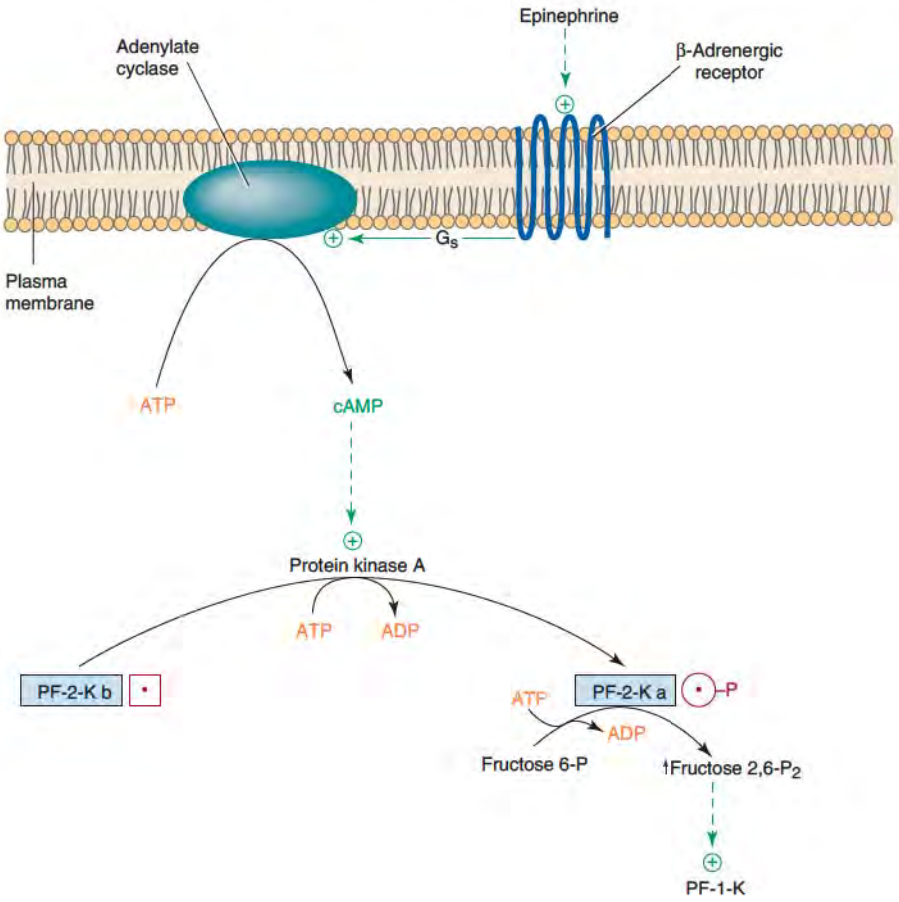

Figure 15.26 Mechanism for acceleration of glycolysis in the heart in response to epinephrine. See legends to Figures 15.17, p. 612, and 15.25, p. 616.

happens in liver, phosphorylation of the bifunctional enzyme in heart increases rather than decreases fructose 2,6-bisphosphate levels. This is because the isoenzyme of the bifunctional enzyme expressed in heart is different from the isoenzyme expressed in liver. Phosphorylation of the heart isoenzyme occurs at a site that activates rather than inhibits the kinase activity (Figure 15.27). Increased fructose 2,6-bisphosphate concentration then increases 6-phosphofructo-1-kinase activity and glycolytic flux.

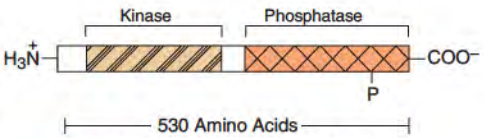

Figure 15.27 Schematic diagram of the primary structure of the heart isoenzyme of 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase. See legend to Figure 15.24, p. 615. The letter P indicates the site (serine 466) phosphorylated by protein kinase A.

Role of 6-Phosphofructo-2-kinase/Fructose 2,6-bisphosphate in Cancer

Many cancer cells express a special isoform of 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase in which the activity of the 2-kinase component greatly exceeds the activity of the 2-phosphatase component. This results in a high steady state concentration of fructose 2,6-bisphosphate which maximally stimulates of 6-phosphofructo-1-kinase activity. This is a major component of the mechanism responsible for the high rate of glycolysis characteristic of rapidly growing tumors (A Closer Look 15.4 and 15.5).

Pyruvate Kinase Is Also a Regulatory Enzyme of Glycolysis

Pyruvate kinase (Clin. Corr. 15.8) is drastically inhibited by physiological concentrations of ATP (see Figure 15.11, p. 606), so much so that its potential activity is probably never fully realized under physiological conditions. The liver isoenzyme is greatly activated by fructose 1,6-bisphosphate (FBP), and thereby linking regulation of pyruvate kinase to that of 6-phosphofructo-1-kinase. Thus, if conditions favor increased flux through 6-phosphofructo-1-kinase, the level of FBP increases and acts as a feed-forward activator of pyruvate kinase. The liver enzyme is also regulated by covalent modification by protein kinase A, being active in the dephosphorylated state and inactive in the phosphorylated state (Figure 15.28, p. 619). Concurrent inhibition of hepatic glycolysis and stimulation of hepatic gluconeogenesis by glucagon can be explained in part by inhibition of pyruvate kinase caused by activation of protein kinase A by cAMP. This aspect is explored more thoroughly in Section 15.5 in the discussion of gluconeogenesis.

A CLOSER LOOK 15.4

6-Phosphofructo-2-kinase/Fructose-2,6-bisphosphatase and Cancer

Aggressive tumors often grow faster than new blood vessels can be formed from existing blood vessels. This can result in a core of oxygen-starved cells within tumors that could die for want of the ATP normally produced by oxidative phosphorylation. However, cancerous cells have an insidious ability to survive hypoxia, afforded by the exceptional capacity they have for the generation of ATP by glycolytic pathway. Expression of an hypoxia-inducible form of 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase is one of the major reasons for the unusual glycolytic activity of cancer cells. As in the liver, the kinase activity greatly exceeds the phosphatase activity of the nonphosphorylated bifunctional enzyme in cancerous cells. Remarkably, and in complete contrast to the liver, phosphorylation of the hypoxia-inducible form of the bifunctional enzyme by AMP-activated protein kinase (AMPK) causes an even greater increase in the kinase activity relative to the phosphatase activity. As a consequence, the increase in AMP that occurs in response to hypoxia activates AMPK which activates 2-kinase activity of the bifunctional enzyme which increases the production of fructose 2,6-bisphosphate which activates 6-phosphofructo-1-kinase which increases the rate of glycolysis which generates the ATP required to meet the energy needs of hypoxia cancerous cells.

Kim, S.-G., Manes, N. P., El-Maghrabi, M. R., and Lee, Y.-H. Crystal structure of the hypoxia-inducible form of 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase (PFKFB3): A possible new target for cancer therapy. *J. Biol. Chem.* 281: 2939, 2006.

A CLOSER LOOK 15.5

TIGAR and Cancer

TIGAR stands for TP53(tumor protein 53)-induced glycolysis and apoptosis regulator. As implied by its name, TIGAR regulates glycolysis and apoptosis and is induced by activation of the TP53 gene. The TP53 gene encodes the tumor-suppressor protein p53, a transcription factor that regulates the expression of several proteins, including TIGAR, that prevent the development of cancer. TIGAR is structurally related to the bisphosphatase domain of the bifunctional enzyme 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase. It lacks kinase activity but possesses phosphatase activity toward fructose 2,6-bisphosphate. Induction of TIGAR by p53 reduces fructose 2,6-biphosphate which reduces 6-phosphofructo-1-kinase activity which in turn reduces flux through the glycolytic pathway. Since glycolysis is important for the survival and growth of cancer cells (see A Closer Look 15.4, p. 618), up-regulation of TIGAR by p53 reduces the likelihood of tumor formation. Loss of this regulatory mechanism as a consequence of mutations in the TP53 gene is common in cancer.

CLINICAL CORRELATION 15.8

Pyruvate Kinase Deficiency and Hemolytic Anemia (OMIM 266200)

Mature erythrocytes are absolutely dependent on glycolytic activity for ATP production. ATP is needed for the ion pumps, especially the Na^+, K^+- transporting-ATPase, which maintains the biconcave disk shape of erythrocytes that helps them slip through the capillaries as they deliver oxygen to the tissues. The cells swell and lyse without ATP. Anemia due to excessive erythrocyte destruction is referred to as hemolytic anemia. Pyruvate kinase deficiency is rare but is the most common genetic defect of glycolysis that causes hemolytic anemia. Most patients have 5% to 25% of normal erythrocyte pyruvate kinase level and flux through the glycolysis is severely restricted, resulting in markedly lower ATP concentrations. The glycolysis intermediates proximal to the pyruvate kinase step accumulate, whereas pyruvate and lactate concentrations decrease. 2,3-Bisphosphoglycerate levels are increased. As a result, anemia is better tolerated in some patients than would be predicted because the affinity of hemoglobin for oxygen is decreased by the increase in 2,3-bisphosphoglycerate. Normal ATP levels are observed in reticulocytes of patients. Although deficient in pyruvate kinase, these immature' red blood cells have mitochondria and can generate ATP by oxidative phosphorylation. Maturation of reticulocytes into erythrocytes results in the loss of mitochondria and complete dependence on glycolysis for ATP production. Thus, the mature cells are lost rapidly from circulation. Anemia results because they cannot be replaced rapidly enough by erythropoiesis.

Pyruvate kinase deficiency and other enzymopathies of the erythrocyte. In Scriver, C. R., Beaudet, A. L., Sly, W. S., and Valle, D. (Eds.), *The Metabolic and Molecular Bases of Inherited Disease,* 8th ed. New York: McGraw Hill, 2001, 4637.

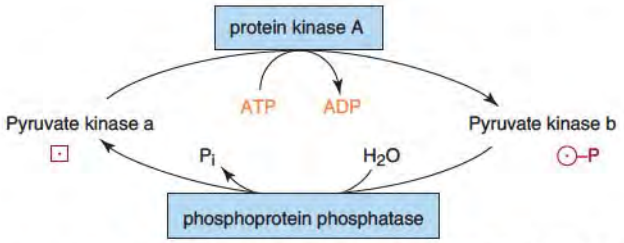

Figure 15.28 Glucagon acts via cAMP to cause phosphorylation and inactivation of hepatic pyruvate kinase.

Pyruvate kinase, like glucokinase, is induced in liver by high carbohydrate intake and high insulin levels. This is one reason why liver of the well-fed individual has much greater capacity for utilizing carbohydrate than that of a fasting or diabetic person (see Clin. Corr. 15.4, p. 609).

Role of Pyruvate Kinase in Cancer

Cancer cells express a special isoform of pyruvate kinase called PKM2, a splicing variant of the muscle form of pyruvate kinase (PKM1). PKM2 is required for rapid growth of tumor cells. Although PKM1 and PKM2 are closely related, PKM1 cannot substitute for PKM2 in cancer cells. Why tumors require this specific pyruvate kinase isoform is an active area of research (A Closer Look 15.6).

15.5 • GLUCONEOGENESIS

Glucose Synthesis Is Required for Survival

Net synthesis or formation of glucose from non-carbohydrate substrates is termed gluconeogenesis. Various amino acids, lactate, pyruvate, propionate, and glycerol are sources of carbon for the pathway (Figure 15.29). Glucose can also be produced from fructose. Glycogenolysis, that is, formation of glucose or glucose 6-phosphate from glycogen, should be differentiated from gluconeogenesis. Glycogenolysis refers to breakdown of glycogen to glucose and does not therefore correspond to *de novo* synthesis of glucose. Gluconeogenesis is essential for survival of humans and other animals as blood glucose levels have to be maintained to support metabolism of tissues that use glucose as their primary substrate (Clin. Corr. 15.9). These include brain, red blood cells, kidney medulla, lens, cornea, and testis. Gluconeogenesis enables the maintenance of blood glucose levels long after all dietary glucose has been absorbed and completely oxidized and glucose stored as glycogen has been used up.

Cori and Alanine Cycles

Gluconeogenesis is involved in two cycles that are critically important for maintaining blood glucose levels. The Cori cycle (or glucose–lactate cycle) and the alanine cycle (or glucose–alanine cycle) (Figure 15.30) depend on gluconeogenesis in liver followed by delivery of glucose and its use in a peripheral tissue. Both cycles provide for a continuous supply

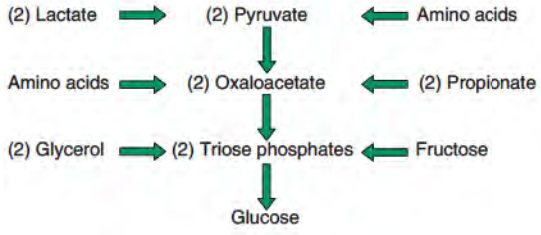

Figure 15.29 Abbreviated pathways of gluconeogenesis, illustrating the major substrate precursors for the process.

A CLOSER LOOK 15.6

Pyruvate Kinase M2 and Cancer

All cancer cells express PKM2, an isoform of pyruvate kinase found in embryos but not in normal adult tissues. For reasons that are not understood, the exceptional capacity that cancer cells have for aerobic glycolysis depends on this particular isoform of pyruvate kinase. Aerobic glycolysis by cancer cells, discovered by Otto Warburg, the recipient of the 1931 Nobel Prize for Physiology and Medicine, refers to an unusually rapid rate of glycolysis and overproduction of lactate in the presence of oxygen. Noncancerous cells extract more ATP per glucose, and therefore use less glucose and produce little or no lactate when oxygen is present. This is because the rate of glycolysis is tightly coordinated with the rates of the TCA cycle and oxidative phosphorylation in normal cells. In cancer cells glycolysis exceeds the capacity for complete glucose oxidation, resulting in overproduction of lactic acid, in spite of the presence of oxygen. Warburg proposed that the replacement of respiration by fermentation is the primary cause of cancer. Subsequent research has shown this is not the case. Cancer is caused by mutations that activate proto-oncogenes and inhibit tumor suppressor genes. Nevertheless, altered expression of genes encoding PDKM2 and other enzymes that increase the capacity for glycolysis provide cancer cells with a survival and growth advantage over noncancer cells.

CLINICAL CORRELATION 15.9

Hypoglycemia and Premature Infants

Premature and small-for-gestational-age neonates are more susceptible to hypoglycemia than full-term, appropriate-for-gestational-age infants. Children in general are also more susceptible than adults, simply because they have larger brain/body weight ratios and the brain utilizes disproportionately greater amounts of glucose than the rest of the body. Newborn infants have a limited capacity for ketogenesis, apparently because the transport of long-chain fatty acids into their liver mitochondria is poorly developed. Since the use of ketone bodies by the brain is directly proportional to the circulating ketone body concentration, the neonate cannot spare glucose to any significant extent by using ketone bodies. Thus the neonate's brain is almost completely dependent on glucose obtained from liver glycogenolysis and gluconeogenesis.

The capacity for hepatic glucose synthesis from lactate and alanine is also limited in newborn infants, as the rate-limiting enzyme, phosphoenolpyruvate carboxykinase, is present in very low amounts during the first few hours after birth. Its induction to the level required to prevent hypoglycemia during the stress of fasting requires several hours. Premature and small-for-gestational-age infants also have smaller stores of liver glycogen. Fasting depletes their glycogen stores more rapidly, making them more dependent on gluconeogenesis than normal infants.

Long-term effects of neonatal hypoglycemia on brain growth and psychomotor development in small-for-gestational-age preterm infants. *J. Pediatr.*134:492, 1999.

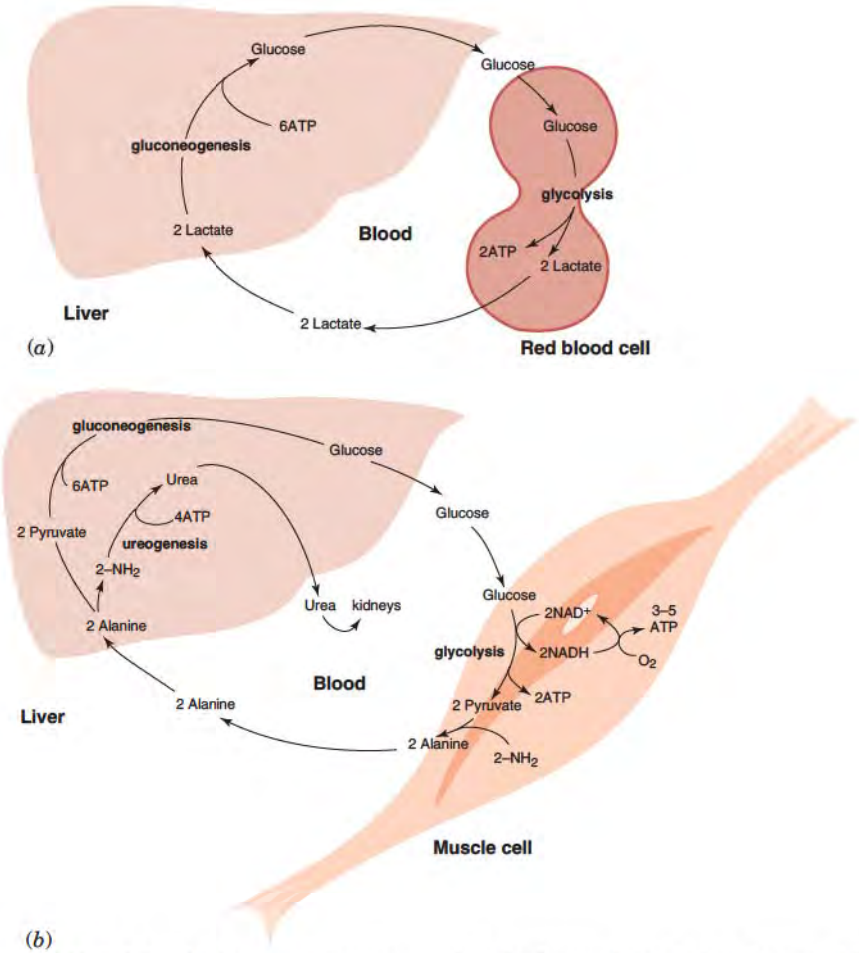

Figure 15.30 Relationship between gluconeogenesis in the liver and glycolysis in the rest of the body. (*a*) Cori cycle. (*b*) Alanine cycle.

of glucose to tissues that require it as their primary energy source. To participate in these cycles, peripheral tissues must release either alanine or lactate as the end product of glucose metabolism. A major difference between the cycles is that NADH generated by glycolysis in the alanine cycle is not used to reduce pyruvate to lactate; if it did, pyruvate would not be available for conversion to alanine by transamination with glutamate. In tissues that have mitochondria, reducing equivalents of NADH are transported into the mitochondria by the malate–aspartate shuttle or the glycerol–phosphate shuttle for the synthesis of ATP by oxidative phosphorylation.

$$NADH + H^+ + 0.5\ O_2 + 2.5\ ADP + 2.5\ P_i \rightarrow NAD^+ + 2.5\ ATP + H_2O$$

or

$$FADH_2 + 0.5\ O_2 + 1.5\ ADP + 1.5\ P_i \rightarrow FAD + 1.5\ ATP + H_2O$$

The consequence is that five to seven molecules of ATP can be formed per glucose molecule in peripheral tissues that participate in the alanine cycle. In the Cori cycle (Figure 15.30*a*), only two molecules of ATP per molecule of glucose are produced.

$$6\ ATP_{liver} + 2\ (ADP + P_i)_{red\ blood\ cells} \rightarrow 6\ (ADP + P_i)_{liver} + 2\ ATP_{red\ blood\ cells}$$

Six molecules of ATP are needed in liver for glucose synthesis. The alanine cycle (Figure 15.30*b*) transfers energy from liver to peripheral tissues and, because of the five to seven molecules of ATP produced per molecule of glucose, is energetically more efficient. However, the alanine cycle presents liver with amino nitrogen that must be disposed of as urea (p. 757). This requires four ATP molecules for every urea molecule produced and increases the amount of ATP required to 10 molecules per glucose molecule during the alanine cycle.

$$10\ ATP_{liver} + 5 - 7\ (ADP + P_i)_{muscle} + O_{2\ muscle} \rightarrow$$
$$10\ (ADP + P_i)_{liver} + 5 - 7\ ATP_{muscle}$$

This and the requirement in peripheral tissue for oxygen and mitochondria distinguish the alanine cycle from the Cori cycle.

Glucose Synthesis from Lactate

Gluconeogenesis from lactate is an ATP-requiring process.

$$2\ \text{L-Lactate}^- + 6\ ATP^{4-} + 6\ H_2O \rightarrow \text{glucose} + 6\ ADP^{3-} + 6\ P_i^{2-} + 4\ H^+$$

Many of the enzymes of glycolysis are used for gluconeogenesis from lactate. However, different reactions are necessary for the process because glycolysis produces two ATPs whereas gluconeogenesis requires six ATPs per molecule of glucose, and three steps of glycolysis are irreversible, namely the reactions catalyzed by glucokinase, 6-phosphofructo-1-kinase, and pyruvate kinase.

The initial step of lactate gluconeogenesis is the conversion of lactate to pyruvate by lactate dehydrogenase (Figure 15.31). The NADH generated is needed for a subsequent step

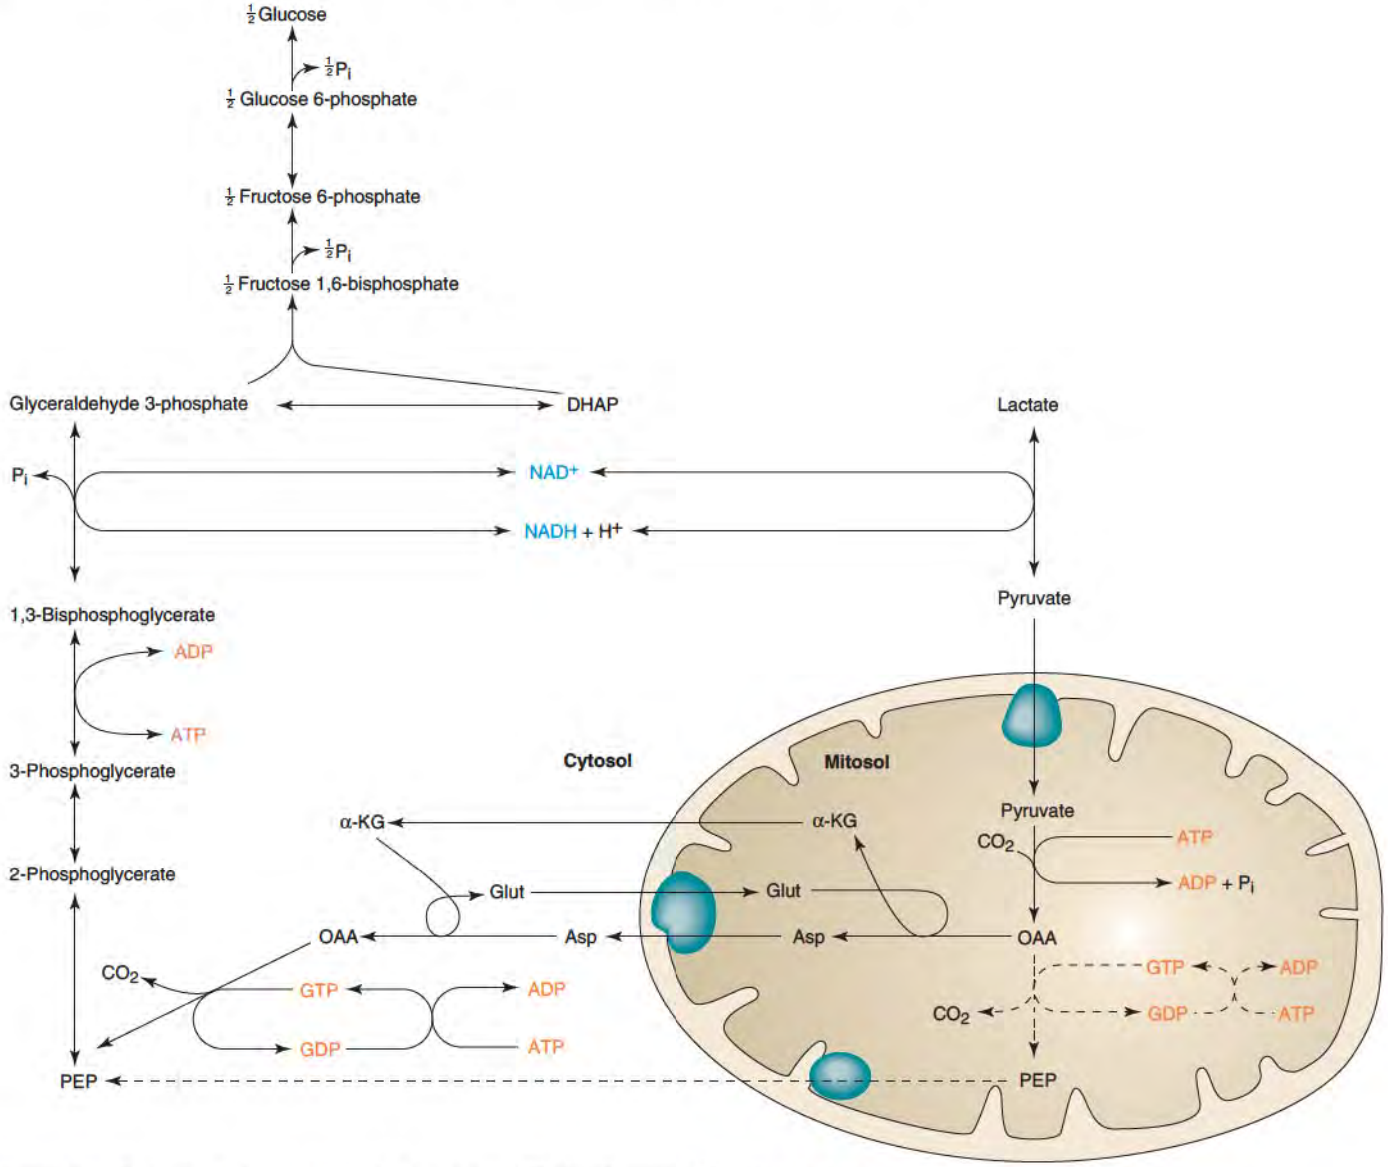

Figure 15.31 Pathway of gluconeogenesis from lactate. The involvement of the mitochondrion in the process is indicated. Dashed arrows refer to an alternative route, which employs mitochondrial PEP carboxykinase rather than the cytosolic isoenzyme. Abbreviations: OAA, oxaloacetate; α-KG, α-ketoglutarate; PEP, phosphoenolpyruvate; and DHAP, dihydroxyacetone phosphate.

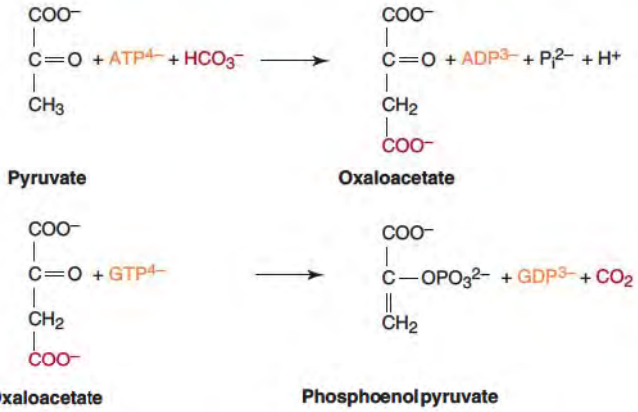

Figure 15.32 Energy-requiring steps involved in phosphoenolpyruvate formation from pyruvate. Reactions are catalyzed by pyruvate carboxylase and PEP carboxykinase, respectively.

in the pathway. Pyruvate cannot be converted to phosphoenolpyruvate (PEP) by pyruvate kinase because the reaction is irreversible under intracellular conditions. Pyruvate is converted into PEP by coupling of the reactions catalyzed by **pyruvate carboxylase**, which requires ATP, and PEP carboxykinase, which requires GTP (Figure 15.32). GTP is equivalent to an ATP through the action of nucleoside diphosphate kinase (GDP + ATP → GTP + ADP). The CO_2 generated by PEP carboxykinase and the HCO_3^- required by pyruvate carboxylase are linked by the reaction catalyzed by carbonic anhydrase ($CO_2 + H_2O \leftrightarrows H_2CO_3 \leftrightarrows H^+ + HCO_3^-$). Summing these reactions with the reactions of Figure 15.32 yields

$$\text{Pyruvate}^- + 2\ \text{ATP}^{4-} \rightarrow \text{phosphoenolpyruvate}^{3-} + 2\ \text{ADP}^{3-} + \text{P}_i^{2-} + 2\ \text{H}^+$$

Thus, conversion of pyruvate into PEP during gluconeogenesis costs the cell two molecules of ATP. This contrasts with the conversion of PEP to pyruvate during glycolysis that yields just one molecule of ATP.

The mitochondrial location of pyruvate carboxylase and the requirement for ATP make mitochondria mandatory for conversion of cytosolic pyruvate into cytosolic PEP (see Figure 15.31). However, because PEP carboxykinase is present in both the cytosol and mitochondrial matrix compartments, there are two routes that oxaloacetate takes to glucose. The first uses mitochondrial PEP carboxykinase, which converts oxaloacetate into PEP which then traverses the mitochondrial inner membrane. The second converts oxaloacetate into aspartate, which exits the mitochondrion by way of the glutamate–aspartate antiport. Aspartate contributes its amino group to α-ketoglutarate in the cytosol to produce oxaloacetate, which is used by cytosolic PEP carboxykinase to produce PEP.

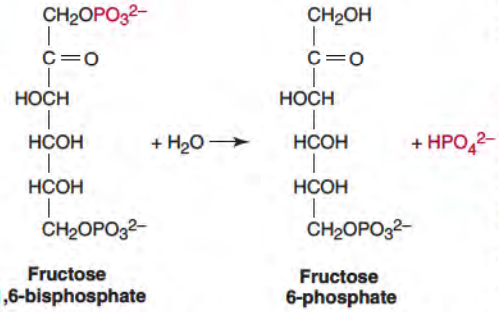

Figure 15.33 Reaction catalyzed by fructose 1,6-bisphosphatase.

Gluconeogenesis Uses Many Glycolytic Enzymes in the Reverse Direction

Enzymes of glycolysis operate in reverse to convert PEP to fructose 1,6-bisphosphate during gluconeogenesis. The generation of reducing equivalents (NADH) by lactate dehydrogenase is balanced by the use of reducing equivalents by glyceraldehyde 3-phosphate dehydrogenase. 6-Phosphofructo-1-kinase catalyzes an irreversible reaction and cannot convert FBP to fructose 6-phosphate. A way around this is provided by fructose 1,6-bisphosphatase, which hydrolyzes fructose 1,6-bisphosphate to F6P (Figure 15.33).

Phosphoglucose isomerase is freely reversible and functions in glycolysis and in gluconeogenesis. Glucose 6-phosphatase replaces glucokinase for the last step of gluconeogenesis (Figure 15.34), its function being to generate glucose for release into the blood stream. Glucose 6-phosphatase is an integral protein of the endoplasmic reticulum membrane with its active site available for G6P hydrolysis on the luminal surface (Figure 15.35). A transporter moves G6P across the endoplasmic reticulum membrane. A genetic defect in either the transporter or the phosphatase interferes with gluconeogenesis and results in accumulation of glycogen in liver, as discussed later for glycogen metabolism.

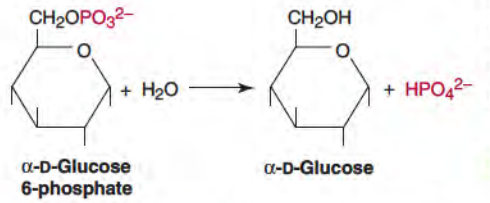

Figure 15.34 Reaction catalyzed by glucose 6-phosphatase.

Glucose Is Synthesized from Most Amino Acids

All amino acids except leucine and lysine can supply carbon for net synthesis of glucose by gluconeogenesis (p. 619). If catabolism of an amino acid produces either pyruvate or oxaloacetate,

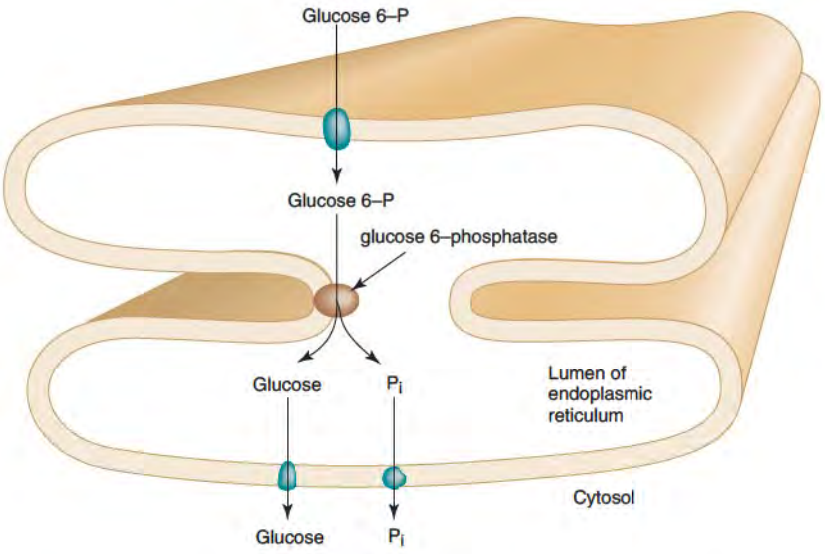

Figure 15.35 Glucose 6-phosphate is hydrolyzed by glucose 6-phosphatase located on the luminal surface of the endoplasmic reticulum. Three transporters are involved: One moves glucose 6-phosphate into the lumen, a second moves P_i back to the cytosol, and a third moves glucose back into the cytosol.

net glucose synthesis can occur from that amino acid. Oxaloacetate is an intermediate in gluconeogenesis and pyruvate is readily converted to oxaloacetate by pyruvate carboxylase (see Figure 15.31, p. 621). Catabolism of amino acids feeds carbon into the TCA cycle at several points. As long as net synthesis of a TCA cycle intermediate occurs, net synthesis of oxaloacetate will follow. Reactions that lead to net synthesis of TCA cycle intermediates are called anaplerotic reactions (anaplerosis) and support gluconeogenesis because they provide for net synthesis of oxaloacetate. Reactions catalyzed by pyruvate carboxylase and glutamate dehydrogenase are good examples of anaplerotic reactions.

$$\text{Pyruvate}^- + \text{ATP}^{4-} + \text{HCO}_3^- \rightarrow \text{oxaloacetate}^{2-} + \text{ADP}^{3-} + \text{P}_i^{2-} + \text{H}^+$$

$$\text{Glutamate}^- + \text{NAD(P)}^+ \rightarrow \alpha\text{-ketoglutarate}^{2-} + \text{NAD(P)H} + \text{NH}_4^+ + \text{H}^+$$

On the other hand, the reaction catalyzed by glutamate-oxaloacetate aminotransferase (α-ketoglutarate + aspartate → glutamate + oxaloacetate) is not anaplerotic because net synthesis of a TCA cycle intermediate is not accomplished; that is, generation of oxaloacetate from aspartate is counterbalanced by conversion of α-ketoglutarate to glutamate.

Since gluconeogenesis from amino acids imposes a nitrogen load on liver, a close relationship exists between urea synthesis and glucose synthesis from amino acids. In Figure 15.36, two alanine molecules are metabolized, one yielding NH_4^+ and the other aspartate, the primary substrates for the urea cycle. Aspartate leaves the mitochondrion and becomes part of the urea cycle after reacting with citrulline. The carbon of aspartate is released as fumarate that is converted to malate by cytosolic fumarase. This malate and another malate from mitochondria are converted to glucose by cytosolic enzymes of gluconeogenesis. A balance is achieved between reducing equivalents (NADH) generated and those required in the cytosol and the mitochondrial matrix. Summation of the reactions given in Figure 15.36 yields simply

$$2\ \text{Alanine} + 10\ \text{ATP} + \text{CO}_2 \rightarrow \text{Glucose} + \text{urea} + 10\ \text{ADP} + 10\ \text{P}_i$$

Leucine and lysine are the only amino acids that cannot function as carbon sources for net synthesis of glucose. They are ketogenic but not glucogenic. All other amino acids are glucogenic or both glucogenic and ketogenic (Table 15.1). Glucogenic amino acids give rise to net synthesis of either pyruvate or oxaloacetate, whereas amino acids that are both glucogenic and ketogenic also yield the ketone body acetoacetate, or acetyl CoA, which is readily converted into acetoacetate. Acetyl CoA is the end product of lysine metabolism, and acetoacetate and acetyl CoA are end products of leucine metabolism. No pathway exists that can convert acetoacetate or acetyl CoA into either pyruvate or oxaloacetate. Acetyl CoA cannot be used for net synthesis of glucose because the reaction of the pyruvate dehydrogenase complex is irreversible.

$$\text{Pyruvate} + \text{NAD}^+ + \text{CoASH} \rightarrow \text{acetyl CoA} + \text{NADH} + \text{CO}_2$$

TABLE 15.1 • Glucogenic and Ketogenic Amino Acids

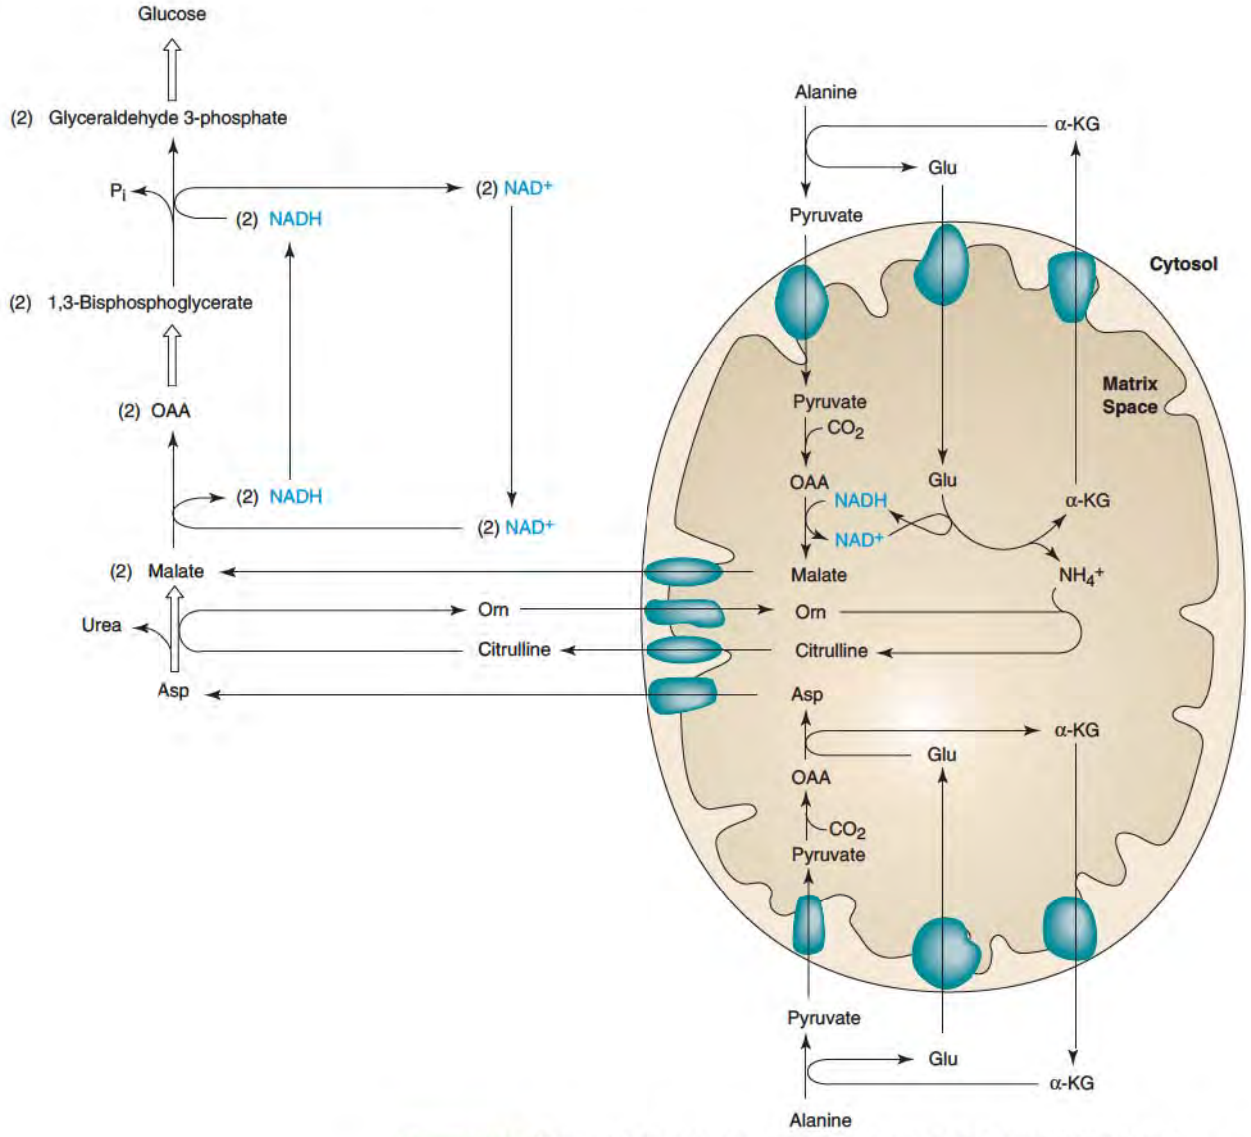

Figure 15.36 Pathway of gluconeogenesis from alanine and its relationship to urea synthesis. Abbreviations: OAA, oxaloacetate; Asp, aspartate; Orn, ornithine; Glu, glutamate; α-KG, α-ketoglutarate.

It could be argued that oxaloacetate is generated from acetyl CoA by the TCA cycle through this series of reactions.

$$\text{Acetyl CoA} \rightarrow \text{citrate} \rightarrow 2\ CO_2 + \text{oxaloacetate}$$

However, this fails to consider the oxaloacetate required for the formation of citrate from acetyl CoA.

$$\text{Acetyl CoA} + \text{oxaloacetate} \rightarrow \text{citrate} + \text{CoA}$$

Decarboxylation of citrate by the TCA cycle regenerates the oxaloacetate.

$$\text{Citrate} \rightarrow \rightarrow 2\ CO_2 + \text{oxaloacetate}$$

Summing these reactions gives the sum reaction for one turn of the TCA cycle.

$$\text{Acetyl CoA} \rightarrow 2CO_2 + \text{CoA}$$

Thus, net synthesis of a TCA cycle intermediate does not occur during complete oxidation of acetyl CoA by the TCA cycle. It is therefore impossible for animals to synthesize glucose from acetyl CoA.

Glucose Can Be Synthesized from Fatty Acids with an Odd but Not an Even Number of Carbons

Most fatty acids found in humans have straight chains with an even number of carbon atoms. Their catabolism by fatty acid oxidation followed by ketogenesis or complete oxidation to CO_2 is abbreviated in Figure 15.37. Since acetyl CoA and other intermediates of even-numbered fatty acid oxidation cannot be converted to oxaloacetate or any other intermediate of gluconeogenesis, it is impossible to synthesize glucose from fatty acids. An exception to this rule applies to fatty acids with methyl branches (e.g., phytanic acid, a breakdown product of chlorophyll; see discussion of Refsum disease, Clin. Corr. 17.6, p. 612), and fatty acids with an odd number of carbon atoms. Catabolism of such fatty acids yields propionyl CoA.

$$\text{Fatty acid with an odd number } (n) \text{ of carbon atoms} \rightarrow \frac{(n-3)}{2} \text{ acetyl CoA} + 1 \text{ propionyl CoA}$$

Propionyl CoA is a good precursor for gluconeogenesis as it yields oxaloacetate (Figure 15.38) by an anaplerotic pathway (see Figure 19.53, page 79). Propionyl CoA is also produced during the catabolism of valine and isoleucine (see Figure 19.50, p. 777) and in the conversion of cholesterol into bile acids (see Figure 18.42, p. 728).

It is sometimes loosely stated that *fat cannot be converted into carbohydrate (glucose) by animals.* This is certainly true for fatty acids with an even number of carbon atoms. However, the term *fat* usually refers to triacylglycerols, which are composed of three O-acyl groups combined with one glycerol molecule. Hydrolysis of a triacylglycerol yields three fatty acids and glycerol, the latter compound being an excellent substrate for gluconeogenesis (Figure 15.39).

Phosphorylation of glycerol by glycerol kinase produces glycerol 3-phosphate, which is converted by glycerol 3-phosphate dehydrogenase into dihydroxyacetone phosphate, an intermediate of the gluconeogenic pathway (see Figure 15.31, p. 607). Depending on the nutritional state, the last stage of glycolysis can compete with the gluconeogenic pathway and convert dihydroxyacetone phosphate into lactate (or into pyruvate for subsequent complete oxidation to CO_2 and H_2O).

Glucose Is Also Synthesized from Fructose

Humans consume considerable quantities of fructose in the form of sucrose, which yields glucose and fructose on hydrolysis by sucrase in the intestine (p. 1050), and as a result of the widespread use of high-fructose corn syrup as a sweetener by the food industry. In the liver, fructose is phosphorylated by fructokinase (Figure 15.40), which yields fructose 1-phosphate rather than fructose 6-phosphate (see Clin. Corr. 15.3, p. 607). The same

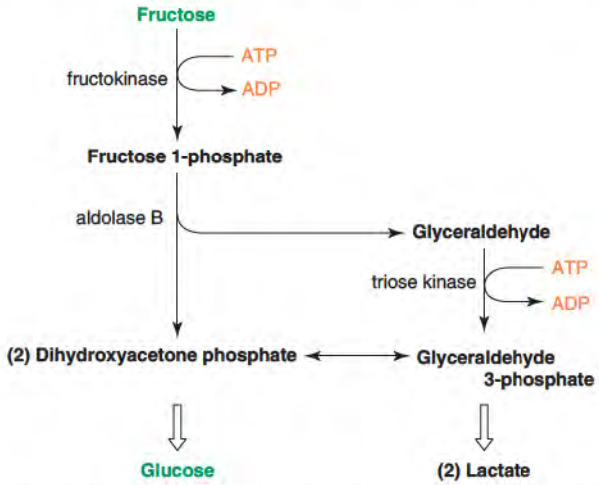

Figure 15.40 Pathway of glucose formation from fructose and the competing pathway of fructolysis. Large arrows indicate steps of the glycolysis and gluconeogenesis given in Figures15.6, p. 597, and 15.31, p, 621, respectively.

The large arrow pointing to fat indicates triacylglycerol and glycerophospholipid synthesis.

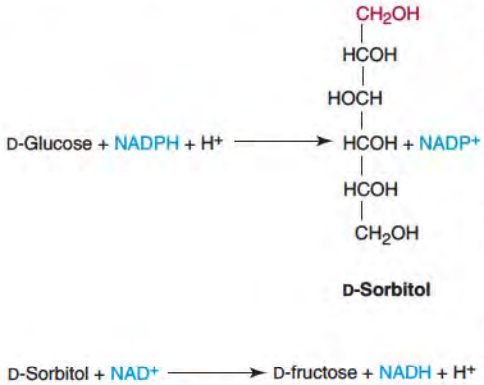

Figure 15.41 Pathway responsible for the formation of sorbitol and fructose from glucose.

aldolase that cleaves fructose 1,6-bisphosphate then cleaves fructose 1-phosphate to yield dihydroxyacetone phosphate and glyceraldehyde. The latter has several possible fates. It can be oxidized by an aldehyde dehydrogenase, reduced by an alcohol dehydrogenase, or phosphorylated by a kinase. The favored pathway is conversion to glyceraldehyde 3-phosphate by triose kinase. Two molecules of dihydroxyacetone phosphate obtainable from one molecule of fructose can be converted to glucose by enzymes of gluconeogenesis or, alternatively, into pyruvate or lactate by the last stage of glycolysis. In analogy to glycolysis, conversion of fructose into lactate is called fructolysis.

The major energy source of spermatozoa is fructose, formed from glucose by cells of seminal vesicles as shown in Figure 15.41. NADPH-dependent reduction of glucose to sorbitol is followed by an NAD^+-dependent oxidation of sorbitol to fructose. Fructose is secreted from seminal vesicles in a fluid that becomes part of semen. Although the fructose concentration in human semen can exceed 10 mM, tissues that are exposed to semen utilize fructose poorly, allowing this substrate to be conserved to meet the energy demands of spermatozoa in their search for ova. Spermatozoa contain mitochondria and thus can metabolize fructose completely to CO_2 and H_2O by the combination of fructolysis and TCA cycle activity.

Gluconeogenesis Requires Expenditure of ATP

Synthesis of glucose is costly in terms of ATP. Six molecules are required for synthesis of one molecule of glucose from lactate, 10 for synthesis of glucose from alanine. ATP for glucose synthesis is provided in large part by fatty acid oxidation. Metabolic conditions under which liver is required to synthesize glucose generally favor increased availability of fatty acids in the blood. These fatty acids are oxidized by liver mitochondria to ketone bodies with concurrent production of large amounts of ATP.

$$\text{Palmitate} + 7\ O_2 + 26\ \text{ADP} + 26\ P_i \rightarrow 4\ \text{Acetoacetate} + 26\ \text{ATP}$$

Gluconeogenesis Has Several Sites of Regulation

Regulation of gluconeogenesis occurs at multiple sites (Figure 15.42). Those enzymes that are used to bypass the irreversible steps of glycolysis are primarily involved in regulation of the pathway, that is, pyruvate carboxylase, PEP carboxykinase, fructose 1,6-bisphosphatase, and glucose 6-phosphatase. Regulation of hepatic gluconeogenesis is very similar to regulation of hepatic glycolysis. Inhibition of glycolysis at its chief regulatory sites or repression of synthesis of enzymes that bypass these sites (glucokinase, 6-phosphofructo-1-kinase, and pyruvate kinase) greatly increases effectiveness of the gluconeogenic enzymes. Activation of gluconeogenesis is therefore accomplished in large part by inhibition of glycolysis.

Fatty acid oxidation invariably occurs hand in hand with gluconeogenesis. It promotes glucose synthesis, in part by supplying the ATP needed and by increasing the steady-state concentrations of mitochondrial acetyl CoA and NADH. Both of these products of fatty acid oxidation are potent activators of pyruvate dehydrogenase kinase, which phosphorylates and inactivates the pyruvate dehydrogenase complex. This prevents pyruvate from being converted into acetyl CoA, thereby conserving pyruvate for glucose synthesis. Acetyl CoA is also a positive allosteric effector of pyruvate carboxylase, which along with inhibition of the pyruvate dehydrogenase complex, directs the carbon of pyruvate into oxaloacetate for the synthesis of glucose. The increase in oxaloacetate due to increased pyruvate carboxylase activity along with the increase in acetyl CoA from fatty acid oxidation also promotes greater synthesis of citrate, a negative allosteric effector of 6-phosphofructo-1-kinase. Inhibition of 6-phosphofructo-1-kinase decreases the fructose 1,6-bisphosphate concentration, an activator of pyruvate kinase. This decreases flux of PEP to pyruvate by pyruvate kinase and, by this means, increases effectiveness of the coupling of pyruvate carboxylase and PEP carboxykinase for the conversion of pyruvate to PEP. An increase in ATP levels with the consequent decrease in AMP levels favors gluconeogenesis by inhibition of 6-phosphofructo-1-kinase and pyruvate kinase and activation of fructose 1,6-bisphosphatase (see Figure 15.42 and p. 627). On the

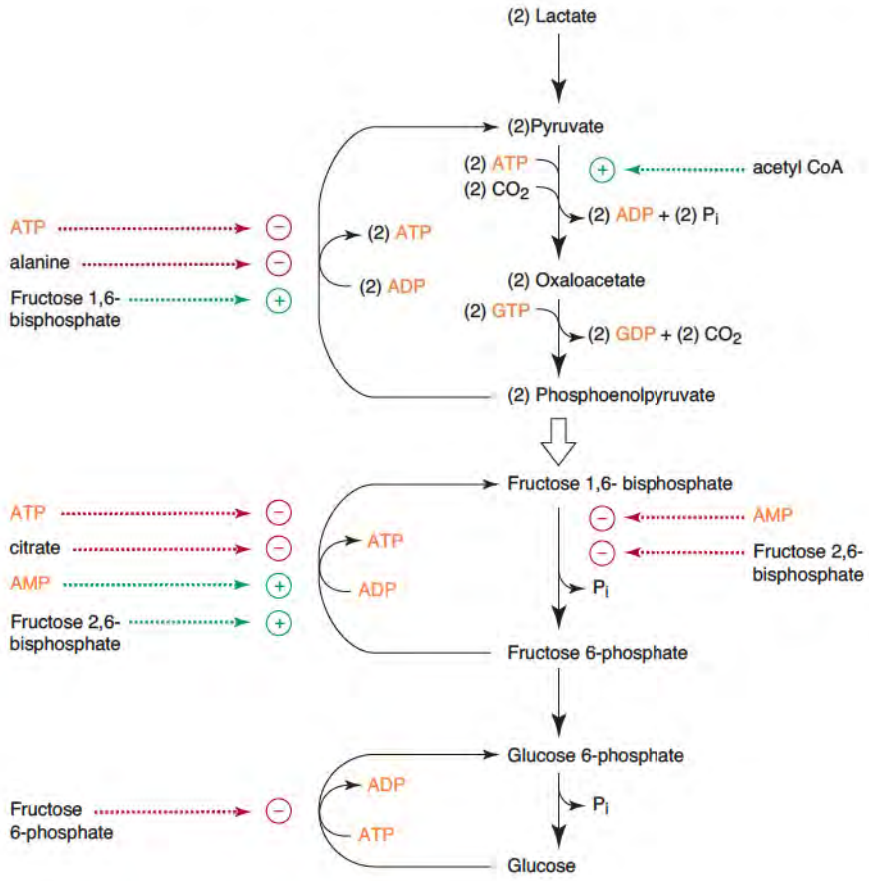

Figure 15.42 Important allosteric regulatory features of the gluconeogenesis.

other hand, a shortage of oxygen, a shortage of fatty acids for oxidation, or an inhibition or uncoupling of oxidative phosphorylation would cause the liver to turn from gluconeogenesis to glycolysis.

Hormonal Control of Gluconeogenesis Is Critical for Homeostasis

Hormonal control of gluconeogenesis is a matter of regulating the supply of fatty acids to liver as well as the activities of enzymes of glycolysis and gluconeogenesis. Catecholamines increase plasma fatty acids by promoting lipolysis in adipose tissue, an action opposed by insulin. The greater availability of fatty acids results in greater fatty acid oxidation by liver, which promotes glucose synthesis. Insulin produces the opposite effect by inhibiting lipolysis in the adipose tissue. Glucagon and insulin also regulate gluconeogenesis directly in the liver by influencing the state of phosphorylation of the hepatic enzymes that are subject to covalent modification. As discussed previously (see Figure 15.28, p. 619), pyruvate kinase is active when dephosphorylated and inactive when phosphorylated. Glucagon activates adenylate cyclase to produce cAMP, which activates protein kinase A, which phosphorylates and inactivates pyruvate kinase. Inactivation of this glycolytic enzyme stimulates gluconeogenesis by blocking the futile conversion of PEP to pyruvate. Glucagon also stimulates gluconeogenesis by decreasing the concentration of fructose 2,6-bisphosphate, an allosteric activator of 6-phosphofructo-1-kinase and an allosteric inhibitor of fructose 1,6-bisphosphatase. Glucagon through its second messenger cAMP lowers fructose 2,6-bisphosphate by stimulating phosphorylation of the bifunctional enzyme 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase which inactivates the kinase activity but activates the phosphatase activity. The glucagon-induced fall in fructose 2,6-bisphosphate levels leads to decrease in activity of 6-phosphofructo-1-kinase while fructose 1,6-bisphosphatase becomes more active (Figure 15.42). The overall effect is increased conversion of FBP to F6P and a corresponding increase in the rate of gluconeogenesis. An increase in fructose 6-phosphate also favors gluconeogenesis by inhibition of

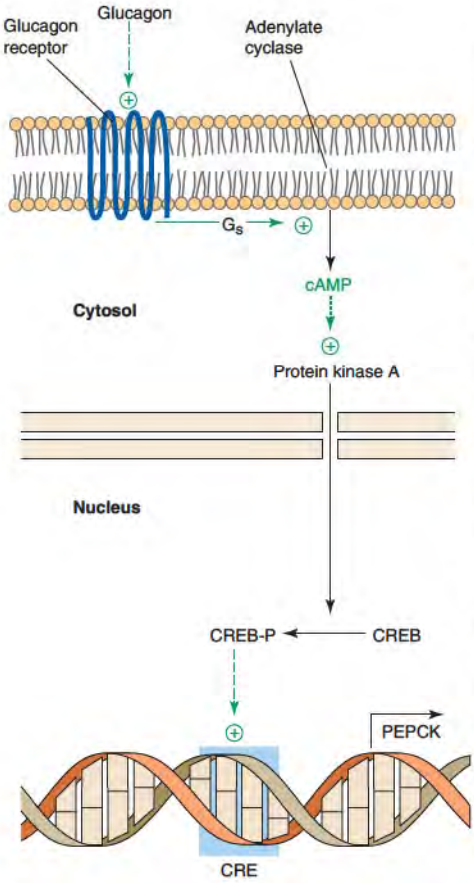

Figure 15.43 Glucagon promotes transcription of the gene for PEP carboxykinase.
Abbreviations: PEPCK, PEP carboxykinase; CRE, cAMP-response element; CREB, cAMP-response element binding protein.

glucokinase via its inhibitory protein. Insulin effects are opposite to those of glucagon by signaling activation of cAMP phosphodiesterase, inhibition of protein kinase A, and activation of phosphoprotein phosphatase.

Glucagon and insulin also have long-term effects on hepatic glycolysis and gluconeogenesis by induction and repression of key enzymes of both pathways. A high glucagon/insulin ratio in blood increases the capacity for gluconeogenesis and decreases that for glycolysis in liver. A low glucagon/insulin ratio has the opposite effects. The glucagon/insulin ratio increases when gluconeogenesis is needed and decreases when glucose from the gastrointestinal track is plentiful. Glucagon signals induction of greater quantities of PEP carboxykinase, fructose-1,6-bisphosphatase, glucose 6-phosphatase, and various aminotransferases. A model for how this occurs is given in Figure 15.43. Binding of glucagon to its plasma membrane receptor increases cAMP which activates protein kinase A. Protein kinase A then phosphorylates a protein called the cAMP-response element binding protein (CREB), a transcription factor that when phosphorylated binds to a cAMP-response element (CRE), a cis acting element within the regulatory region of genes responsive to cAMP. Phosphorylated CREB promotes transcription of genes for key gluconeogenic enzymes such as PEP carboxykinase. By repression of gene transcription, glucagon decreases the amounts of glucokinase, 6-phosphofructo-1-kinase, and pyruvate kinase. Insulin opposes the action of glucagon through a kinase-mediated signaling cascade that culminates in the inactivation of a transcription factor for genes of key gluconeogenic enzymes (page 905; Figure 22.21). When glucose synthesis is not needed, synthesis of key gluconeogenic enzymes is decreased and synthesis of key glycolytic enzymes increases because of a decrease in the blood glucagon/insulin ratio.

Alcohol Oxidation Inhibits Gluconeogenesis

Oxidation of alcohol (ethanol) by the liver produces a large load of reducing equivalents in the form of NADH that have to be transported into the mitochondria by the malate–aspartate shuttle. Excess NADH in the cytosol interferes with gluconeogenesis (Clin. Corr. 15.10) because it forces the equilibrium of the reactions catalyzed by lactate dehydrogenase and malate dehydrogenase toward lactate and malate formation, respectively:

CLINICAL CORRELATION 15.10

Hypoglycemia and Alcohol Intoxication

Consumption of alcohol, especially by an undernourished person, can cause hypoglycemia. The same effect can result from drinking alcohol after strenuous exercise. In both cases the hypoglycemia results from the inhibitory effects of alcohol on hepatic gluconeogenesis and occurs under circumstances of hepatic glycogen depletion. The liver simply cannot handle the reducing equivalents provided by ethanol oxidation fast enough to prevent metabolic derangements. The extra reducing equivalents block the conversion of lactate to glucose and promote conversion of alanine into lactate with considerable lactate accumulation in the blood and lactic acidosis (see Clin. Corr. 15.5, p. 611) can develop, although it is usually mild.

Low doses of alcohol cause impaired motor and intellectual performance; high doses are depressant and can lead to stupor and anesthesia. Low blood sugar can contribute to these undesirable effects of alcohol. What is more, a patient may be thought to be inebriated when in fact she or he is suffering from hypoglycemia that may lead to irreversible damage to the central nervous system. Children are highly dependent on gluconeogenesis while fasting, and accidental ingestion of alcohol by a child can produce severe hypoglycemia (see Clin. Corr. 15.9, p. 620). Alcohol potentiates the hypoglycemic effect of insulin. It is therefore not uncommon for patients with diabetes to present at the emergency room with hypoglycemia due to the combination of self-administered insulin and alcohol consumption.

Krebs, H. A., Freedland, R. A., Hems, R., and Stubbs, M. Inhibition of hepatic gluconeogenesis by ethanol. *Biochem. J.* 112: 117, 1969; Service, F. J. Hypoglycemia. *Med. Clin. North America* 79:1, 1995; and Gibson, E. M., and Tingen, M. S. Nursing care for diabetic patients with alcohol induced hypoglycemia. *J. Emer. Nursing* 24: 165, 1998.

$$CH_3CH_2OH + NAD^+ \longrightarrow CH_3\overset{O}{\overset{\|}{C}}H + NADH + H^+$$

Ethanol — Acetaldehyde

$$\text{pyruvate} + NADH + H^+ \longrightarrow \text{lactate} + NAD^+$$

$$\text{Sum: ethanol} + \text{pyruvate} \longrightarrow \text{acetaldehyde} + \text{lactate}$$

or

$$\text{oxaloacetate} + NADH + H^+ \longrightarrow \text{malate} + NAD^+$$

$$\text{Sum: ethanol} + \text{oxaloacetate} \longrightarrow \text{acetaldehyde} + \text{malate}$$

This inhibits gluconeogenesis by limiting the availability of pyruvate and oxaloacetate for the reactions catalyzed by pyruvate carboxylase and PEP carboxykinase, respectively.

15.6 • GLYCOGENOLYSIS AND GLYCOGENESIS

Glycogen Is the Storage Form of Glucose

Glycogenolysis refers to the breakdown of glycogen to glucose or glucose-6-phosphate; glycogenesis to the synthesis of glycogen. These processes occur in almost every tissue but especially in muscle and liver. In the well-fed human, liver glycogen content can account for as much as 10% of wet weight of this organ. Muscle stores less glycogen when expressed on the same basis—a maximum of only 1% – 2% of its wet weight. However, most people have more muscle than liver, with total muscle glycogen adding up to about double the amount of liver glycogen.

Glycogen granules are abundant in liver of the well-fed animals (Figure 15.44) but are virtually absent from this organ after 24 h of fasting. Heavy exercise causes the same loss of glycogen granules in muscle fibers. These granules are clusters of individual glycogen molecules that have a mass up to 2×10^7 Da. Glycogen is composed of glucosyl residues, mostly linked together by α-1,4-glycosidic linkages (Figure 15.45). Branches arise from frequent α-1,6-glycosidic linkages. A limb of the glycogen "tree" (Figure 15.46) is characterized by branches at every fourth glucosyl residue within the more central core of the molecule and much less frequently in outer regions. Glycogen stands in contrast to proteins and nucleic acids because of this branching, but of course, it is a storage form of fuel and does not catalyze reactions or convey information within a cell.

Glycogen is stored in muscle and liver for quite different reasons. Muscle glycogen is a fuel reserved for the production of ATP within that tissue, whereas liver glycogen is a glucose reserve for the maintenance of blood glucose concentrations. Liver glycogen levels

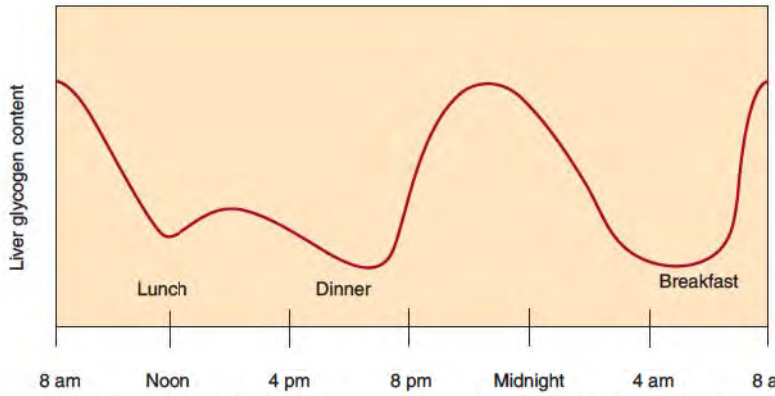

Figure 15.47 Variation of liver glycogen content between meals and during the nocturnal fast.

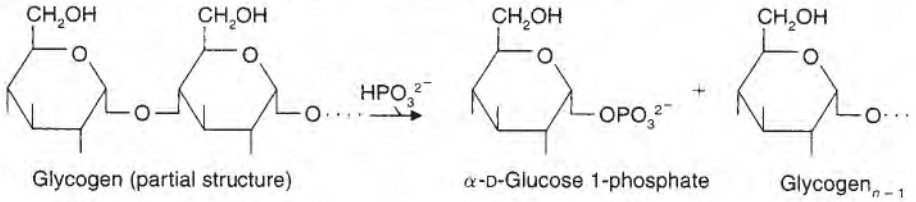
are high shortly after a meal and then decrease slowly as it is used to help maintain the blood glucose level (Figure 15.47) between meals and during the nocturnal fast. In humans and rats, the stored glycogen lasts between 12 and 24 h during fasting, depending greatly, of course, on whether the individual under consideration is caged or running wild.

Most of the muscle glycogen is consumed by that tissue without formation of free glucose. However, because of the way branched points are cleaved, about 8% of muscle glycogen is converted into free glucose within the tissue, most of which undergoes glycolysis in muscle. Since muscle lacks glucose 6-phosphatase and most of the free glucose formed is catabolized, muscle glycogen is not important for maintenance of blood glucose levels during fasting. In contrast, liver glycogen is a critical source of blood glucose in the postabsorptive state. On the other hand, muscle glycogenesis plays an important role in clearing glucose from the blood after a high carbohydrate meal. Liver glycogenesis contributes but is less important than glycogen synthesis in muscle.

Exercise mobilizes muscle glycogen for formation of ATP. Red muscle fibers have a rich blood flow, contain a large amount of myoglobin, and are packed with mitochondria. Glycogen mobilized within these cells is converted into pyruvate, which is then converted into CO_2 and H_2O by the TCA cycle. White muscle fibers contain less myoglobin and fewer mitochondria. Glycogenolysis within these cells only supplies substrate for glycolysis, with the end product being mostly lactate. White muscle fibers have greater capacity for glycogenolysis and glycolysis but can only function at full capacity for short periods of time. Breast and leg muscle of chicken are good examples of white and red muscles, respectively. Breast muscle of chicken is not continuously carrying out work, but enables the chicken to fly rapidly for short distances, as in fleeing from predators (or amorous roosters). It is designed for maximal activity over short periods. Most skeletal muscles of the human body are a mixture of red and white fibers, which provide for both rapid and sustained capacity for contraction. The distribution of white and red muscle fibers in cross sections of a human skeletal muscle is demonstrated by a special staining procedure in Figure 15.48.

Glycogen Phosphorylase Initiates Glycogenolysis

Glycogen phosphorylase catalyzes phosphorolysis of glycogen, a reaction in which P_i is used to cleave α-1,4-glycosidic linkages to yield glucose 1-phosphate. This reaction always occurs at terminal, nonreducing ends of a glycogen molecule:



This reaction is different from that of α-amylase, which uses water rather than inorganic phosphate (P_i) to cleave α-1,4-glycosidic bonds of glycogen and starch in the gut (p. 1050). Although a molecule of glycogen may contain up to 100,000 glucose residues, it

is most convenient to abbreviate its structure as simply (glucose)n where n is the number of glucosyl residues in the molecule. The reaction can then be written as

$$(\text{Glucose})_n + P_i^{2-} \rightarrow (\text{glucose})_{n-1} + \alpha\text{-D-glucose 1-phosphate}^{2-}$$

The next step in glycogenolysis is catalyzed by phosphoglucomutase.

$$\text{Glucose 1-phosphate} \rightarrow \text{glucose 6-phosphate}$$

This is a near-equilibrium reaction used in both glycogen degradation and synthesis.

The next enzyme depends on the tissue (Figure 15.49). In liver, glucose 6-phosphate is hydrolyzed by glucose 6-phosphatase to free glucose.

$$\text{Glucose 6-phosphate}^{2-} + H_2O \rightarrow \text{glucose} + P_i^{2-}$$

Lack of either this enzyme or of the transporter for the translocation of G6P into the endoplasmic reticulum (see Figure 15.35, p. 623) results in type I glycogen storage disease (Clin. Corr. 15.11).

As a result of the action of glucose 6-phosphatase, the overall balanced equation for glycogenolysis in the liver adds up to be simply glycogen hydrolysis.

$$(\text{Glucose})_n + H_2O \rightarrow (\text{glucose})_{n-1} + \text{glucose}$$

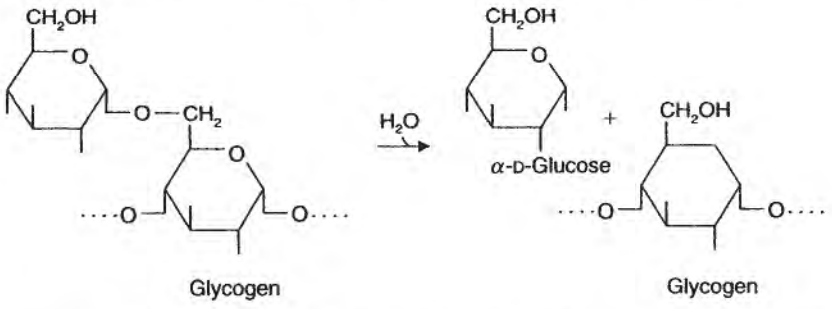
Note that ATP is neither used nor produced in the process.

In peripheral tissues the G6P undergoes glycolysis, leading primarily to lactate in white muscle fibers and primarily to CO_2 in red muscle fibers (Figure 15.49). Since no ATP had to be invested in white muscle fibers to produce G6P from glycogen, the overall equation for glycogenolysis followed by glycolysis is

$$(\text{Glucose})_n + 3\ ADP^{3-} + 3\ P_i^{2-} + H^+ \rightarrow (\text{glucose})_{n-1} + 2\ \text{lactate}^- + 3\ ATP^{4-} + 2\ H_2O$$

Debranching Enzyme Is Required for Glycogenolysis

Glycogen phosphorylase is specific for α-1,4-glycosidic linkages. It stops attacking α-1,4-glucosidic linkages four glucosyl residues from an α-1,6-branch point. A glycogen molecule that has been degraded to the limit by phosphorylase because of the branches is called phosphorylase limit dextrin. The action of the debranching enzyme allows phosphorylase to continue to degrade glycogen. Debranching enzyme is a bifunctional enzyme that catalyzes two reactions necessary for debranching of glycogen. The first is a 4-α-D-glucanotransferase activity that removes a strand of three glucosyl residues from a four glucosyl residue branch of the glycogen molecule, leaving a single glucosyl residue in α-1,6-linkage (Figure 15.50). The three glucosyl residue strand remains covalently attached to the enzyme until transferred to a free 4-hydroxyl of a glucosyl residue at the end of the same or an adjacent glycogen molecule to produce a longer branch. The α-1,6-linkage of the single glucosyl residue is hydrolyzed by the second enzyme activity of debranching enzyme, which is its amylo-α-1,6-glucosidase activity.



The cooperative and repetitive action of phosphorylase and debranching enzyme results in complete breakdown of glycogen to glucose 1-phosphate and glucose. Glycogen storage diseases result when either of these enzymes is defective. An average molecule of glycogen yields about 12 molecules of glucose 1-phosphate by action of phosphorylase for every molecule of free glucose produced by debranching enzyme.

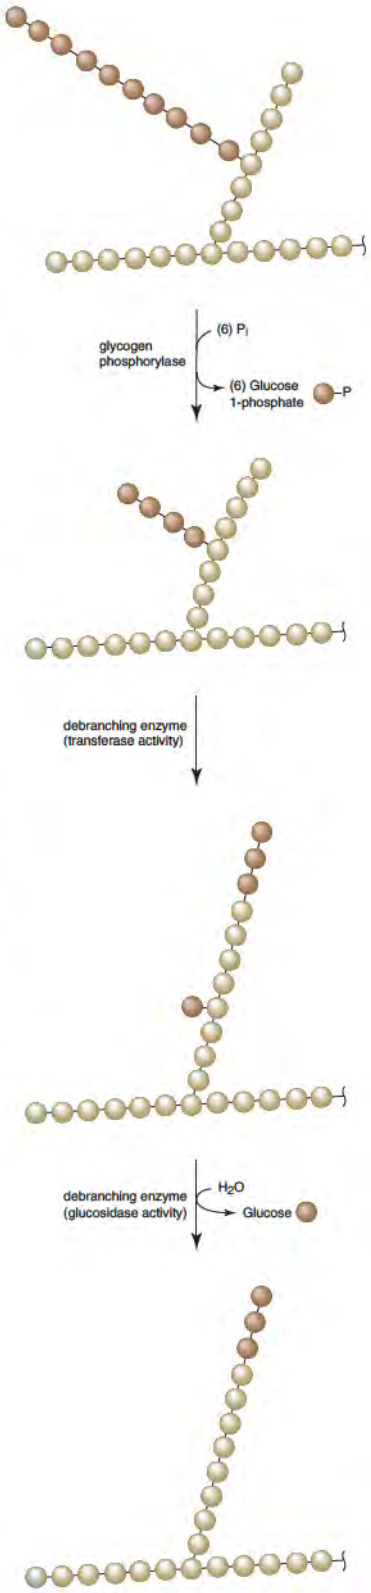


Figure 15.50 Concerted action of glycogen phosphorylase and glycogen debranching enzyme is required for glycogenolysis.

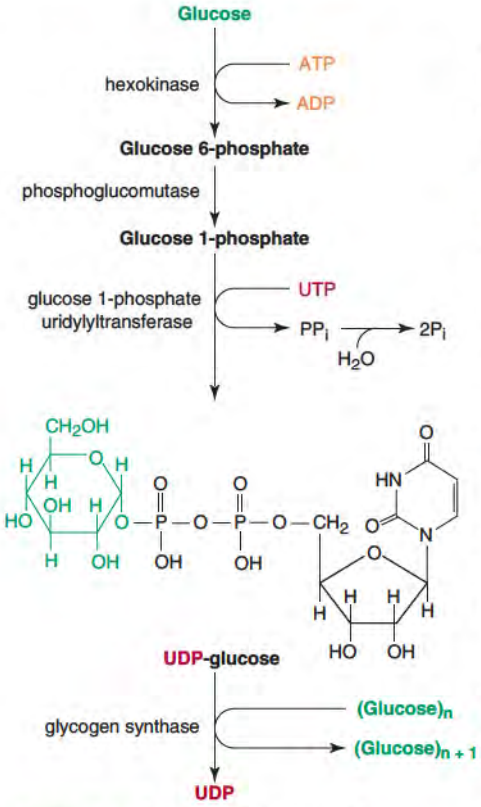

Figure 15.51 **Pathway of glycogenesis.**

There is another, albeit quantitatively less important, pathway for glycogen degradation that depends on glucosidases present in lysosomes. Glycogen that enters lysosomes during normal turnover of intracellular components has to be degraded. Failure to degrade glycogen taken up by lysosomes creates a major medical problem described in Clin. Corr. 15.11.

Glycogenesis Requires Unique Enzymes

The first reaction (Figure 15.51) is that of glucokinase in liver and hexokinase in peripheral tissues.

$$\text{Glucose} + \text{ATP} \rightarrow \text{glucose 6-phosphate} + \text{ADP}$$

Phosphoglucomutase then forms glucose 1-phosphate.

$$\text{Glucose 6-phosphate} \leftrightarrows \text{glucose 1-phosphate}$$

Glucose 1-phosphate uridylyltransferase then produces UDP-glucose.

$$\text{Glucose 1-phosphate} + \text{UTP} \rightarrow \text{UDP-glucose} + \text{PP}_\text{i}$$

The latter reaction generates UDP-glucose, an activated glucose molecule, from which glycogen can be synthesized. Formation of UDP-glucose is made energetically favorable and irreversible by hydrolysis of pyrophosphate to inorganic phosphate by pyrophosphatase.

$$\text{PP}_\text{i}^{4-} + \text{H}_2\text{O} \rightarrow 2\ \text{P}_\text{i}^{2-}$$

Glycogen synthase then transfers the activated glucosyl moiety of UDP-glucose to the carbon 4 of a glucosyl residue of the growing glycogen chain to form a new glycosidic bond at the hydroxyl group of carbon 1 of the activated sugar. The reducing end of glucose (carbon 1, an aldehyde that can reduce other compounds during its oxidation to a carboxylic acid) is always added to a nonreducing end (carbon 4 of a glucosyl residue) of the glycogen chain. According to this, each molecule of glycogen should have one free reducing end tucked away within its core. In fact it does not have a free reducing end because its one potentially free aldehyde group is covalently linked to a protein called glycogenin within its core (described on p. 634). The UDP formed as a product of the glycogen synthase reaction is converted back to UTP by nucleoside diphosphate kinase.

$$\text{UDP} + \text{ATP} \leftrightarrows \text{UTP} + \text{ADP}$$

Glycogen synthase cannot form the α-1,6 glycosidic linkages. Working alone, it would only produce amylose, a straight-chain polymer of glucose with α-1,4-glycosidic linkages. Once an amylose chain of at least 11 residues has been formed, a *branching enzyme* called 1,4-α-glucan branching enzyme removes a block of about 7 glucosyl residues from a growing chain and transfers it to another chain to produce an α-1,6 linkage (Figure 15.52). The new branch has to be introduced at least four glucosyl residues from the nearest branch point. Thus, the creation of the highly branched structure of glycogen requires the concerted actions of glycogen synthase and branching enzyme. The overall balanced equation for glycogen synthesis as outlined is

$$(\text{Glucose})_n + \text{glucose} + 2\ \text{ATP}^{4-} + \text{H}_2\text{O} \rightarrow (\text{glucose})_{n+1} + 2\ \text{ADP}^{3-} + 2\ \text{P}_\text{i}^{2-} + 2\ \text{H}^+$$

As already noted, the combination of glycogenolysis and glycolysis yields three molecules of ATP per glucosyl residue.

$$(\text{Glucose})_n + 3\ \text{ADP}^{3-} + 3\ \text{P}_\text{i}^{2-} + \text{H}^+ \rightarrow (\text{glucose})_{n-1} + 2\ \text{lactate}^- + 3\ \text{ATP}^{4-} + 2\ \text{H}_2\text{O}$$

Thus the combination of glycogenesis and glycogen degradation to lactate yields only one ATP.

$$\text{Glucose} + \text{ADP}^{3-} + \text{P}_\text{i}^{2-} \rightarrow 2\ \text{lactate}^- + \text{ATP}^{4-} + \text{H}_2\text{O} + \text{H}^+$$

Recall, however, that glycogen synthesis and degradation are normally carried out at different times in a cell. For example, white muscle fibers synthesize glycogen at rest when glucose is plentiful and less ATP is needed for muscle contraction. Glycogen is then used

CLINICAL CORRELATION 15.11

Glycogen Storage Diseases

There are a number of well-characterized glycogen storage diseases, all due to inherited defects in enzymes involved in the degradation of glycogen. The liver is usually the tissue most affected, but heart and muscle glycogen metabolism can also be defective.

Von Gierke Disease (OMIM 232200)

The most common glycogen storage disease, referred to as type I or von Gierke disease, arises from a deficiency of liver, intestinal mucosa, and kidney glucose 6-phosphatase. Thus, diagnosis by intestinal biopsy is possible. Patients with this disease may lack the glucose 6-phosphatase itself (type Ia) or the glucose 6-phosphate transporter (type Ib) (see Figure 15.37, p. 625). Glucose 6-phosphatase deficiency occurs in about 1 person in 200,000 and is transmitted as an autosomal recessive trait. It manifests as fasting hypoglycemia, lactic academia, hyperlipidemia, and hyperuricemia with gouty arthritis. The fasting hypoglycemia is a consequence of the glucose 6-phosphatase deficiency. The liver of these patients does release some glucose by the action of the glycogen debrancher enzyme. The lactic acidemia occurs because the liver cannot use lactate effectively for gluconeogenesis and because it inappropriately produces lactic acid in response to glucagon. This hormone should trigger glucose release without lactate production; however, the opposite occurs because of the lack of glucose 6-phosphatase. Hyperuricemia may result from increased purine degradation in the liver, hyperlipidemia because of increased availability of lactic acid for lipogenesis, and lipid mobilization from the adipose tissue caused by high catecholamine levels in response to hypoglycemia. These manifestations can be greatly diminished by providing carbohydrate throughout the day to prevent hypoglycemia. During sleep this can be done by infusion of carbohydrate into the gut by a nasogastric tube.

Pompe Disease (OMIM 232300)

Type II glycogen storage disease or Pompe disease is caused by the absence of α-1,4-glucosidase (or acid maltase) normally found in lysosomes. This leads to accumulation of glycogen mostly in lysosomes in virtually every tissue. This is somewhat surprising, but lysosomes take up glycogen granules and become defective with respect to other functions if they lack the capacity to hydrolyze the granules. Because other synthetic and degradative pathways of glycogen metabolism are intact, metabolic derangements such as those in von Gierke disease are not seen. Severe hypotonia, massive cardiomegaly, and cardiomyopathy occur and death results from heart failure, usually in the first months of life. An adult onset form of the disease causes severe muscle weakness, particularly of respiratory muscles (diaphragm), with death often resulting from respiratory insufficiency.

Cori Disease (OMIM 232400)

Type III glycogen storage disease or Cori disease is caused by deficiency of glycogen debranching enzyme. Glycogen accumulates because only the outer branches can be removed by phosphorylase. Hepatomegaly occurs, but diminishes with age. The clinical manifestations are similar to, but much milder than, those in von Gierke disease because gluconeogenesis is unaffected, and hypoglycemia and its complications are less severe.

McArdle Disease (OMIM 232600)

Type V glycogen storage disease or McArdle disease is caused by absence of muscle phosphorylase. Patients suffer from painful muscle cramps and are unable to perform strenuous exercise, presumably because muscle glycogen stores are not available to the exercising muscle. Thus, the normal increase in plasma lactate (released from the muscle) following exercise is absent. The muscles are probably damaged because of inadequate energy supply and glycogen accumulation. Release of creatine kinase, aldolase, and myoglobin from muscle is common; elevated levels of these proteins in the blood suggest a muscle disorder.

during periods of exertion. Although not a very efficient process, the storage of glucose in the form of glycogen provides cells with a fuel reserve that can be quickly mobilized.

Special Features of Glycogenolysis and Glycogenesis

Why Store Glucose as Glycogen?

The fact that glycogen is such a good fuel reserve makes it obvious why we synthesize and store glycogen in liver and muscle. But, why not store our excess glucose calories entirely as fat instead of glycogen? The answer is at least threefold: (1) Fatty acids cannot be released from fat nearly as rapidly as glucose can be released from glycogen, (2) fat cannot be used as a source of energy in the absence of oxygen, and (3) fat cannot be converted to glucose to maintain blood glucose levels required by the brain. Why not just pump glucose into cells and store it as free glucose until needed? Why waste ATP making a polymer out of glucose?

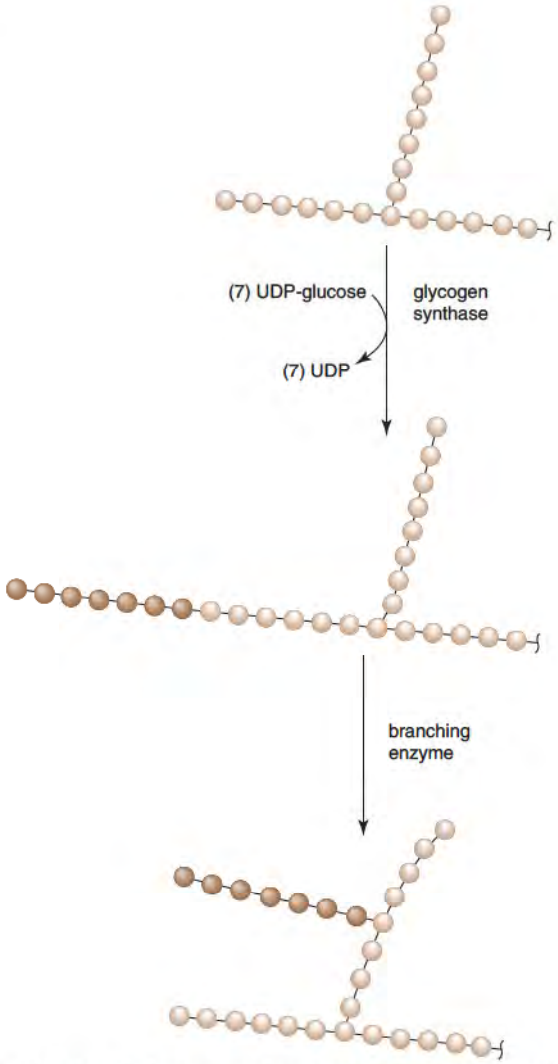

Figure 15.52 Concerted action of glycogen synthase and glycogen branching enzyme is required for glycogenesis. Action of glycogen-branching enzyme.

The problem is that glucose is osmotically active. It would cost ATP to "pump" glucose into a cell against a concentration gradient, and its concentration would have to reach about 400 mM in liver cells to match the *glucose reserve* provided by the usual liver glycogen content. Unless balanced by outward movement of some other osmotically active compound, accumulation of glucose would cause considerable uptake of water with osmotic lysis of the cell. Assuming the mass of a glycogen molecule is about 10^7 Da, 400 mM glucose is in effect stored at a glycogen concentration of only 0.01 μM. Storage of glucose as glycogen, therefore, creates no osmotic pressure problem for the cell.

Glycogenin Is Required as a Primer for Glycogen Synthesis

As in DNA synthesis, a primer is needed for glycogen synthesis. No template, however, is required. Glycogen itself is the usual primer, since glycogen synthesis adds glucosyl units to glycogen core molecules, which are almost invariably present in cells. The outer regions of glycogen molecules are removed and resynthesized more rapidly than the inner core. Glycogen within a cell is frequently sheared by the combined actions of glycogen phosphorylase and debranching enzyme but is seldom obliterated before one eats again and glycogen synthase and branching enzyme rebuild the molecule. This begs the question why glycogen is a branched molecule with only one real beginning (the original starting glucose residue) and many branches terminating in nonreducing glucosyl units. The answer is that this gives numerous sites of attack for glycogen phosphorylase on a mature glycogen molecule and the same number of sites to serve as primers for the addition of glucosyl units by glycogen synthase. If cells synthesized α amylose,

an unbranched glucose polymer, there would only be one nonreducing end per molecule. This would make glycogen degradation and synthesis much slower. As it is, glycogen phosphorylase and glycogen synthase occur in tight association with glycogen granules and have ready access to a multitude of nonreducing sugars at the ends of the branches. This is not the case in Lafora disease, a juvenile-onset myoclonus epilepsy characterized by neuronal accumulation of insoluble poorly branched glycogen deposits called Lafora bodies (A Closer Look 15.7)

A primer is needed for glycogen synthesis because glycogen synthase cannot initiate glycogen synthesis with a single glucose molecule as the acceptor of an activated glucosyl residue from UDP-glucose. Glycogen synthase has a very low K_m for large glycogen molecules, and therefore readily adds glucosyl residues to make even larger glycogen molecules. However, the K_m gets larger and larger as the glycogen molecule gets smaller and smaller so that glucose, at its physiological concentration, cannot function as a primer. This led for some time to the notion that glycogen might be immortal; that is, some glycogen might have to be handed down from one cell generation to the next in order for glycogen to be synthesized. However, a polypeptide of 332 amino acids called glycogenin serves as a primer for glycogen synthesis. Glycogenin is a self-glucosylating enzyme that uses UDP-glucose to link glucose to one of its own tyrosine residues (Figure 15.53). Glycogenin forms a chain of glucosyl residues on itself by catalyzing the addition of seven more glucosyl residues with α-1,4 linkages. Glycosylated glycogenin then serves as a primer for synthesis of glycogen by glycogen synthase. Alas, glycogen is not immortal.

Glycogen Limits Its Own Synthesis

If glycogen synthase becomes more efficient as the glycogen molecule gets bigger, how is synthesis of this ball of sugar curtailed? Adipocytes have an almost unlimited capacity to pack away fat, but then adipocytes have nothing else to do. Muscle cells participate in mechanical activity and liver cells carry out many processes other than glycogen synthesis. Even in the face of excess glucose, there has to be a way to limit the intracellular accumulation of glycogen. Glycogen itself inhibits glycogen synthase by a mechanism discussed later.

Glycogen Synthesis and Degradation Are Highly Regulated

Glycogen synthase and glycogen phosphorylase are the regulatory enzymes of glycogen synthesis and degradation, respectively. Both catalyze nonequilibrium reactions, and both are subject to control by allosteric effectors and covalent modification.

Regulation of Glycogen Phosphorylase

Glycogen phosphorylase is activated by AMP and inhibited by glucose and ATP (Figure 15.54). Control by these allosteric effectors is integrated with a very elaborate control by covalent modification. Phosphorylase exists in an active *a* form and an inactive *b* form. These forms are interconverted by phosphorylase kinase and phosphoprotein phosphatase. A conformational change caused by phosphorylation creates a more active catalytic state. Nonphosphorylated phosphorylase, that is the *b* form, has low activity but is greatly stimulated by AMP. This effector has little activating effect on the already active phosphorylase *a*. Thus, regulation by covalent modification can be bypassed by an AMP-mediated mechanism.

Phosphorylase kinase phosphorylates and activates phosphorylase (Figure 15.54) and is itself subject to regulation by **phosphorylation-dephosphorylation**. Protein kinase A phosphorylates and activates phosphorylase kinase; phosphoprotein phosphatase dephosphorylates and inactivates it. Phosphorylase kinase is a complex (1.3 million Da) composed of four different subunits with four copies of each subunit in the complex ($\alpha_4\beta_4\gamma_4\delta_4$). Catalytic activity resides in the γ-subunit; α-, β-, and δ-subunits exert regulatory control. The α- and β-subunits are phosphorylated in the transition from the inactive *b* form to the active *a* form. Protein kinase A can only exert an effect on phosphorylase via phosphorylation and activation of phosphorylase kinase. Thus, a bicyclic system is required for activation of phosphorylase in response to cAMP-mediated signals.

The δ-subunit is the Ca^{2+}-binding regulatory protein calmodulin (p. 493). It is present in cells in its free form and bound tightly in enzyme complexes. It functions as a Ca^{2+} receptor in cells, responding to changes in intracellular Ca^{2+} concentration and affecting the activity of several enzyme systems. Binding of Ca^{2+} to calmodulin makes phosphorylase kinase more active. As shown in Figure 15.55, p. 637, Ca^{2+} is an activator of both phosphorylase

A CLOSER LOOK 15.7

Phosphorylated Glycogen and Lafora Disease

Lafora disease is due to a gene defect in laforin, a phosphatase that removes phosphate residues from phosphorylated glycogen. Surprisingly, prior to studies on the mechanism responsible for Lafora disease it was not appreciated that glycogen is phosphorylated. How this occurs and whether it serves a purpose is still not known. Glycogen isolated from mice with Lafora disease is less branched but more heavily phosphorylated than glycogen isolated from wild type mice. This suggests that the presence of phosphate groups on glycogen promotes the formation of Lafora bodies by inhibiting the branching enzyme.

Tagliabracci, V. S., Turnbill, J., Wang, W., Girard, J.-M., et al. Laforin is a glycogen phosphatase, deficiency of which leads to elevated phosphorylation of glycogen in vivo. *Proc. Natl. Acad. Sci. USA* 104:19262, 2007.

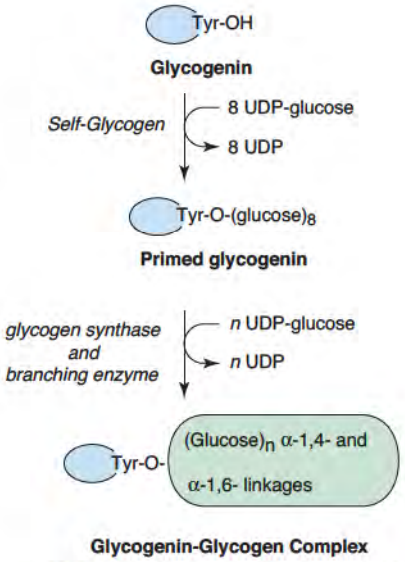

Figure 15.53 Glycogenin provides a primer for glycogen synthesis by glycogen synthase. Tyr designates a tyrosine residue of glycogenin.

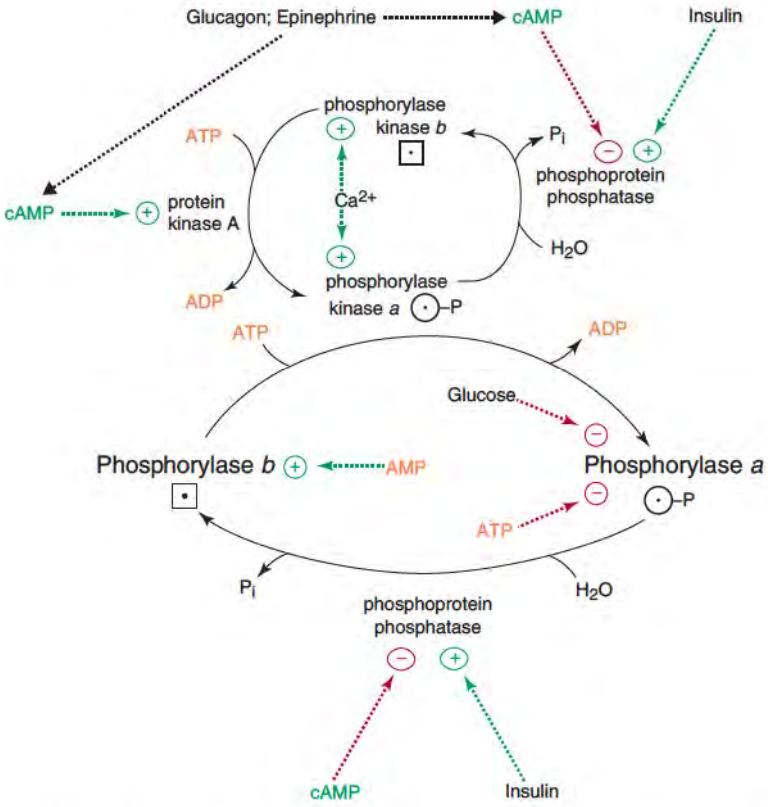

Figure 15.54 Regulation of glycogen phosphorylase by covalent modification and allosteric effectors. Phosphorylation converts glycogen phosphorylase and phosphorylase kinase from their inactive *b* forms to their active *a* forms.

kinase *a* and phosphorylase kinase *b*. Maximum activation of phosphorylase kinase requires phosphorylation of specific serine residues plus interaction of Ca^{2+} with calmodulin. This is one way by which Ca^{2+} functions as a second messenger of hormone action.

Activation of phosphorylase kinase by phosphorylation and Ca^{2+} has a substantial effect on the activity of glycogen phosphorylase. It is obvious, however, that inhibiting the phosphoprotein phosphatase that modulates both phosphorylase kinase and glycogen phosphorylase could achieve the same effect. Ultimate control of glycogen phosphorylase therefore involves reciprocal regulation of phosphoprotein phosphatase and phosphorylase kinase activities. Regulation of phosphoprotein phosphatase activity involves cAMP. Hormones that increase cAMP levels, such as glucagon and epinephrine, promote activation of glycogen phosphorylase by signaling activation of phosphorylase kinase and inactivation of phosphoprotein phosphatase. Insulin, though a kinase-mediated signal cascade, has the opposite effect on phosphorylase by promoting activation of phosphoprotein phosphatase activity.

Glycogen Phosphorylase Is Regulated by a Cascade That Greatly Amplifies a Small Signal into a Very Large Effect

The bicyclic control system for phosphorylation of glycogen phosphorylase amplifies enormously a very small initial signal. Activation of adenylate cyclase by one molecule of epinephrine causes formation of many molecules of cAMP. Each cAMP molecule activates a protein kinase A molecule, which in turn phosphorylates many molecules of phosphorylase kinase, which are activated, as well as many molecules of phosphoprotein phosphatase, which are inactivated. In turn phosphorylase kinase phosphorylates many molecules of glycogen phosphorylase, which in turn catalyzes phosphorolysis of many glycosidic bonds of glycogen. This is therefore an amplification system in which the signal provided by a few molecules of hormone is amplified into an enormous number of glucose 1-phosphate molecules. If each step represents an amplification factor of 100, then four steps would result in an amplification of 100 million! This system is so rapid that all of the stored glycogen of white muscle fibers could be converted to glucose 6-phosphate within seconds.

Regulation of Glycogen Synthase

Glycogen synthase has to be active for glycogenesis and inactive for glycogenolysis. The combination of the reactions of glycogen synthase, glycogen phosphorylase, glucose 1-phosphate uridylyltransferase, and nucleoside diphosphate kinase adds up to a futile cycle with the

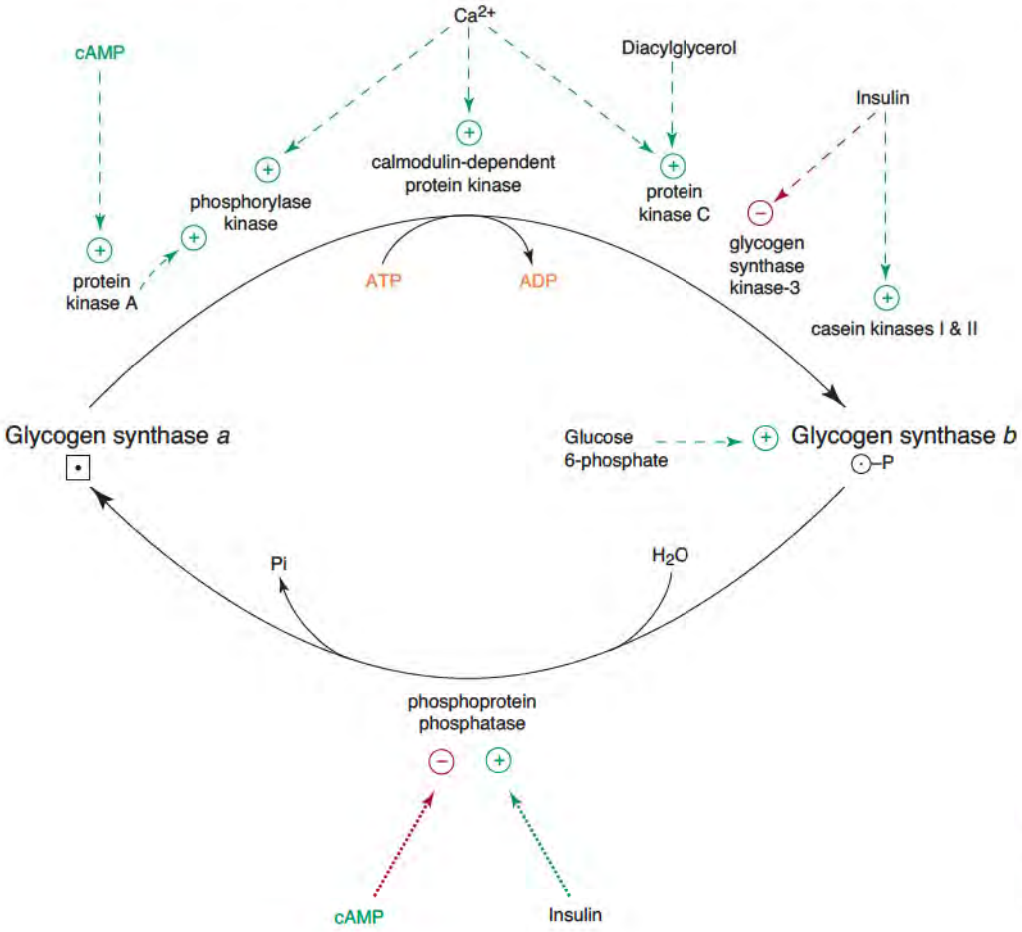

Figure 15.55 Regulation of glycogen synthase by covalent modification. Phosphorylation converts glycogen synthase from its active *a* form to its inactive *b* form.

overall equation ATP + $H_2O \rightarrow$ ADP + P_i. Hence, glycogen synthase needs to be inhibited when glycogen phosphorylase is active, and vice versa.

Whether G6P activates glycogen synthase depends on its phosphorylation state (Figure 15.55). Glycogen synthase exists in a phosphorylated "D" form that is dependent on the presence of G6P for activity and a nonphosphorylated "I" form which is independent of G6P. The D form corresponds to the *b*, or inactive, form of the enzyme, the I form to the *a*, or active, form of the enzyme. Phosphorylation of glycogen synthase is catalyzed by several protein kinases, which in turn are regulated by second messengers of hormone action, including cAMP, Ca^{2+}, diacylglycerol, and probably others yet to be identified. Each protein kinase identified in Figure 15.55 can phosphorylate and contribute to inactivation of glycogen synthase. Glycogen synthase is a homotetramer (α_4) of mass 85 kDa that can be phosphorylated on at least nine different serine residues. Eleven protein kinases have been identified that can phosphorylate glycogen synthase. This is in striking contrast to glycogen phosphorylase, which is regulated by phosphorylation at one site by one specific kinase.

Cyclic AMP induces opposite effects on the activities of glycogen synthase (Figure 15.55) and glycogen phosphorylase (Figure 15.54). An increase in cAMP signals activation of glycogen phosphorylase and inactivation of glycogen synthase via activation of protein kinase A and inhibition of phosphoprotein phosphatase. Ca^{2+} likewise influences the phosphorylation states of both enzymes and reciprocally regulates their activity by its effects on phosphorylase kinase. Two cAMP-independent, Ca^{2+}-activated protein kinases have been identified that may have physiological significance. One is a calmodulin-dependent protein kinase and the other a Ca^{2+}- and phospholipid-dependent protein kinase (protein kinase C). Both phosphorylate glycogen synthase, but neither can phosphorylate glycogen phosphorylase. Protein kinase C requires phospholipid, diacylglycerol, and Ca^{2+} for full activity. It is of considerable interest because tumor-promoting agents called phorbol esters mimic diacylglycerol as activators of its activity. Diacylglycerol is a second messenger of hormone action, acting via protein kinase C to regulate numerous cellular processes.

Glycogen synthase is also phosphorylated by glycogen synthase kinase-3, casein kinase I, and casein kinase II. These kinases are not subject to regulation by cAMP or Ca^{2+} but special regulatory mechanisms exist for them. An insulin-signaling cascade results in activation of protein kinase B, which inactivates glycogen synthase kinase-3 by phosphorylation, an action that allows activation of glycogen synthase to occur via dephosphorylation by phosphoprotein phosphatase.

The phosphoprotein phosphatase that converts glycogen synthase *b* to the *a* form (Figure 15.55) is regulated in a manner analogous to that of glycogen phosphorylase (Figure 15.54). Cyclic AMP promotes inactivation whereas insulin promotes activation of glycogen synthase through opposite effects upon phosphoprotein phosphatase activity.

In general, phosphoprotein phosphatases are present as catalytic subunits associated with regulatory subunits that control their activity, determine which substrate(s) can be dephosphorylated, and target association with specific structures within a cell. A regulatory protein important for glycogen metabolism is the G subunit or glycogen-binding protein. G subunit binds both glycogen and a phosphatase catalytic subunit (Figure 15.56) making the phosphatase 10 times more active toward glycogen synthase and glycogen phosphorylase. However, phosphorylation of G subunit by protein kinase A releases the phosphatase catalytic subunit, which is then less active. Interaction of the free catalytic subunit with yet another regulatory protein (called inhibitor 1) further inhibits phosphatase activity. Effective inhibition of the residual phosphatase activity requires phosphorylation of inhibitor 1 by protein kinase A, thereby creating yet another link to hormones that increase cAMP levels. Insulin has effects opposite to those of cAMP; that is, it promotes activation of the catalytic subunit of the phosphatase.

Effector Control of Glycogen Metabolism

Certain muscles mobilize their glycogen stores rapidly in response to anaerobic conditions without marked conversion of phosphorylase *b* to the *a* form or glycogen synthase *a* to the *b* form. Presumably this is accomplished by effector control in which ATP levels decrease, causing less inhibition of phosphorylase; glucose 6-phosphate levels decrease, causing less activation of glycogen synthase; and AMP levels increase, causing activation of phosphorylase. This enables muscle to keep working, for at least a short period, by using ATP produced by glycolysis of glucose 6-phosphate derived from glycogen.

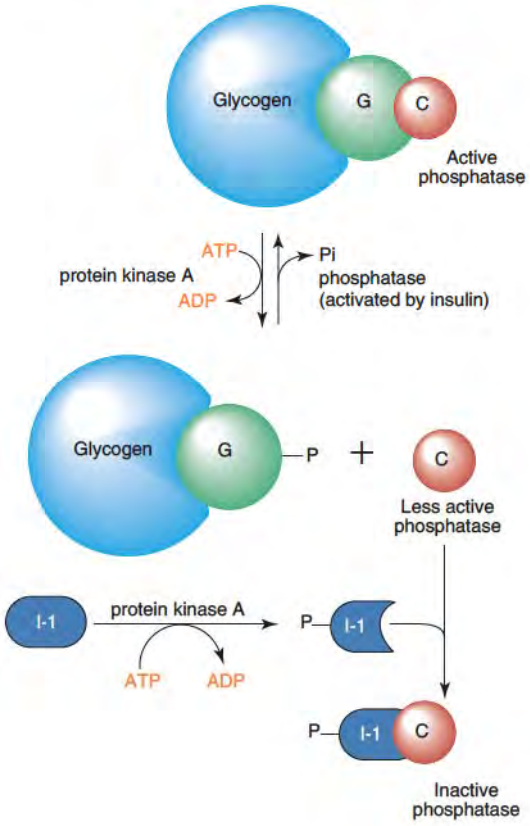

Figure 15.56 Mechanism for regulation of a phosphatase that binds to glycogen. The glycogen binding subunit G binds directly to glycogen; the phosphoprotein phosphatase catalytic subunit C binds to glycogen by the G subunit; and the phosphorylated inhibitor 1 (I-1) binds the free catalytic subunit. Protein kinase A inactivates the phosphatase by phosphorylating G subunit and I-1. Insulin signals activation of the phosphatase by promoting dephosphorylation of the G subunit and I-1 (not shown).

Proof that effector control can operate has also been obtained from a strain of mice deficient in muscle phosphorylase kinase. Phosphorylase *b* in muscle of such mice cannot be converted into phosphorylase *a*. Nevertheless, heavy exercise results in depletion of muscle glycogen because of stimulation of phosphorylase *b* by AMP.

Negative Feedback Control of Glycogen Synthesis by Glycogen

Glycogen exerts feedback control over its own formation. The portion of glycogen synthase in the active *a* form decreases as glycogen accumulates in a tissue. The mechanism is not well understood, but glycogen may make the *a* form a better substrate for a protein kinase or, alternatively, glycogen may inhibit dephosphorylation of glycogen synthase *b* by phosphoprotein phosphatase. Either mechanism would account for the shift in the steady state in favor of glycogen synthase *b* that occurs in response to glycogen accumulation.

Phosphorylase *a* Is a "Glucose Receptor" in Liver

A carbohydrate-rich meal increases blood and liver glucose, which increases glycogen synthesis in liver tissue. The mechanism involves glucose stimulation of insulin release from the pancreas and its effects on hepatic glycogen phosphorylase and glycogen synthase. However, hormone-independent mechanisms also appear to be important in liver (Figure 15.57). Direct inhibition of phosphorylase *a* by glucose is probably of importance. Binding of glucose to phosphorylase makes the *a* form of phosphorylase a better substrate for dephosphorylation by phosphoprotein phosphatase. Therefore, phosphorylase *a* in liver functions as an intracellular glucose receptor. Binding of glucose to phosphorylase *a* promotes its inactivation, thereby inhibiting glycogenolysis. This *negative-feedback* control of glycogenolysis by glucose would not necessarily promote glycogen synthesis. However, phosphorylase *a* inhibits dephosphorylation of glycogen synthase *b* by phosphoprotein phosphatase. This inhibition is lost once phosphorylase *a* has been converted to the *b* form (Figure 15.57). In other words, phosphoprotein phosphatase can turn its attention to glycogen synthase *b* only after dephosphorylation of phosphorylase *a*. Thus, as a result of interaction of glucose with phosphorylase *a*, glycogen is synthesized rather than degraded in liver. Phosphorylase *a* can serve this function of "glucose receptor" in liver because the concentration of glucose in liver reflects that in blood. This is not true for extrahepatic tissues. Liver cells have a very high-capacity transporter for glucose (GLUT2) and a high $S_{0.5}$ enzyme for glucose phosphorylation (glucokinase) whereas in extrahepatic tissues glucose

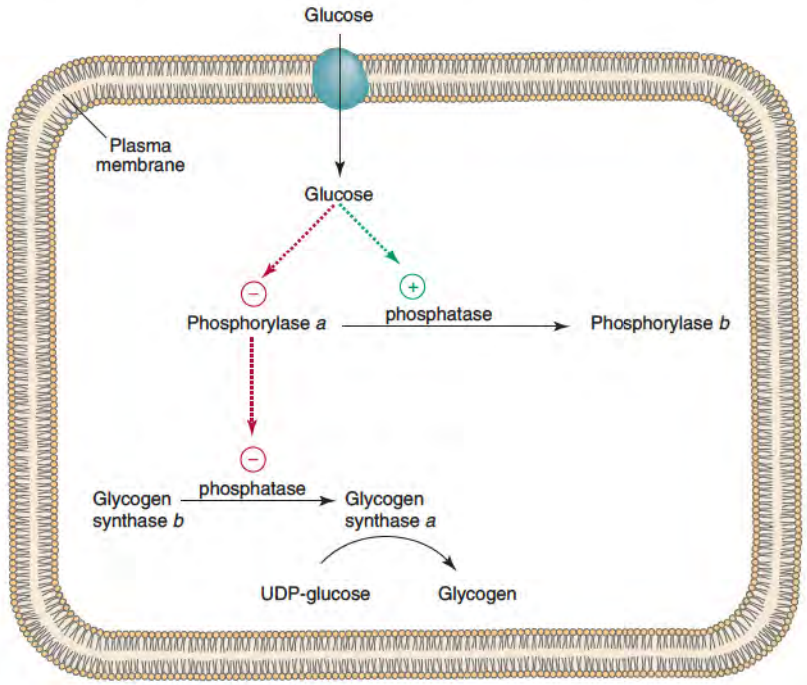

Figure 15.57 Overview of the mechanism for glucose stimulation of glycogenesis in the liver.

transport and phosphorylation systems maintain intracellular glucose at a concentration too low for phosphorylase *a* to function as a "glucose receptor."

Hormonal and Neural Control of Glycogen Synthesis and Degradation

Glucagon and Epinephrine Stimulate Glycogenolysis in Liver

Glucagon is released from α cells of pancreas in response to low blood glucose levels. Under such conditions, for example, during fasting, glucagon stimulates glycogenolysis so as to ensure that adequate blood glucose is available for glucose-dependent tissues (Figure 15.58). Binding of glucagon to its receptors on liver cells activates adenylate cyclase and triggers the cascades that activate glycogen phosphorylase and inactivate glycogen synthase (see Figures 15.54 and 15.55, respectively). It also inhibits glycolysis at the level of 6-phosphofructo-1-kinase and pyruvate kinase as shown in Figures 15.25, p. 616, and 15.28, p. 619, respectively. The net result of all these effects mediated by cAMP and covalent modification is a very rapid increase in normal blood glucose levels. Hypergly-cemia does not occur because less glucagon is released from the pancreas as blood glucose levels increase.

Epinephrine is released into blood from chromaffin cells of the adrenal medulla in response to stress. This "fright, flight or fight" hormone prepares the body for either combat or escape. Binding of epinephrine with β-adrenergic receptors on liver cells activates adenylate cyclase (Figure 15.58) and cAMP has the same effects as glucagon, that is, activation of glycogenolysis and inhibition of glycogenesis and glycolysis to maximize the release of glucose. Binding of epinephrine to α-adrenergic receptors on liver cells signals formation of inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (Figure 15.59). These are

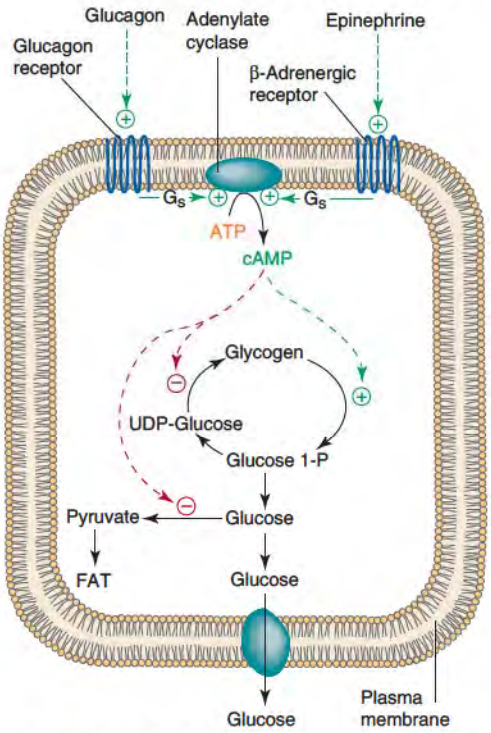

Figure 15.58 Cyclic AMP mediates stimulation of glycogenolysis in liver by glucagon and β agonists (epinephrine). See legends to Figures 15.17, p. 612, and 15.23, p. 615.

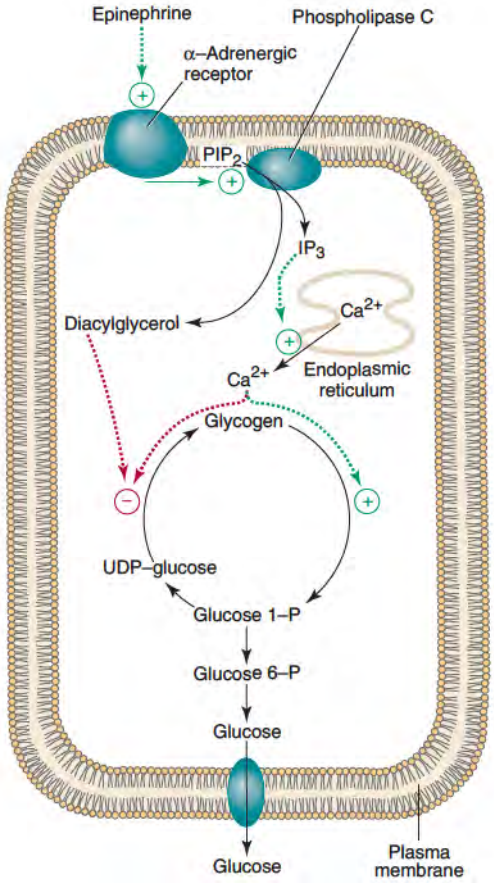

Figure 15.59 Inositol trisphosphate (IP_3) and Ca^{2+} mediate stimulation of glycogenolysis in liver by α agonists. The α-adrenergic receptor and glucose transporter are intrinsic components of the plasma membrane. Phosphatidylinositol 4,5-bisphosphate (PIP_2) is also a component of the plasma membrane.

second messengers, produced by the action of a phospholipase C on phosphatidylinositol 4,5-bisphosphate of the plasma membrane (Figure 15.60). IP_3 stimulates the release of Ca^{2+} from the endoplasmic reticulum, which activates phosphorylase kinase which in turn activates glycogen phosphorylase (see Figure 15.54, p. 636). In addition, Ca^{2+}-mediated activation of phosphorylase kinase and calmodulin-dependent protein kinase as well as diacylglycerol-mediated activation of protein kinase C may all contribute to inactivation of glycogen synthase (see Figure 15.55, p. 637).

An increased rate of glucose release into blood is a major consequence of epinephrine action on the liver. This makes glucose available to tissues that are called on to meet the challenge of the stressful situation that triggered the release of epinephrine from the adrenal medulla.

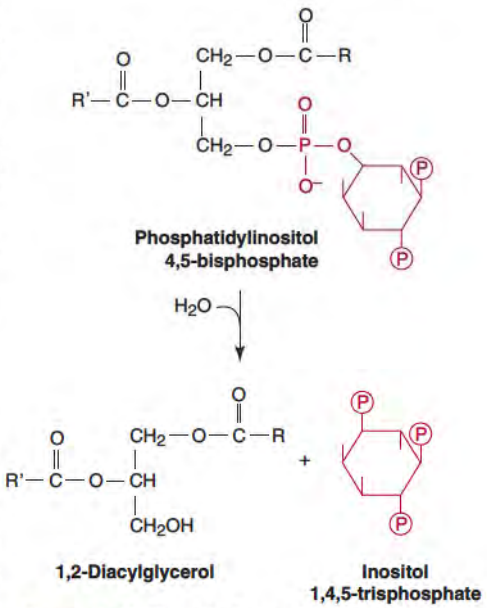

Figure 15.60 Phospholipase C cleaves phosphatidylinositol 4,5-bisphosphate to 1,2-diacylglycerol and inositol 1,4,5-trisphosphate.

Epinephrine Stimulates Glycogenolysis in Heart and Skeletal Muscle

Epinephrine also stimulates glycogenolysis in heart and skeletal muscle (Figure 15.61). It binds to β-adrenergic receptors, which stimulates adenylate cyclase to produce cAMP which activates glycogen phosphorylase and inactivates glycogen synthase. Since these tissues lack glucose 6-phosphatase, this leads to stimulation of glycolysis rather than release of glucose into the blood. Thus, the effect of epinephrine in heart and skeletal muscle is to make more glucose 6-phosphate available for glycolysis. ATP generated by glycolysis can then meet the need for energy imposed on these muscles by the stress that triggered epinephrine release.

Neural Control of Glycogenolysis in Skeletal Muscle

Nervous excitation of muscle activity is mediated by changes in intracellular Ca^{2+} concentration (Figure 15.62). A nerve impulse causes membrane depolarization, which causes Ca^{2+}

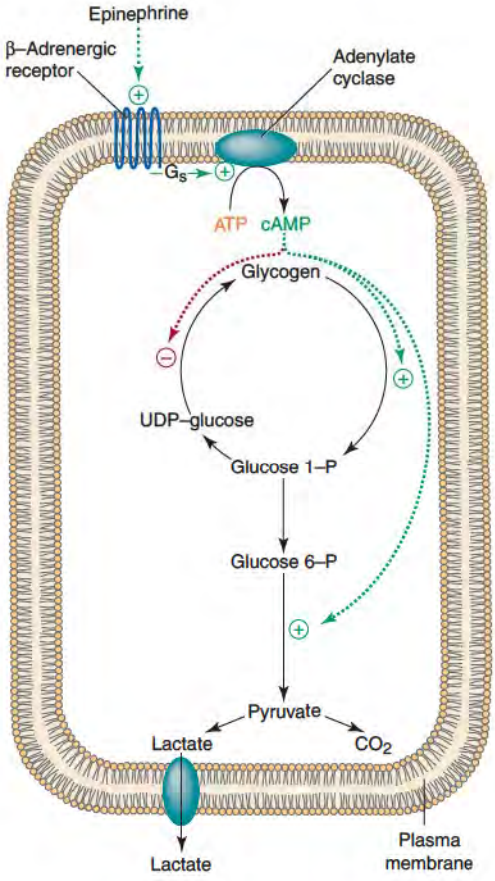

Figure 15.61 Cyclic AMP mediates stimulation of glycogenolysis in muscle by β agonists (epinephrine). The β-adrenergic receptor is an intrinsic component of the plasma membrane that stimulates adenylate cyclase by a stimulatory G protein (G_s).

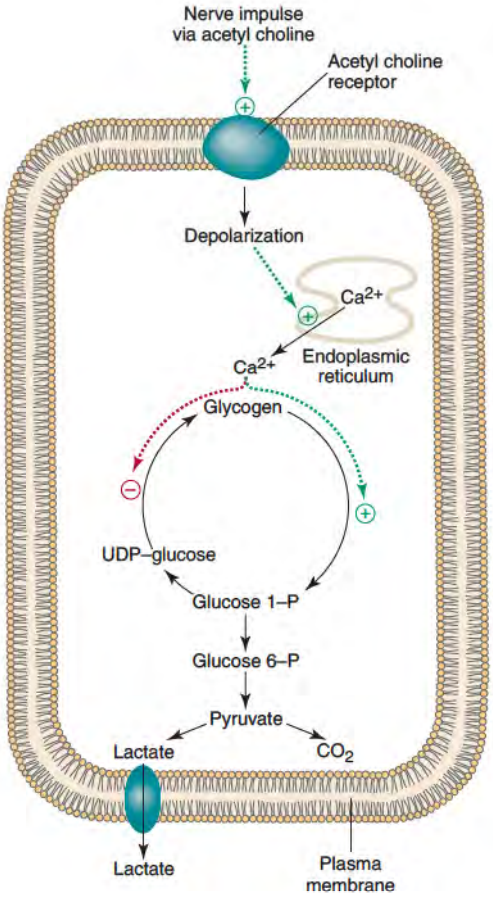

Figure 15.62 **Ca^{2+} mediates the stimulation of glycogenolysis in muscle by nervous excitation.**

release from the sarcoplasmic reticulum into the sarcoplasm of muscle cells. This triggers muscle contraction, whereas reaccumulation of Ca^{2+} by the sarcoplasmic reticulum causes relaxation. The change in Ca^{2+} concentration also activates phosphorylase kinase and glycogen phosphorylase and perhaps inactivates glycogen synthase. Thus, more glycogen is converted to glucose 6-phosphate so that more ATP is produced to meet the greater energy demand of muscle contraction.

Insulin Stimulates Glycogenesis in Muscle and Liver

An increase in blood glucose signals release of insulin from β cells of the pancreas. Insulin receptors on the plasma membranes of insulin-responsive cells respond to insulin binding through a signaling cascade that promotes glucose use (Figures 15.63 and 15.64). The pancreas responds to a decrease in blood glucose with less release of insulin and more release of glucagon. These hormones have opposite effects on glucose utilization by liver, thereby establishing the pancreas as a fine-tuning device that prevents dangerous fluctuations in blood glucose levels.

Insulin increases glucose utilization in part by promoting glycogenesis and inhibiting glycogenolysis in muscle and liver. Insulin stimulation of glucose transport is essential for these effects in muscle but not liver. Hepatocytes have a high-capacity, insulin-insensitive glucose transporter (GLUT2), whereas skeletal muscle cells and adipocytes have an insulin-sensitive glucose transporter (GLUT4) (p. 489). Insulin increases the number of glucose transporter 4 proteins associated with the plasma membrane by promoting their translocation from an intracellular pool (see Figure 15.5, p. 595). Insulin promotes glycogen accumulation in both tissues by activating glycogen synthase and inhibiting glycogen phosphorylase.

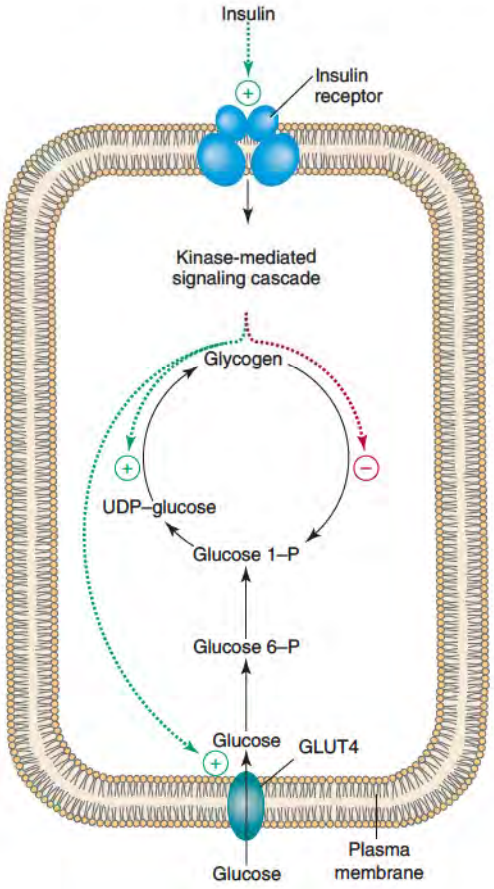

Figure 15.63 **Insulin acts by a plasma membrane receptor to promote glycogenesis in muscle.**

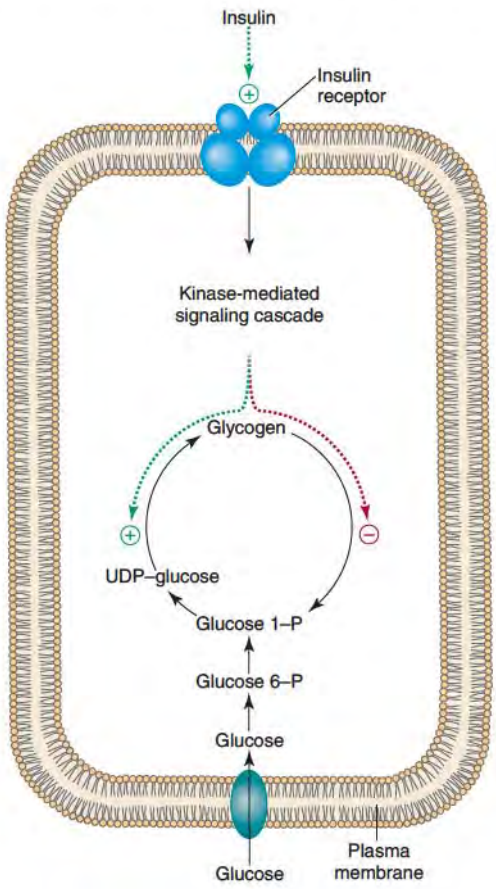

Figure 15.64 **Insulin acts by a plasma membrane receptor to promote glycogenesis in liver.**

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. Glucokinase
   - **A.** has a $S_{0.5}$ greater than the normal blood glucose concentration.
   - **B.** is found in muscle.
   - **C.** is inhibited by glucose 6-phosphate.
   - **D.** is also known as the GLUT-2 protein.
   - **E.** has glucose 6-phosphatase activity as well as kinase activity.

2. 6-Phosphofructo-1-kinase activity can be decreased by all of the following except
   - **A.** ATP at high concentrations.
   - **B.** citrate.
   - **C.** AMP.
   - **D.** low pH.
   - **E.** decreased concentration of fructose 2,6-bisphosphate.

3. In the Cori cycle,
   - **A.** only tissues with aerobic metabolism (i.e., mitochondria and O_2) are involved.
   - **B.** a three-carbon compound arising from glycolysis is converted to glucose at the expense of energy from fatty acid oxidation.
   - **C.** glucose is converted to pyruvate in anaerobic tissues, and this pyruvate returns to the liver, where it is converted to glucose.
   - **D.** the same amount of ATP is used in the liver to synthesize glucose as is released during glycolysis, leading to no net effect on whole body energy balance.
   - **E.** nitrogen from alanine must be converted to urea, increasing the amount of energy required to drive the process.

4. When blood glucagon rises, which of the following hepatic enzyme activities falls?
   - **A.** Adenyl cyclase
   - **B.** Protein kinase
   - **C.** 6-Phosphofructo-2-kinase
   - **D.** Fructose 1,6-bisphosphatase
   - **E.** Hexokinase

5. Glucose 6-phosphatase, which is deficient in Von Gierke disease, is necessary for the production of blood glucose from
   A. liver glycogen.
   B. fructose.
   C. amino acid carbon chains.
   D. lactose.
   E. all of the above.

6. UDP-glucose
   A. is formed by the reaction between UTP and glucose.
   B. is an intermediate in both the synthesis of glycogen and its degradation.
   C. formation is irreversible because it generates pyrophosphate.
   D. adds glucose units to the preexisting glycogen in α-1,6 linkages.
   E. is the substrate for branching enzyme.

Questions 7 and 8: Alcohol intoxication can lead to hypoglycemia especially if the alcohol is consumed by an undernourished individual or after strenuous exercise. In both cases the hypoglycemia results from the inhibitory effects of alcohol on hepatic gluconeogenesis and occurs under circumstances of hepatic glycogen depletion. Alcohol potentiates the hypoglycemic effect of insulin so diabetics who have self-administered insulin and then consumed alcohol are at increased risk.

7. Alcohol metabolism produces large amounts of NADH which inhibit gluconeogenesis by
   A. shifting the pyruvate–lactate equilibrium toward lactate.
   B. favoring the production of oxaloacetate from malate.
   C. preventing the movement of phosphoenolpyruvate from the mitochondria to the cytosol.
   D. inhibiting the electron transport chain.
   E. inhibiting the malate–aspartate shuttle.

8. Insulin promotes hypoglycemia by a variety of mechanisms including all of the following except
   A. inactivating a transcription factor for genes of key gluconeogenic enzymes.
   B. inhibiting lipolysis in adipose tissue, thus decreasing the energy supply for gluconeogenesis in the liver.
   C. decreasing levels of cAMP.
   D. increasing activation of phosphoprotein phosphatase.
   E. increasing the activity of cAMP-response element binding protein (CREB) and its binding to the cAMP-response element (CRE).

Questions 9 and 10: Malignant hyperthermia is a genetic abnormality in which exposure to certain agents, especially the widely used general anesthetic halothane, produces a dramatic rise in body temperature, acidosis, hyperkalemia, and muscle rigidity. Death is rapid if the condition is untreated and may occur the first time a susceptible person is anaesthetized. The defect causes an inappropriate release of Ca^{2+} from the sarcoplasmic reticulum of muscle. Many heat-producing processes are stimulated in an uncontrolled fashion by the release of Ca^{2+}, including glycolysis and glycogenolysis.

9. Ca^{2+} increases glycogenolysis by
   A. activating phosphorylase kinase b, even in the absence of cAMP.
   B. binding to phosphorylase b.
   C. activating phosphoprotein phosphatase.
   D. inhibiting phosphoprotein phosphatase.
   E. protecting cAMP from degradation.

10. Phosphorylation–dephosphorylation and allosteric activation of enzymes play roles in stimulating glycogen degradation. All of the following result in enzyme activation except
    A. phosphorylation of phosphorylase kinase.
    B. binding of AMP to phosphorylase b.
    C. phosphorylation of phosphorylase.
    D. phosphorylation of protein kinase A.
    E. dephosphorylation of glycogen synthase.

Questions 11 and 12: Patients with hereditary fructose intolerance are deficient in the liver form of the enzyme aldolase. Consumption of fructose leads to a depletion of ATP and P_i in the liver, which, in turn, leads to cell damage. Much of the cell damage can be attributed to the inability to maintain normal ion gradients by ATP-dependent pumps.

11. The first step in liver's metabolism of fructose is
    A. isomerization to glucose.
    B. phosphorylation to fructose 1,6-bisphosphate by ATP.
    C. phosphorylation to fructose 1-phosphate by ATP.
    D. phosphorylation to fructose 6-phosphate by ATP.
    E. cleavage by aldolase.

12. The products initially produced by aldolase action on the substrate formed from fructose are
    A. two molecules of dihydroxyacetone phosphate.
    B. two molecules of glyceraldehyde 3-phosphate.
    C. two molecules of lactate.
    D. dihydroxyacetone phosphate and glyceraldehyde 3-phosphate.
    E. dihydroxyacetone phosphate and glyceraldehyde.

Problems

13. If a cell is forced to metabolize glucose anaerobically, how much faster would glycolysis have to proceed to generate the same amount of ATP as it would get if it metabolized glucose aerobically?

14. The alanine cycle requires more ATP per glucose molecule formed than does the Cori cycle. Why is this?

Answers

1. **A** Blood glucose is ~ 5 mM. $S_{0.5}$ of glucokinase is ~ 7 mM. B: Glucokinase is hepatic, and unlike the muscle hexokinase, it is not inhibited by glucose 6-phosphate.
2. **C** AMP is an allosteric regulator that relieves inhibition by ATP. B and D are probably important physiological regulators in muscle, and E is critical in liver.
3. **B** The liver derives the energy required for gluconeogenesis from aerobic oxidation of fatty acids. A: The liver is an essential organ in the Cori cycle; it is aerobic. C: In anaerobic tissues the end product of glycolysis is lactate; in aerobic tissues it is pyruvate, but there the pyruvate would likely be oxidized aerobically. D: Gluconeogenesis requires six ATP per glucose synthesized; glycolysis yields two ATP per glucose metabolized. E: Alanine is not part of the Cori cycle.
4. **C** As blood glucagon rises, A is activated, producing cAMP; cAMP activates B, and B inactivates C. Low levels of fructose 2,6-bisphosphate increase the activity of D. E is not an important hepatic enzyme; its role is filled in liver by glucokinase.
5. **E** To get into the blood, glucose must be free, not phosphorylated. A: Glycogen is degraded to glucose 1-phosphate, which is converted to glucose 6-phosphate. B: Fructose is metabolized to dihydroxyacetone phosphate, which can either continue through glycolysis or reverse to glucose 6-phosphate, depending on the state of the cell. C and D: Amino acid carbon chains and lactate are substrates for gluconeogenesis.
6. **C** The hydrolysis of the pyrophosphate to inorganic phosphate makes the reaction irreversible. A: Glucose 1-phosphate reacts with UTP. B: It is an intermediate in synthesis but not degradation. D: It is added only in an α-1,4 linkage. E: Branching enzyme removes a chain of glucosyl units from the end of a long branch and moves it to another place.
7. **A** Lactate must be converted to pyruvate to start gluconeogenesis. B: NADH shifts oxaloacetate to malate. C and D: The NADH is not in the mitochondria. E: NADH reducing equivalents can be moved into the mitochondria by the shuttle but the large amounts generated by alcohol metabolism overwhelm the capacity of the shuttle and mitochondrial oxidation.
8. **E** CREB is activated by phosphorylation (and would lead to increased gluconeogenic enzymes) but insulin promotes dephosphorylation. A: This is true. B: Gluconeogenesis is dependent on a supply of fatty acids to liver to provide energy. C: This occurs by activating cAMP phosphodiesterase. D: This promotes dephosphorylation of key enzymes, for example, increasing glycogen synthesis and decreasing glycogenolysis.
9. **A** The γ-subunit of phosphorylase kinase is a calmodulin-type protein. Both a and b forms of the enzyme are activated by Ca^{2+}. B and E: These do not happen. C and D: Ca^{2+} does not affect the phosphatase.
10. **D** Protein kinase A catalyzes phosphorylations but is activated by binding cAMP. A and C: Both of these enzymes are phosphorylated in their a forms. B: Phosphorylase B is allosterically activated by binding AMP. E: The a form of the synthase is the nonphosphorylated form.
11. **C** The ADP formed is converted to ATP at the expense of P_i. Inability to further metabolize fructose 1-phosphate results in depletion of P_i. A: This does not happen. B: This would require two phosphorylations. D: This does not happen in liver. E: The fructose must be phosphorylated first.
12. **E** Glyceraldehyde can be converted to glyceraldehyde 3-phosphate so both products feed into the glycolytic pathway or gluconeogenesis.
13. Anaerobically there is a net of two moles of ATP/mol glucose. Aerobically the same net of 2 ATP is obtained plus 2 NADH because pyruvate is the product. Let us assume the cell uses the malate–aspartate shuttle where each NADH yields 2.5 ATP. Therefore, there is a net of 7 moles ATP/mol glucose. Each pyruvate is converted to AcCoA and the AcCoA is oxidized by the tricarboxylic acid cycle. Each mol of pyruvate then yields 12.5 moles ATP, or 25 moles ATP for the two pyruvates. This gives a total of 32 moles ATP/mol glucose aerobically. (See Chapter 14.) Therefore, glycolysis must proceed 16 times as rapidly under anaerobic conditions to generate the same amount of ATP as occurs aerobically.
14. Both cycles require the same amount of ATP to convert pyruvate to glucose (lactate to pyruvate and alanine to pyruvate). In the alanine cycle, the NADH produced is not used to reduce pyruvate to lactate and could be oxidized by the electron transport system to produce energy. But the alanine cycle presents the liver with amino nitrogen that must be disposed of as urea. This requires four ATP per urea molecule produced, and this ATP is not required in the Cori cycle.

Key Concepts

- Glucose phosphorylation mediated by hexokinases yields glucose-6-phosphate, which has a pivotal role as a common precursor for several metabolic pathways utilizing glucose.
- Glucose-6-phosphate metabolism through the pentose phosphate pathway conserves redox equivalents of glucose-6-phosphate as NADPH, whereas glycolysis promotes energy production.
- The pentose phosphate pathway supplies ribose-5-phosphate for nucleic acid synthesis.
- The pentose phosphate pathway degrades the sugar molecule one carbon at a time in two distinct phases.
- The first and rate-limiting step in the pentose phosphate pathway is catalyzed by glucose-6-phosphate dehydrogenase, which oxidizes glucose-6-phosphate to 6-phosphogluconate.
- Most sugar components of biomolecules are derived from glucose through a variety of chemical transformations and interconversions. Nucleotide-linked sugars are key to many sugar transformations as well as synthesis of complex polysaccharides.

- Oligo- or polysaccharides are linked to proteins via a limited number of *N*- or *O*-glycosyl bonds in glycoproteins and proteoglycans.
- *N*-glycosylation entails a dolichol-linked assembly pathway and a multi-compartment cellular processing pathway.
- Glycan structures modulate numerous molecular interactions like cell signaling, adhesion, and receptor activation.
- Genetic disorders of glycosylation cause a wide range of phenotypes, with examples from all clinical specialties. Many genetic diseases of complex carbohydrate metabolism result from deficiencies of glycosidases.

16.1 • PENTOSE PHOSPHATE PATHWAY

Pentose Phosphate Pathway Has Two Phases

The pentose phosphate pathway provides a means for degrading the carbon chain of a sugar molecule one carbon at a time. However, this pathway does not constitute a consecutive set of reactions that lead directly to CO_2, but occurs in two phases. In the first, hexose is decarboxylated to pentose via two oxidation reactions that form NADPH; in the second, by a series of transformations, six molecules of pentose undergo rearrangements to yield five molecules of hexose.

Glucose 6-Phosphate Oxidization Conserves Redox Equivalents as NADPH and Decarboxylation Supplies Pentose Phosphates

The first reaction, catalyzed by glucose 6-phosphate (G6P) dehydrogenase (Figure 16.1) is **dehydrogenation** of G6P to form **6-phosphoglucono-δ-lactone** and **NADPH**, and is a major regulatory site for this pathway. Special interest in this enzyme stems from the severe anemia that may result from absence of **G6P dehydrogenase** in erythrocytes or from the presence of one of many genetic variants of the enzyme (Clin. Corr.16.1). The lactone product of this reaction is a substrate for gluconolactonase, which ensures that the reaction goes to completion. The overall equilibrium of both reactions lies far in the direction of NADPH, maintaining a high NADPH/$NADP^+$ ratio within cells. A second dehydrogenation and **decarboxylation**, catalyzed by **6-phosphogluconate dehydrogenase**, produces the pentose phosphate, **ribulose 5-phosphate** and a second molecule of NADPH. Ribulose 5-phosphate is then **isomerized** to ribose 5-phosphate through an enediol intermediate.

CLINICAL CORRELATION 16.1

Glucose 6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common human enzyme defect and may be present in as many as 400 million people worldwide. About 140 mutations have been described in this protein of 516 amino acids, accounting for a wide range of symptoms. The most frequent clinical manifestations of G6PD deficiency are neonatal jaundice and acute hemolytic anemia, which is usually triggered by an exogenous agent. When certain seemingly harmless drugs, such as antimalarials, antipyretics, or sulfa antibiotics, are administered to susceptible patients, an acute hemolytic anemia may result in 48–96 h. Susceptibility to drug-induced hemolytic disease is most often due to a deficiency of glucose 6-phosphate (G6P) dehydrogenase activity in erythrocytes, and was an early indication that X-linked genetic deficiencies of this enzyme exist. The enzyme is particularly important, since the pentose phosphate pathway is the major pathway of NADPH production in the red cell. Red blood cells with the relatively mild A-type G6P dehydrogenase deficiency can oxidize glucose at a normal rate when the demand for NADPH is normal. However, if the rate of NADPH utilization is increased, the cells cannot increase the activity of the pathway adequately. In addition, cells do not reduce enough $NADP^+$ to maintain glutathione in its reduced state, and hence to protect against lipid peroxidation. Reduced glutathione is necessary for the integrity of the erythrocyte membrane, thus rendering enzyme-deficient red cells more susceptible to hemolysis by a wide range of compounds. This deficiency illustrates the interplay of heredity and environment in the production of disease. The most effective management of G6PD deficiency is to prevent hemolysis by avoiding oxidative stress. Complete deficiency of G6PD is lethal.

Luzzatto, L., Mehta, A., and Vulliamy, T. Glucose 6-phosphate dehydrogenase deficiency. In Scriver ,C. R., Beaudet, A.R., Sly, W. S., and Valle, D. (Eds.). *The Metabolic and Molecular Bases of Inherited Disease,* 8th ed. New York: McGraw Hill, 2001, III: 4517; and Cappellini, M. D., and Fiorelli, G. *Lancet* 371:64, 2008.

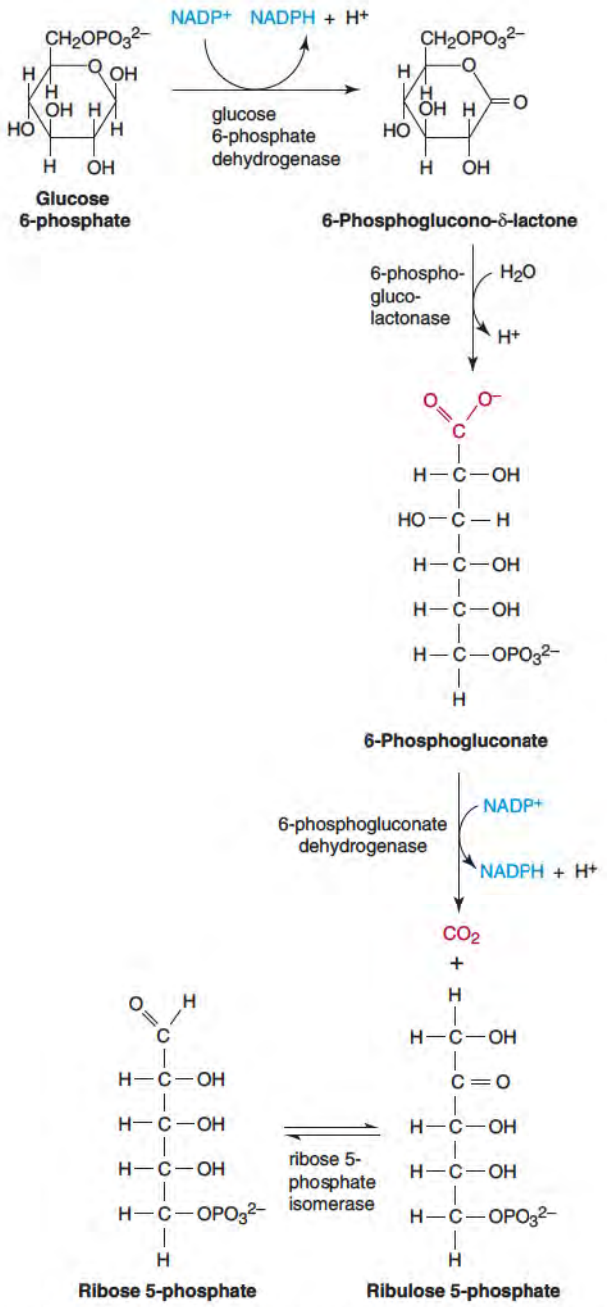

Figure 16.1 Oxidative phase of the pentose phosphate pathway: Formation of pentose phosphate and NADPH.

Under certain metabolic conditions, the pentose phosphate pathway can end at this point, with utilization of NADPH for reductive biosynthetic reactions and ribose 5-phosphate as a precursor for nucleotide synthesis. The overall equation may be written as

$$\text{Glucose 6-phosphate} + 2\text{NADP}^+ + \text{H}_2\text{O} \rightleftharpoons \text{ribose 5-phosphate} + 2\text{NADPH} + 2\text{H}^+ + \text{CO}_2$$

Interconversions of Pentose Phosphates Lead to Intermediates of Glycolysis

If more NADPH is needed for **reductive biosynthesis** than ribose 5-phosphate for incorporation into nucleotides, a sugar **interconversion** system (Figure 16.2) forms triose, tetrose, hexose, and heptose sugars from the pentoses and provides a reversible link between the

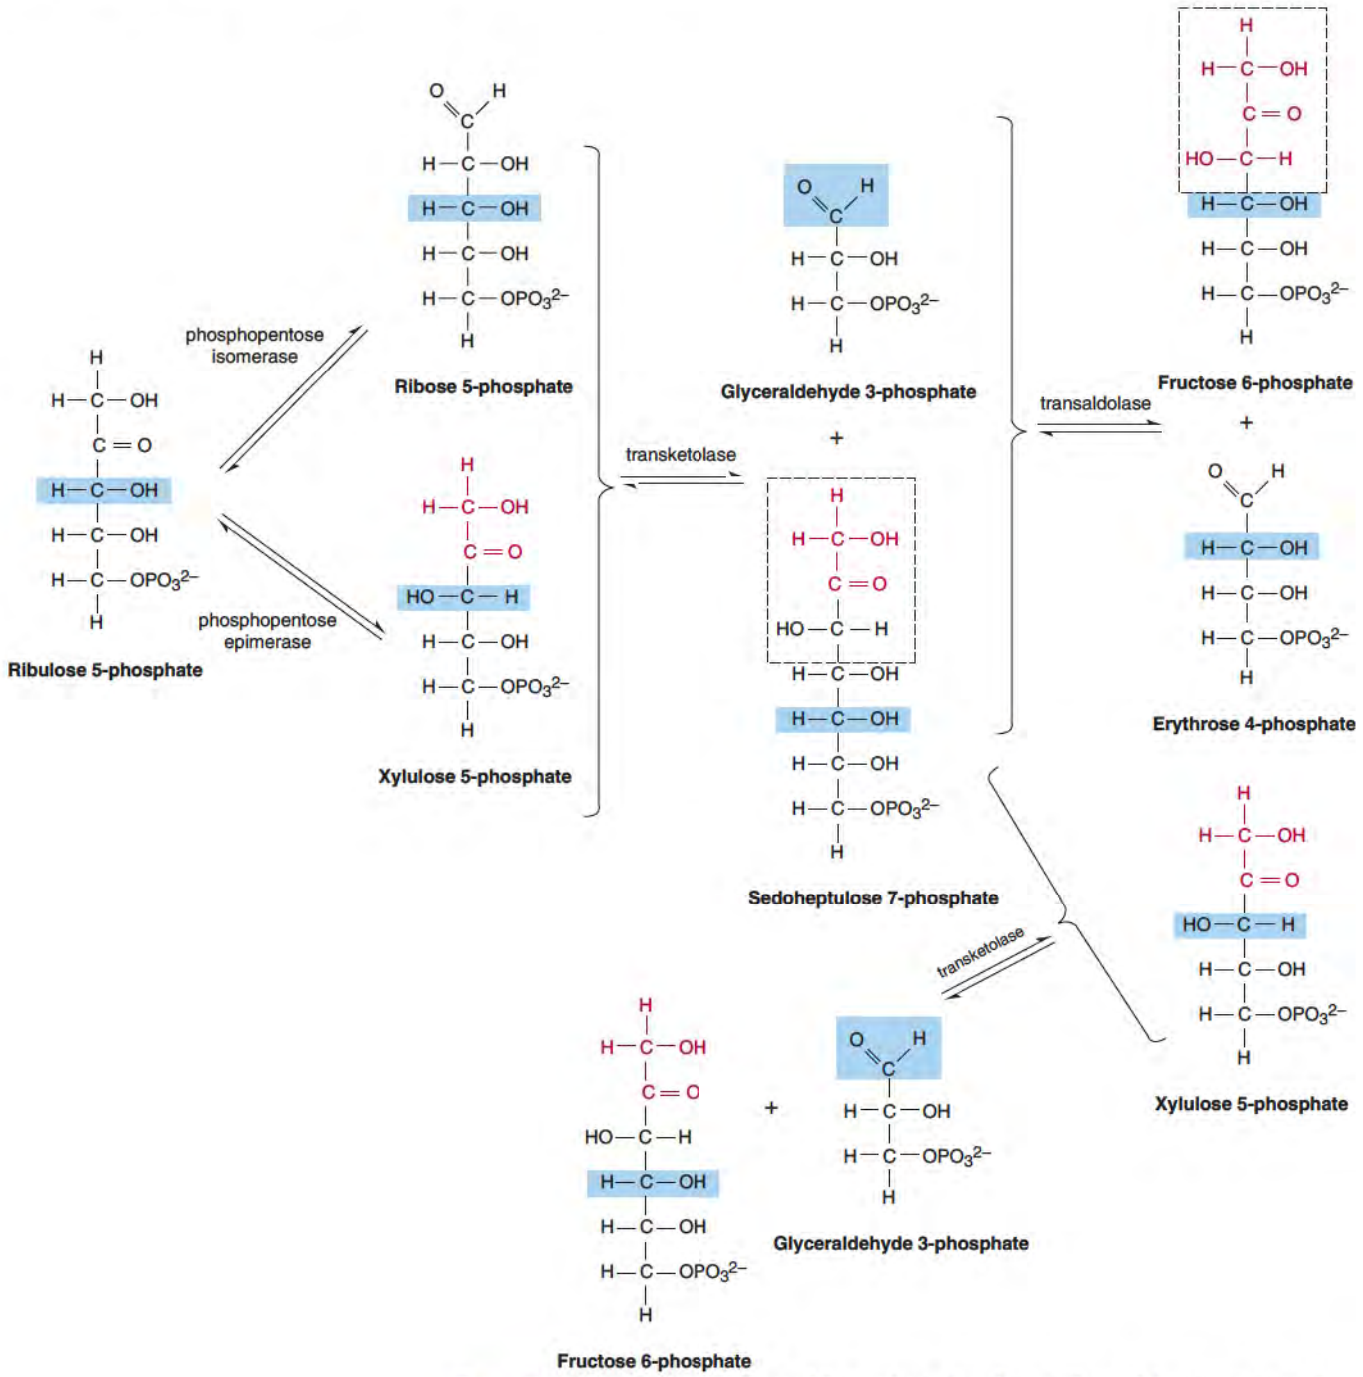

Figure 16.2 Nonoxidative reactions of the pentose phosphate pathway: Interconversions of pentose phosphates.

pentose phosphate pathway and glycolysis via common intermediates. **Xylulose 5-phosphate** is formed through isomerization of ribulose 5-phosphate by **phosphopentose epimerase**; ribulose 5-phosphate, ribose 5-phosphate, and xylulose 5-phosphate thus exist as an equilibrium mixture and can undergo transformations catalyzed by transketolase and transaldolase.

Transketolase requires **thiamin pyrophosphate** (TPP) and divalent cations, transfers a C_2 unit of *active glycolaldehyde* from xylulose 5-phosphate to ribose 5-phosphate, and produces **sedoheptulose** and **glyceraldehyde 3-phosphate**, an intermediate of glycolysis. Alterations in transketolase can lead to Wernicke–Korsakoff syndrome (Clin. Corr.16.2). **Transaldolase** transfers a C_3 unit (dihydroxyacetone) from sedoheptulose 7-phosphate to glyceraldehyde 3-phosphate forming **erythrose 4-phosphate**, and **fructose 6-phosphate**, another intermediate of glycolysis. Transketolase produces fructose 6-phosphate and

glyceraldehyde 3-phosphate, from erythrose 4-phosphate and xylulose 5-phosphate. The sum of these reactions is

$$2\ \text{Xylulose 5-phosphate} + \text{ribose 5-phosphate} \rightleftharpoons 2\ \text{fructose 6-phosphate} + \text{glyceraldehyde 3-phosphate}$$

Since xylulose 5-phosphate is derived from ribose 5-phosphate, the net reaction starting from ribose 5-phosphate is

$$3\ \text{Ribose 5-phosphate} \rightleftharpoons 2\ \text{fructose 6-phosphate} + \text{glyceraldehyde 3-phosphate}$$

Thus, excess ribose 5-phosphate, produced in the first stage of the pentose phosphate pathway or from degradation of nucleic acids, is effectively converted to intermediates of glycolysis.

Glucose 6-Phosphate Can Be Completely Oxidized to CO_2

Complete oxidation of glucose 6-phosphate (G6P) to CO_2, with reduction of $NADP^+$ to NADPH, may also occur (Figure 16.3). G6P continually enters this pathway, and CO_2 and NADPH are produced in the first phase. A balanced equation includes the oxidation of six molecules of G6P to six of ribulose 5-phosphate and six of CO_2. This results in transfer of 12 pairs of electrons to $NADP^+$, the requisite amount for total oxidation of one glucose to six CO_2. Six molecules of ribulose 5-phosphate are then rearranged to generate five molecules of G6P. The overall equation then becomes

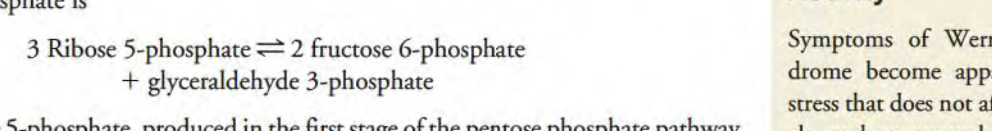
$$6\ \text{Glucose 6-phosphate} + 12NADP^+ + 7H_2O \rightleftharpoons 5\ \text{glucose 6-phosphate} + 6CO_2 + 12NADPH + 12H^+ + P_i$$

And the net reaction is

$$\text{Glucose 6-phosphate} + 12NADP^+ + 7H_2O \rightleftharpoons 6CO_2 + 12NADPH + 12H^+ + P_i$$

Pentose Phosphate Pathway Serves as a NADPH Regenerating System and Supplier of Pentose Phosphates

The pentose phosphate pathway serves several purposes, including synthesis and degradation of sugars other than hexoses, particularly ribose 5-phosphate for synthesis of nucleotides, and



CLINICAL CORRELATION 16.2

Wernicke–Korsakoff Syndrome (OMIM 277730): Associated Anomalies in Transketolase Activity

Symptoms of Wernicke–Korsakoff syndrome become apparent after moderate stress that does not affect normal individuals, and an anomaly in transketolase has been noted. Cloning and sequencing of the transketolase gene appears to exclude a genetic defect. Rather, the dysfunction of transketolase may be related to a thiamin deficiency, since transketolase utilizes thiamin pyrophosphate as a cofactor. The syndrome presents as a mental disorder, with memory loss and partial paralysis, and can become manifest in alcoholics, whose diets may be vitamin deficient. The medical importance of the pentose phosphate pathway is also highlighted by deficiencies in transaldolase, which are linked to a spectrum of clinical diseases, including liver cirrhosis and male infertility.

Perl, A. The pathology of transaldolase deficiency. *Life* 59:365, 2007

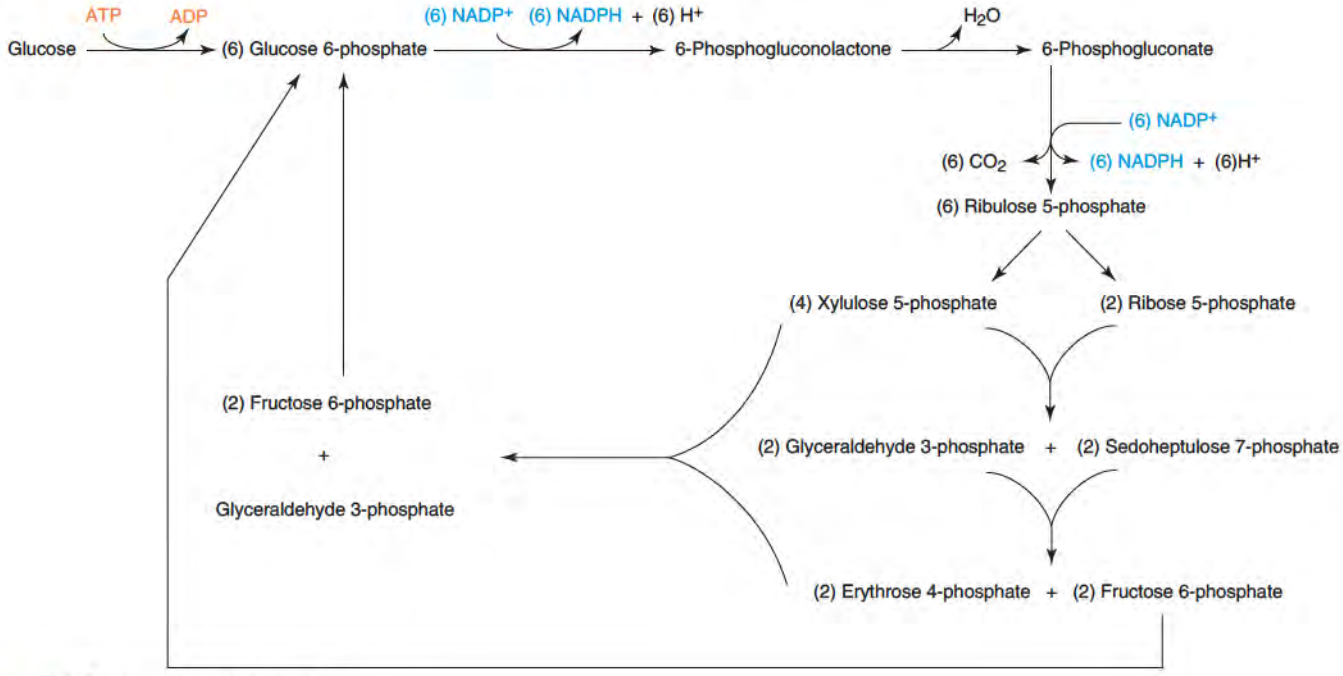


Figure 16.3 Pentose phosphate pathway.

synthesis of NADPH. The processing flow of G6P after entry into the pathway is determined largely by the needs of the cell for NADPH or sugar intermediates. When more NADPH than ribose 5-phosphate is required, the path leading to complete oxidation of G6P to CO_2 and resynthesis of G6P from ribulose 5-phosphate is favored. Alternatively, if NADPH demand is relatively low, conversion of G6P to ribulose 5-phosphate for nucleic acid synthesis or recycling to produce intermediates of the glycolytic pathway predominates.

The tissue distribution of the pentose phosphate pathway is consistent with its functions. NADPH, required to maintain reduced glutathione which protects the integrity of red blood cell membranes, is produced in erythrocytes, as well as in liver, mammary gland, testis, and adrenal cortex, which are sites of fatty acid or steroid synthesis. The balance between glucose entry into glycolysis or the pentose phosphate pathway depends on the metabolic requirements of the organ. 20%–30% of the CO_2 produced in the liver may arise from the pentose phosphate pathway. In mammalian striated muscle, which carries on little fatty acid or steroid synthesis, all catabolism of G6P proceeds via glycolysis and the TCA cycle with no direct oxidation of glucose 6-phosphate through the pentose phosphate pathway.

16.2 • SUGAR INTERCONVERSIONS AND NUCLEOTIDE-LINKED SUGAR FORMATION

Most monosaccharides found in biological compounds derive from glucose. The most common sugar **transformations** in mammalian systems are summarized in Figure 16.4.

Isomerization and Phosphorylation Are Common Reactions for Interconverting Carbohydrates

Formation of some sugars can occur directly, starting from glucose via modification reactions such as the **aldose-ketose isomerization** catalyzed by **phosphomannose isomerase**, which produces **mannose 6-phosphate**. Deficiency in this enzyme leads to one form of **c**ongenital **d**isorders of **g**lycosylation **s**yndrome (**CDGS**) (p. 662).

Phosphorylation and internal transfer of a phosphate group on the same sugar molecule are also common modifications. Glucose 1-phosphate, resulting from glycogenolysis, is converted to G6P by **phosphoglucomutase**. Galactose is phosphorylated to galactose 1-phosphate

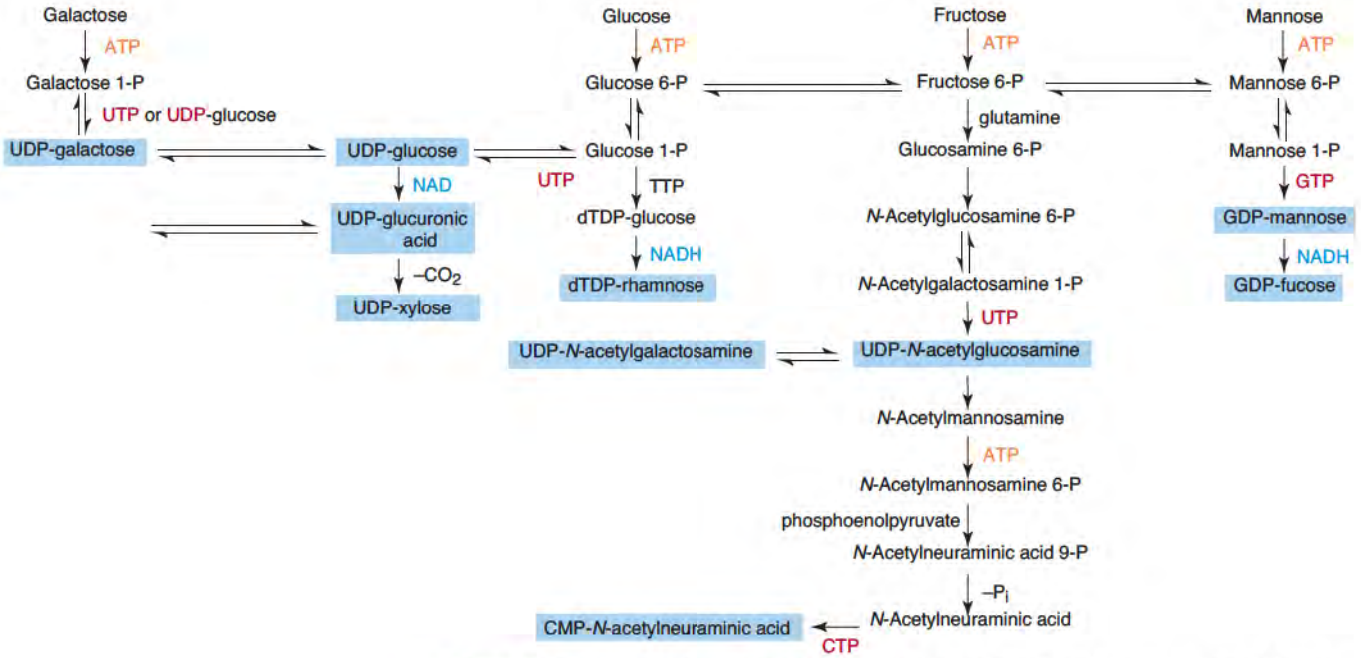

Figure 16.4 Pathways of formation of nucleotide-linked sugars and interconversion of some hexoses.

CLINICAL CORRELATION 16.3

Essential Fructosuria (OMIM 229800) and Fructose Intolerance (OMIM 229600): Deficiency of Fructokinase and Fructose 1-Phosphate Aldolase

Fructose may account for 30%–60% of the total carbohydrate intake of mammals and is predominantly metabolized by a fructose-specific pathway. Fructokinase is deficient in essential fructosuria. This disorder is a benign asymptomatic metabolic anomaly which appears to be inherited as an autosomal recessive trait. Following intake of fructose, blood and urinary fructose levels of affected individuals are unusually high; however, 90% of their fructose intake is eventually metabolized. In contrast, hereditary fructose intolerance is characterized by severe hypoglycemia, jaundice, hemorrhage, hepatomegaly, uricemia, and eventual kidney failure. Ingestion of fructose or prolonged ingestion by affected young children may lead to death. Fructose 1-phosphate aldolase may also be deficient, in which case fructose 1-phosphate accumulates intracellularly (see Clin. Corr. 15.3, p. 607).

Steinmann, B., Gitzelmann, R., and Vanden Berghe, G. Disorders of fructose metabolism. In Scriver ,C. R., Beaudet, A.R., Sly, W. S., and Valle, D. (Eds.). *The Metabolic and Molecular Bases of Inherited Disease,* 8th ed. New York: McGraw Hill, 2001, I:1489.

by **galactokinase** and mannose to mannose 6-phosphate by **mannokinase**. Free fructose, an important dietary constituent, is phosphorylated in the liver to fructose 1-phosphate by a special fructokinase. However, no mutase interconverts fructose 1-phosphate and fructose 6-phosphate, and phosphofructokinase cannot synthesize fructose 1,6-bisphosphate from fructose 1-phosphate. Rather, **fructose 1-phosphate aldolase** cleaves fructose 1-phosphate to **dihydroxyacetone phosphate** (DHAP), which enters the glycolytic pathway directly, and glyceraldehyde, which is first reduced to glycerol, phosphorylated, and then reoxidized to DHAP (Figure 15.39, p. 625). Lack of this aldolase leads to fructose intolerance (Clin. Corr. 16.3).

Nucleotide-Linked Sugars Are Intermediates in Many Sugar Transformations

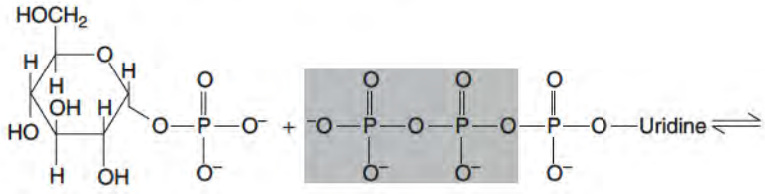
Many sugar transformation reactions require conversion into **nucleotide-linked sugars**. A **pyrophosphorylase** joins hexose 1-phosphate and nucleoside triphosphate (NTP) to produce a nucleoside diphosphate (NDP)-sugar and pyrophosphate. **Pyrophosphatase** rapidly hydrolyzes the pyrophosphate, thereby driving the synthesis reaction. These reactions are summarized as follows:

$$\text{NTP} + \text{sugar 1-phosphate} + H_2O \rightleftharpoons \text{NDP-sugar} + PP_i$$
$$PP_i + H_2O \rightleftharpoons 2P_i$$

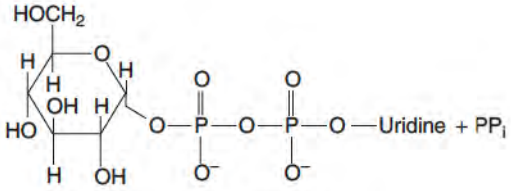
The net reaction is

$$\text{NTP} + \text{sugar 1-phosphate} + H_2O \rightleftharpoons \text{NDP-sugar} + 2P_i$$

For example, UDP-glucose is used in synthesis of glycogen and glycoproteins and is synthesized by **UDP-glucose pyrophosphorylase**.



Glucose



UDP-glucose

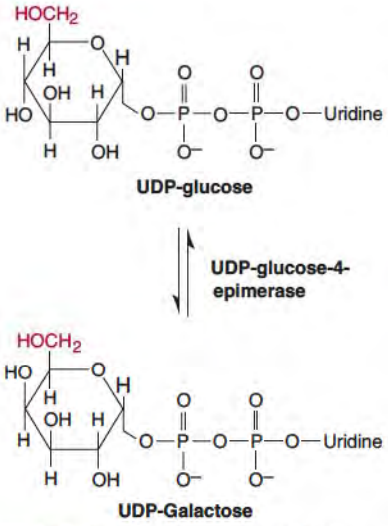


Figure 16.5 Conversion of glucose into galactose.

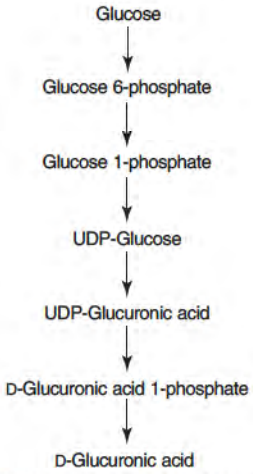

Figure 16.6 Biosynthesis of D-glucuronic acid from glucose.

Nucleoside diphosphate-sugars are important constructs: They contain two phosphoryl bonds, each with a large negative ΔG of hydrolysis that underlies their value as glycosyl donors in further transformation and transfer reactions, and they confer substrate specificity in those reactions. UDP is usually the glucosyl carrier, whereas ADP, GDP, and CMP are carriers for other sugars. Many sugar transformation reactions occur only at the level of nucleotide-linked sugars (Figure 16.4, p. 652).

Epimerization Interconverts Nucleotide-Linked Glucose and Galactose

Interconversion of glucose and galactose in animal cells occurs by epimerization of UDP-glucose to UDP-galactose, catalyzed by **UDP-glucose-4-epimerase** (Figure. 16.5). UDP-galactose is also formed from free galactose, derived from hydrolysis of lactose in the intestinal tract. Galactose is phosphorylated by **galactokinase** and ATP to yield galactose 1-phosphate. Then **galactose 1-phosphate uridylyltransferase** forms UDP-galactose by galactose 1-phosphate displacing glucose 1-phosphate from UDP-glucose. These reactions are summarized as follows:

$$\text{Galactose} + \text{ATP} \rightleftharpoons \text{galactose 1-phosphate} + \text{ADP}$$

$$\text{UDP-glucose} + \text{galactose 1-phosphate} \rightleftharpoons \text{UDP-galactose} + \text{glucose 1-phosphate}$$

Dietary galactose can be transformed by a combination of these reactions into glucose 1-phosphate and metabolized as previously described, or the 4-epimerase can produce UDP-galactose needed for biosynthesis. A severe form of hereditary galactosemia results from absence of the uridylyltransferase (Clin. Corr. 16.4).

Synthesis of GDP-fucose (see Figure. 16.4) begins with the conversion of GDP-mannose to GDP-4-keto-6-deoxymannose by **GDP-mannose-4,6-dehydratase**, followed by epimerization to GDP-4-keto-6-deoxy-L-galactose, and finally reduction to GDP-fucose. These latter reactions are catalyzed by the bifunctional **GDP-4-keto-6-deoxymannose 3,5-epimerase-4-reductase** (FX protein), which is abundant in red blood cells. Epimerization of D-glucuronic acid to L-iduronic acid occurs after the former is incorporated into heparin or dermatan sulfate (p. 665).

Glucuronic Acid Is Formed by Oxidation of UDP-Glucose

The synthesis of glucuronic acid from glucose is summarized in Figure 16.6. A critical step is the oxidation of UDP-glucose by **UDP-glucose dehydrogenase** (Figure 16.7). Glucuronic acid is reduced by NADPH to L-gulonic acid (Figure 16.8). Gulonic acid can be oxidized to 3-ketogulonic acid and decarboxylated to L-xylulose. In humans, L-xylulose is the ketopentose excreted in essential pentosuria (Clin. Corr. 16.5). L-Xylulose is normally reduced to xylitol, reoxidized to D-xylulose and phosphorylated to xylulose 5-phosphate,

CLINICAL CORRELATION 16.4

Galactosemia: Inability to Transform Galactose into Glucose

Reactions of galactose are of particular interest because in humans they are subject to genetic defects that produce the hereditary disorder galactosemia. When a defect is present, individuals are unable to metabolize the galactose derived from lactose (milk sugar) to glucose metabolites, often resulting in cataract formation, growth failure, mental retardation, or eventual death from liver damage. These phenotypes may be due to a cellular deficiency of galactokinase (Type 2, GALK1 gene) (OMIM 230200), causing a relatively mild disorder characterized by early cataract formation; galactose 1-phosphate uridylyltransferase (Type 1, GALT gene) (OMIM 606999), resulting in severe disease; or UDP galactose-4-epimerase deficiency (Type 3, GALE gene) (OMIM 230350). Galactose is reduced to galactitol in a reaction similar to that of glucose to sorbitol. Galactitol initiates cataract formation in the lens and may play a role in central nervous system damage. Accumulation of galactose-1-phosphate is responsible for liver failure; the toxic effects of galactose metabolites disappear when galactose is removed from the diet.

Petry, K. G., and Reichardt, J. K. The fundamental importance of human galactose. *Trends Genet.* 14:98, 1998; Scriver, C. R., Beaudet, A. L., Valle, D., Sly, W. S., Vofelstrin, B., and Kinzler, K.W. Galactosemia Online Metabolic and Molecular Basis of Inherited Disease (http://www.ommbid.com/). New York: McGraw Hill, 2006.

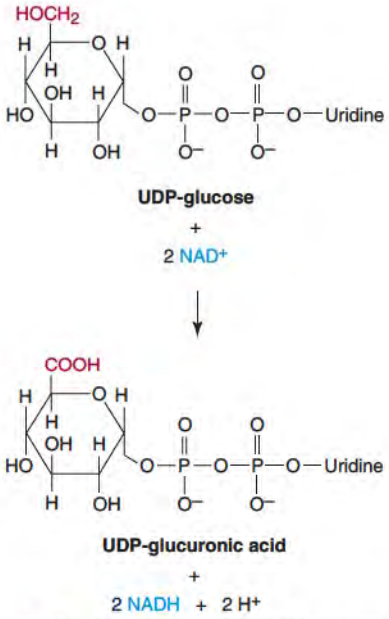

Figure 16.7 **Formation of UDP-glucuronic acid from UDP-glucose.**

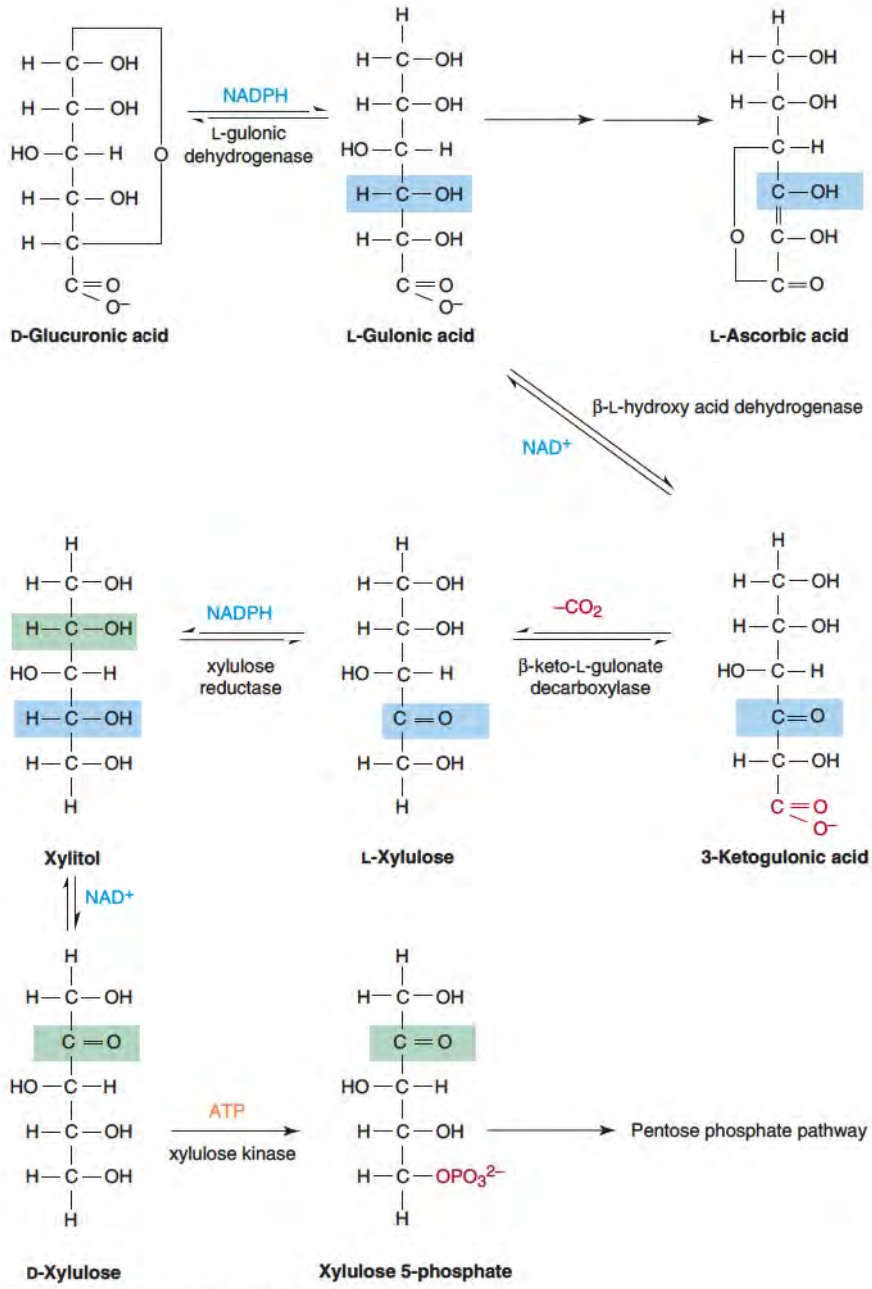

Figure 16.8 **Glucuronic acid oxidation pathway.**

which can enter the pentose phosphate pathway described previously. Glucuronic acid is also a precursor of **L-ascorbic acid** (Figure 16.8) in those animals that synthesize vitamin C (Clin. Corr. 16.6). Glucuronic acid also participates in detoxification by formation of glucuronide conjugates (Clin. Corr. 16.7). The glucuronic acid pathway operates in adipose tissue, and its activity is usually increased in tissue from starved or diabetic animals.

Decarboxylation, Oxidoreduction, and Transamidation of Sugars Yield Necessary Products

The only known **decarboxylation** of a nucleotide-linked sugar is the conversion of UDP-glucuronic acid to UDP-xylose, which is necessary for synthesis of proteoglycans (p. 664) and is a potent inhibitor of the production of UDP-glucuronic acid by UDP-glucose dehydrogenase (Figure 16.7), thus regulating the level of these nucleotide-linked sugar precursors by a sensitive feedback mechanism.

CLINICAL CORRELATION 16.5

Pentosuria (OMIM 260800): Deficiency of Xylitol Dehydrogenase; L-Xylulose Reductase

The glucuronic acid oxidation pathway does not appear to be essential for human carbohydrate metabolism, since individuals in whom the pathway is blocked suffer no ill effects. A metabolic variation, called idiopathic pentosuria, results from reduced activity of NADP-linked L-xylulose reductase that reduces xylulose to xylitol. Hence, affected individuals excrete large amounts of pentose into the urine, especially following intake of glucuronic acid.

Hiatt, H. Pentosuria. In Scriver,C. R., Beaudet, A. R., Sly, W. S., and Valle, D. (Eds.), *The Metabolic and Molecular Bases of Inherited Disease,* 8th ed. New York: McGraw Hill, 2001, I: 1589.

CLINICAL CORRELATION 16.6

Ascorbic Acid (Vitamin C) Is Derived from Glucuronic Acid

Glucuronic acid is reduced to L-gulonic acid and then converted through L-gulonolactone to L-ascorbic acid (vitamin C) in plants and most higher animals. Humans, other primates, and guinea pigs lack the enzyme that converts L-gulonolactone to L-ascorbic acid, and for them, ascorbic acid is a vitamin. The lack of vitamin C in the diet causes scurvy, a condition of connective tissues, which leads to multiple hemorrhages and decreased wound healing.

CLINICAL CORRELATION 16.7

Glucuronic Acid: Physiological Significance of Glucuronide Formation

The biological significance of glucuronic acid includes its conjugation with certain endogenous and exogenous substances to form glucuronides in a reaction catalyzed by UDP-glucuronyltransferase. Conjugation with glucuronic acid produces a strongly acidic compound that is more water soluble at physiological pH than its precursor, thereby enhancing its transport or excretion. Glucuronide formation is important in drug detoxification, steroid excretion, and bilirubin metabolism. Bilirubin is the major metabolic breakdown product of heme, the prosthetic group of hemoglobin. The central step in bilirubin excretion is conjugation with glucuronic acid by UDP-glucuronyltransferase. This enzyme may take from several days to two weeks after birth to become fully active in humans. Most cases of *physiological jaundice of the newborn* result from inability of neonatal liver to form bilirubin glucuronide at a rate comparable to that of bilirubin production. The mutant strain of Wistar Gunn rats has a deficiency of UDP-glucuronyltransferase, which results in hereditary hyperbilirubinemia. In humans, a similar defect occurs in congenital familial nonhemolytic jaundice (Crigler–Najjar syndrome); patients cannot efficiently conjugate foreign compounds with glucuronic acid.

Chowdhury, J. R., Wolkoff, W., Chowdhury, N. R., and Arias, I. W. Hereditary jaundice and disorders of bilirubin metabolism. In Scriver, C. R., Beaudet, A. R., Sly, W. S., and Valle, D. (Eds.), The *Metabolic and Molecular Bases of Inherited Disease,* 8th ed. New York: McGraw Hill, 2001, II: 3063.

Deoxyhexoses and **dideoxyhexoses** are also synthesized from precursor sugars attached to nucleoside diphosphates. L-rhamnose is synthesized from glucose by a series of oxidation–reduction reactions starting with dTDP-glucose and yielding dTDP-rhamnose; GDP-fucose is similarly synthesized from GDP-mannose as are various dideoxyhexoses.

Formation of amino sugars, major components of human complex oligo- and polysaccharides and constituents of antibiotics, occurs by **transamidation**; **glucosamine 6-phosphate** is formed from fructose 6-phosphate and glutamine by this mechanism (Figure 16.9).

Glucosamine 6-phosphate can be *N*-acetylated to ***N*-acetylglucosamine 6-phosphate**, followed by isomerization to *N*-acetylglucosamine 1-phosphate and subsequent formation of UDP-*N*-acetylglucosamine. The latter is a precursor of glycoprotein synthesis and of UDP-*N*-acetylgalactosamine, which is necessary for proteoglycan synthesis. Fructose 6-phosphate-glutamine transamidase is under negative feedback control by UDP-*N*-acetylglucosamine (see Figure 16.4, p. 652). This regulation is meaningful in certain tissues such as skin, in which this pathway accounts for up to 20% of the glucose flux.

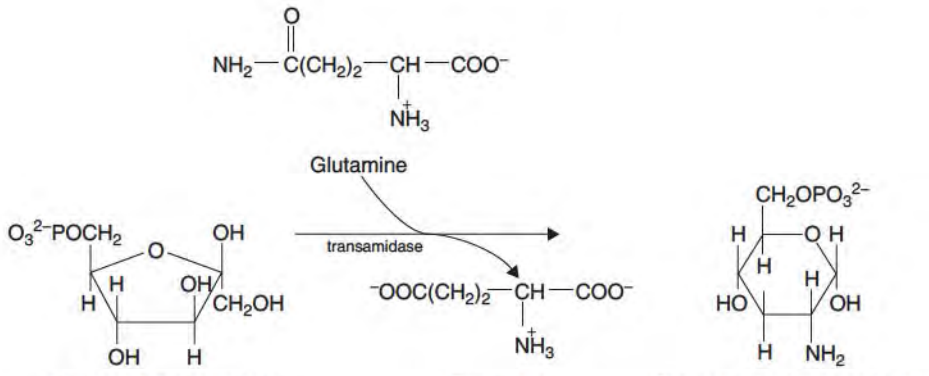

Figure 16.9 **Formation of amino sugars.**

Sialic Acids Are Derived from *N*-Acetylglucosamine

Another product of UDP-*N*-acetylglucosamine is ***N*-acetylneuraminic acid**, one of a family of C_9 sugars called **sialic acids** (Figure 16.10). Epimerization of UDP-*N*-acetylglucosamine by a 2-epimerase produces *N*-acetylmannosamine. This reaction likely proceeds by *trans* elimination of UDP and formation of the unsaturated intermediate, 2-acetamidoglucal. In mammalian tissues *N*-acetylmannosamine is phosphorylated to *N*-acetylmannosamine 6-phosphate, which

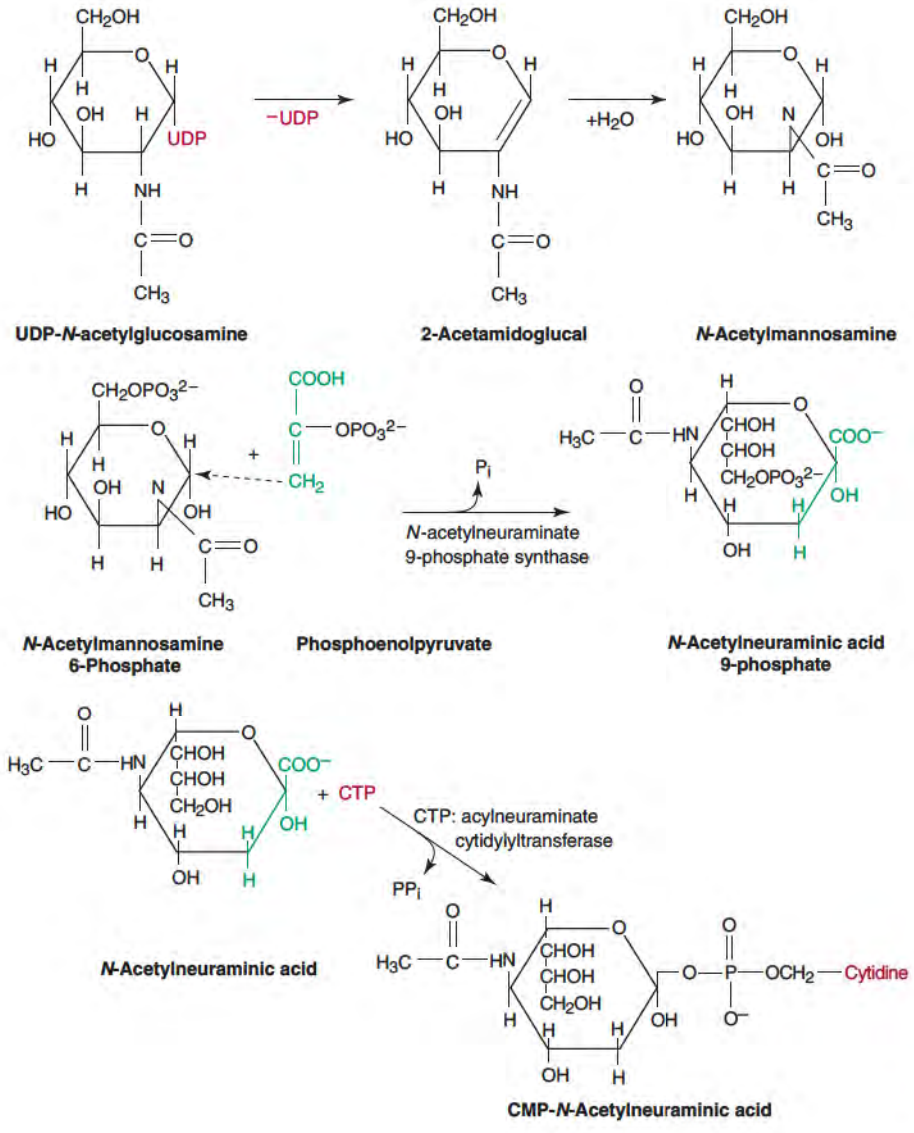

Figure 16.10 **Biosynthesis of CMP-*N*-acetylneuraminic acid.**

condenses with phosphoenolpyruvate to form ***N*-acetylneuraminic acid 9-phosphate**. Removal of the phosphate and formation of CMP-*N*-acetylneuraminic acid follows. All of these reactions occur in the cytosol, except the last which occurs in the nucleus with subsequent export of the CMP-*N*-acetylneuraminic acid to the cytoplasm.

16.3 • BIOSYNTHESIS OF COMPLEX POLYSACCHARIDES

Sugar moieties in polysaccharides are linked by glycosidic bonds formed by specific **glycosyltransferases** that transfer the glycosyl unit from a nucleotide derivative to the nonreducing end of an acceptor sugar. Over 180 glycosyltransferase genes have been identified. A given glycosyltransferase is specific for the sugar acceptor, the sugar transferred, and the linkage formed. A glycosyltransferase reaction is as follows:

$$\underset{\text{(donor)}}{\text{Nucleoside diphosphate-glycose}} + \underset{\text{(acceptor)}}{\text{glycose}} \xrightleftharpoons{\text{glycosyltransferase}} \underset{\text{(glycoside)}}{\text{glycosyl}_1\text{-}O\text{-glycose}_2} + \text{nucleoside diphosphate}$$

More than 40 types of glycosidic bonds have been identified in mammalian oligosaccharides and about 15 more in glycosaminoglycans. The multitude of linkages arises from the diversity of monosaccharides involved and from the formation of α and β linkages with each of the available hydroxyl groups on the acceptor saccharide. This suggests that oligosaccharides have the potential for great informational content; accordingly, the bioactivity of many molecules is determined by the nature of the composite sugar residues. For example, the antigenic specificity of the major blood types is determined by the sugar composition of cell surface molecules (Clin. Corr. 16.8). *N*-Acetylgalactosamine is the immunodeterminant of blood type A and galactose of blood type B. Removal of *N*-acetylgalactosamine from type A erythrocytes or of galactose from type B erythrocytes converts them to type O erythrocytes. Increasingly, other examples of sugars as determinants of specificity for cell surface receptor and lectin interactions, targeting of cells to certain tissues, and persistence in or clearance from the circulation of certain molecules, are being recognized. All glycosidic bonds identified in biological compounds are degraded by specific hydrolytic enzymes, **glycosidases**. In addition to their being valuable tools for the structural elucidation of oligosaccharides, this class of enzymes is of interest based on the many genetic diseases of complex carbohydrate metabolism that result from defects in glycosidases (see Clin. Corrs. 16.10, p. 663, and 16.11, p. 664).

CLINICAL CORRELATION 16.8

Blood Group Substances

The surface of human erythrocytes is covered by a complex mosaic of specific antigenic determinants, many of which are complex polysaccharides. There are about 100 blood group determinants, belonging to 21 independent blood group systems. The most widely studied are those of the ABO blood group system and the closely related Lewis system. Genetic variation is achieved through specific glycosyltransferases responsible for synthesis of the heterosaccharide determinants. The H gene codes for a fucosyltransferase, which adds fucose to a peripheral galactose in the heterosaccharide precursor. The A allele encodes an *N*-acetylgalactosamine glycosyltransferase, the B allele a galactosyltransferase, and the O allele an inactive protein. The sugars transferred by the A and B enzymes are added to the H-specific oligosaccharide. The Lewis (Le) gene codes for another fucosyltransferase, which adds fucose to a peripheral *N*-acetylglucosamine residue in the precursor. Absence of the H gene product gives rise to the Le^a specific determinant, whereas absence of both H and Le enzymes is responsible for the Le^b specificity. Elucidation of the structures of these oligosaccharide determinants represents a milestone in carbohydrate chemistry. This knowledge is essential to blood transfusion practices and important for legal and historical purposes.

Yamamoto, F., Clausen, I., White, T., Mark, J., and Hakomori, S. Molecular genetic basis of the histo-blood group ABO system. *Nature* 345:229, 1990.

16.4 • GLYCOPROTEINS

Glycoproteins are defined as conjugated proteins, which contain one or more saccharides lacking a serial repeat unit and which are bound covalently to a protein. This definition excludes proteoglycans (p. 664). Glycoproteins in cell membranes have an important role in the behavior of cells and especially in the biological functions of the membrane. Glycoproteins are constituents of the mucus secreted by certain epithelial cells, serving to lubricate and protect tissues lining the respiratory, gastrointestinal, and female reproductive systems. Many secreted proteins are glycoproteins and include hormones such as follicle stimulating hormone, luteinizing hormone, and chorionic gonadotropin and plasma proteins, such as the orosomucoids, ceruloplasmin, plasminogen, prothrombin, and immunoglobulins.

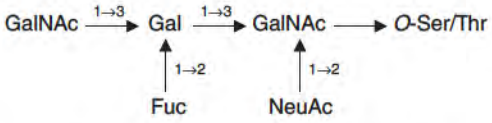
Glycoproteins Contain Variable Amounts of Carbohydrate

The amount of carbohydrate in glycoproteins is highly variable. IgGs contain about 4% carbohydrate by weight, whereas glycophorin contains 60%, human ovarian cyst glycoprotein 70%, and human gastric glycoprotein 82%. The carbohydrate may be distributed fairly evenly along a polypeptide chain or concentrated in defined regions. In human glycophorin A the carbohydrate is restricted to the extracellular NH_2-terminal half of the polypeptide chain.

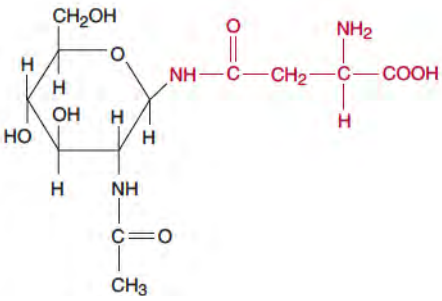
The carbohydrate components of glycoproteins usually contain less than 12–15 sugar residues. Some consist of a single sugar moiety, as in the submaxillary gland glycoprotein (one *N*-acetyl-α-D-galactosaminyl residue) and in some mammalian collagens (one α-D-galactosyl residue). In general, the sugar residues are of the D form, except for L-fucose, L-arabinose, and L-iduronic acid. Orthologous glycoproteins from different animal species often have identical primary protein structures, but different carbohydrate components. Heterogeneity of a given protein also occurs within an organism. For example, pancreatic ribonucleases A and B have identical primary structures and similar specificity toward substrates, but differ significantly in their carbohydrate compositions.

Carbohydrates Are Linked to Glycoproteins by *N*- or *O*-Glycosyl Bonds

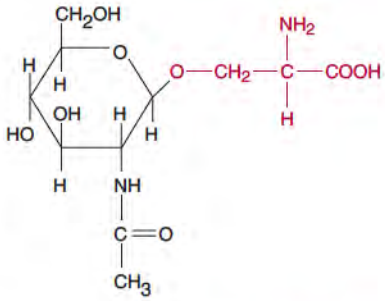
Carbohydrate structures have been completely elucidated for only a limited number of glycoproteins. Microheterogeneity of glycoproteins, arising from incomplete synthesis or partial degradation, makes structural analyses extremely difficult. However, certain generalities have emerged. Covalent linkage of sugar to the protein is an essential feature of glycoprotein structure, and only a small number of bond types are found (p. 112). The three major types of glycopeptide bonds, as shown in Figure 16.11, are *N*-glycosyl to **asparagine** (Asn), *O*-glycosyl to **serine** (Ser) or **threonine** (Thr), and *O*-glycosyl to **5-hydroxylysine**, generally confined to the collagens. N- and O-linkages are present in many glycoproteins and bind two types of oligosaccharides (simple and complex). The simple class has a core structure of galactose(Gal)-linked β (1→3) to *N*-acetylgalactosamine (GalNAc) *O*-glycosidically linked to serine or threonine residues. L-Fucose (Fuc), sialic acid (NeuAc), and *N*-acetylgalactosamine are present at the nonreducing end. The general structure is as follows:



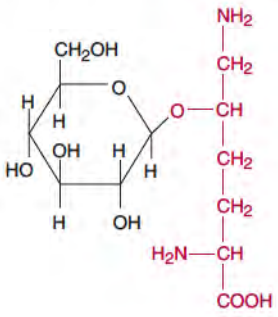
The complex class is exemplified by the ABO and Lewis blood group substances (see Clin. Corr. 16.8, p. 658), in which the oligosaccharide is *N*-glycosidically linked to asparagine. These glycoproteins commonly contain a core structure consisting of mannose (Man) residues linked to *N*-acetylglucosamine (GlcNAc) in the structure.



Type I ***N*-Glycosyl linkage to asparagine**



Type II ***O*-Glycosyl linkage to serine**



Type III ***O*-Glycosyl linkage to 5-hydroxylysine**

Figure 16.11 Structure of three major types of glycopeptide bond.

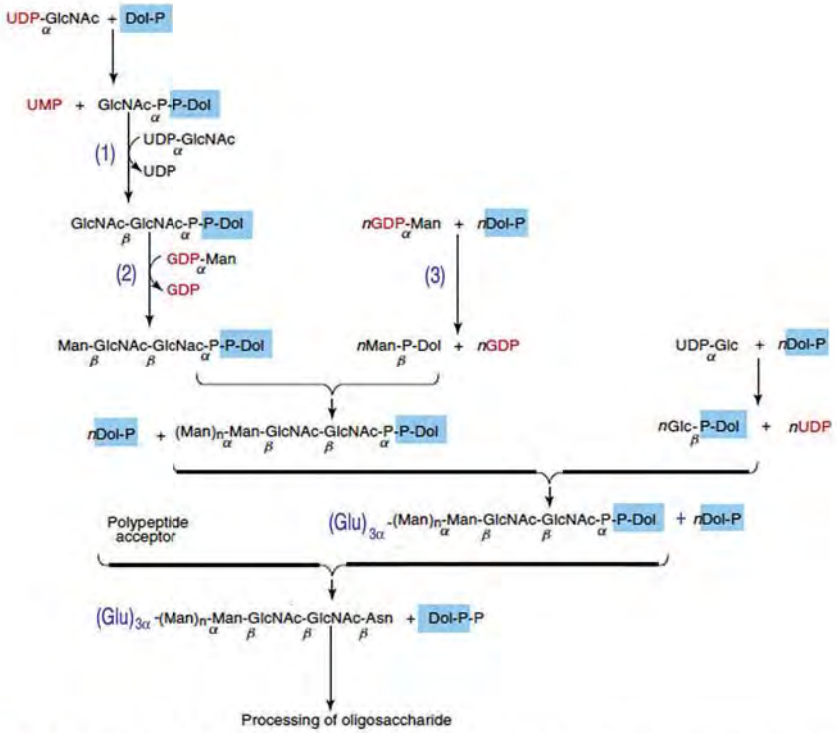


Figure 16.12 Biosynthesis of the oligosaccharide core in asparagine-*N*-acetylglucosamine-linked glycoproteins. Dol, dolichol.

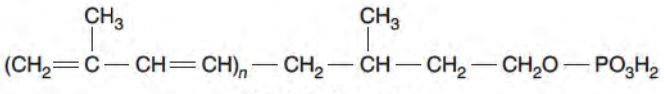
Structural diversity of N-linked glycoproteins arises from assembly and processing of this core to produce a large repertoire of high-mannose, hybrid, or complex *N*-glycan subtypes.

Synthesis of *N*-Linked Glycoproteins Involves Dolichol Phosphate

Whereas synthesis of *O*-glycosidically linked glycoproteins involves sequential action of glycosyltransferases, synthesis of *N*-glycosidically linked glycoproteins involves a different and more complex mechanism (Figure 16.12). A common core is preassembled as a **lipid-linked oligosaccharide** on the cytoplasmic side of the ER and then "flipped" across the bilayer to the lumen of the ER and transferred as a unit to the polypeptide. During synthesis, the oligosaccharide intermediates are bound to **dolichol phosphate**.



Dolichol phosphate

Dolichols are polyprenols (C_{80}–C_{100}) that contain 16–20 isoprene units, in which the final unit is saturated. These lipids function in two ways during oligosaccharide synthesis. The first involves formation of *N*-acetylglucosaminyl pyrophosphoryldolichol from the UDP-linked and dolichol phosphate-linked sugars. The second involves *N*-acetylglucosamine, and the mannose is transferred directly from the nucleotide without formation of intermediates. In either case, the oligosaccharide is transferred in a final step from the dolichol pyrophosphate to an asparagine residue in the polypeptide chain.

After transfer to the polypeptide, the core structures are completed by glycosyltransferases without further participation of lipid intermediates (Figure 16.13). A series of early processing reactions, which are highly conserved among vertebrate species and cell types, occur largely in the ER and appear to be coupled with proper folding of the glycoprotein. Following the initial trimming and release from the ER, *N*-glycans undergo further

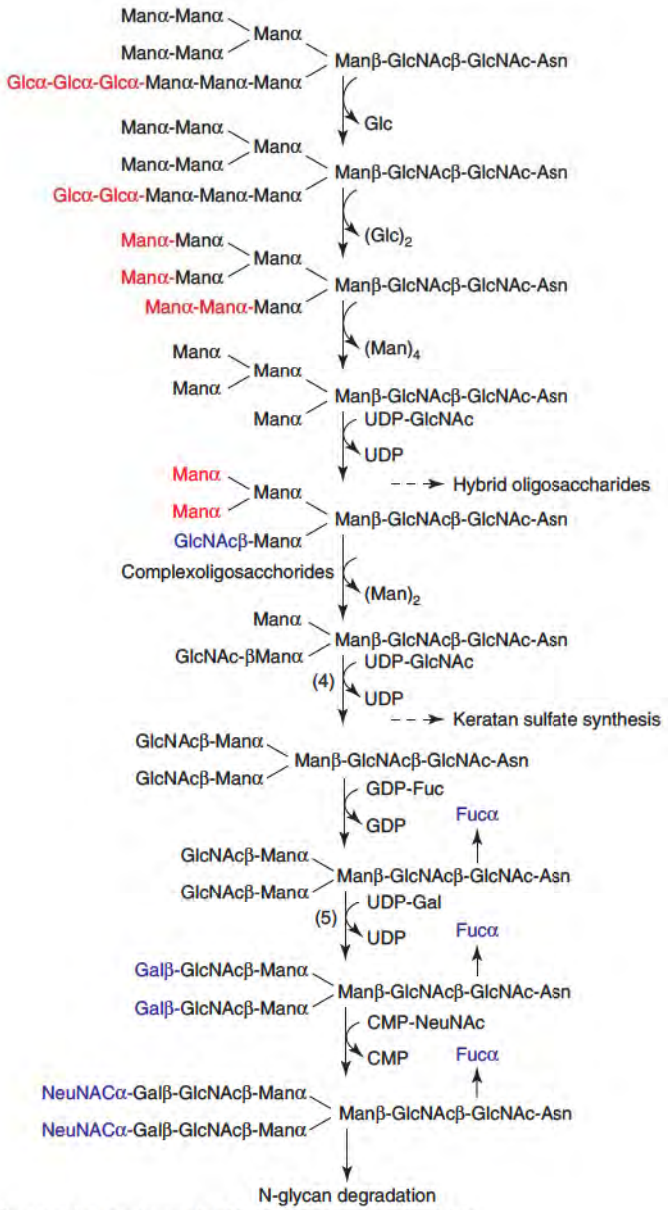


Figure 16.13 Processing pathway for N-linked oligosaccharides.

glycosidase and glycosyltransferase modifications, mostly in the Golgi. Several avenues exist in the processing pathway that determine the final diversity of glycan structure (i.e., high mannose, hybrid or complex subtypes) as well as the trafficking fate of glycoproteins. The Man_8 $GlcNAc_2$-Asn *N*-glycan on glycoproteins destined for the lysosomal compartment is modified by addition of a GlcNAc residue catalyzed by a **GlcNAc-phosphotransferase** and subsequent removal by **GlcNAc phosphodiester glycosidase**, exposing a Man-6-P residue. A defect in this process forms the basis of the **lysosomal storage disease** known as **I-cell disease** (see Clin. Corr. 6.8, p. 238).

As complex oligosaccharide structures require complicated and intricate pathways of synthesis, there has been a rapid expansion in the number of **c**ongenital **d**isorders of **g**lycosylation (**CDG**) identified as genetic diseases resulting from deficient or increased glycosylation. At present, 28 disorders have been identified, including 16 in protein *N*-glycosylation, 6 in protein *O*-glycosylation, 4 in both *O*- and *N*-glycosylation, and 2 in lipid glycosylation. A remarkably wide range of phenotypes, from mild to lethal and from organ-specific to multisystem, have been recorded (Clin. Corr. 16.9).

Catabolism of glycoconjugates may also produce abnormal phenotypes. Degradation of hetero-oligosaccharides is catalyzed by specific glycosidases. Exoglycosidases remove sugars

CLINICAL CORRELATION 16.9

Congenital Disorders of Glycosylation (CDGs)

The congenital disorders of glycosylation (CDGs) are clinically heterogeneous disorders of glycosylation. Using the glycosylation state of serum transferrin as a sensitive indicator, several types of CDGs have been identified. Type I is the most common, representing disorders of *N*-glycan assembly in the early mannose biosynthethic pathway. Numerous defective genes have been identified leading to human genetic disorders (see table). For example, mannosyltransferase I adds the first mannose residue to the lipid-linked oligosaccharide (see Figure 16.12, p. 660). Patients with deficits in this enzyme present with epilepsy, severe psychomotor retardation, dysmorphy, microcephaly, hypotonia, cardiomyop-athy, and nephrotic syndrome followed by early (1 week to 10 months) death. CDG-II disorders involve enzymatic defects in *N*-glycan processing enzymes (see Figure 16.13 and table). Note the carbohydrate transformation enzymes (see Section 16.3, p. 658) CDG-1a (phosphomannomutase II) and CDG-1b (phosphomannose isomerase), which also cause glycosylation disorders. Other disorders may involve defects in *O*-glycosylation, such as Walker–Warburg syndrome, due sometimes to deficiencies of *O*-mannosyltransferase I; combined *N*- and *O*- glycosylation defects, such as CMP-sialic acid transporter deficiency and defects in lipid glycosylation like glycosylphosphatidylinositol deficiency. Little progress in therapy for any of these disorders has been made; only CDG-1b is efficiently treatable.

Enzymic Defects in *N*-linked Glycoprotein Synthesis

Disorder	*Defective protein*
CDG-Ia	Phosphomannomutase II
CDG-Ib	Phosphomannose isomerase

sequentially from the nonreducing end, exposing the substrate for the next glycosidase. Absence of a particular glycosidase causes cessation of catabolism, resulting in accumulation of the proceeding product (Clin. Corr. 16.10). Endoglycosidases with broader specificity also exist, so that catabolism of glycoproteins results from the combined action of endo- and exoglycosidases. Many of the same *N*- or *O*-linked glycan chains are found on both

CLINICAL CORRELATION 16.10

Defects in Catabolism of Glycoproteins

Some human inborn errors of metabolism involve storage of glycolipids, glycopeptides, mucopolysaccharides, and hetero-oligosaccharides. These diseases are caused by defects in lysosomal glycosidase activity, which prevent the catabolism of oligosaccharides. They involve gradual accumulation in tissues and urine of compounds derived from incomplete degradation of the oligosaccharides, and may be accompanied by skeletal abnormalities, hepatosplenomegaly, cataracts or mental retardation. For example, a defect in catabolism of asparagine-*N*-acetylglucosamine-linked oligosaccharides leads to aspartylglycosylaminuria in which a deficiency of 4-L-aspartylglycosylamine amidohydrolase allows accumulation of aspartylglucosamine-linked structures (see table). Other disorders involve accumulation of oligosaccharides derived from both glycoproteins and glycolipids, which share common oligosaccharide structures (see table and Clin. Corr. 16.11).

glycoproteins and glycolipids, hence certain enzyme defects may affect degradation of both types of glycoconjugates (Clin. Corr. 16.11).

Glycan Function

Glycosylation is one of the most common posttranslational modifications and nearly half of all known proteins in eukaryotes are glycosylated. The carbohydrate or **glycan** component of glycoproteins and glycolipids participate in many important biological processes including receptor activation, signal transduction, endocytosis, cell adhesion, and leukocyte trafficking. The cell surface glycans are the first molecules to be encountered and recognized by other cells, antibodies, viruses, and bacteria. For instance, the glycan repertoire provides oncofetal and stem cell biomarkers that reflect the binding specificity of various monoclonal antibodies; one of the barriers to antibody neutralization of HIV is the array of protective carbohydrates that cover the antigens on the virus surface. Although the diversity of glycan structures is large, specificity is provided by the glycosylation enzymes, glycosyltransferases and glycosidases. Thus, regulation of the biosynthetic processes of these abundant and diverse biopolymers direct the molecular mechanisms by which glycans contribute to development and disease.

CLINICAL CORRELATION 16.11

Glycolipid Disorders

A host of human genetic diseases arise from deficiencies in hydrolases which act predominantly on glycolipid substrates, resulting in accumulation of glycolipid and ganglioside products. The clinical symptoms associated with each of the glycoconjugates may vary greatly. However, because of the preponderance of lipids in the nervous system, such disorders often have associated neurodegeneration and severe mental and motor deterioration.

16.5 • PROTEOGLYCANS

Proteoglycans are complex macromolecules that may be composed of 95% or more carbohydrate, resembling polysaccharides more than proteins. Their carbohydrate chains are called **glycosaminoglycans** (or **mucopolysaccharides**) especially in reference to the storage diseases, the **mucopolysaccharidoses**, which result from an inability to degrade these molecules (see Clin. Corr. 16.14, p. 668).

There Are Six Classes of Proteoglycans

Proteoglycans consist of one or more of many different glycosaminoglycan chains linked covalently to a protein core. Six distinct classes are recognized: **chondroitin sulfate**, **dermatan sulfate**, **keratan sulfate**, **heparan sulfate**, **heparin**, and **hyaluronate**. Certain features are common to the different classes of glycosaminoglycans. These long, unbranched heteropolysaccharide chains are made up largely of disaccharide repeating units, consisting of a hexosamine and a uronic acid. Common substituents of glycosaminoglycans are sulfate groups, linked by ester bonds to certain monosaccharides or by amide bonds to the amino group of glucosamine. Only hyaluronate is not sulfated and is not covalently attached to protein. The carboxyls of uronic acids and the sulfate groups contribute to the highly charged nature of glycosaminoglycans. Their electrical charge and their macromolecular structure are important in their roles as lubricants and support elements in connective tissue. Glycosaminoglycans of proteoglycans are predominantly components of the extracellular matrices and cell surfaces where they participate in cell adhesion and signaling.

Hyaluronate Is a Copolymer of *N*-Acetylglucosamine and Glucuronic Acid

Hyaluronate differs from the other types of glycosaminoglycans. It is unsulfated, not covalently linked with protein, and produced by bacteria as well as animal cells. It is classified as a glycosaminoglycan because of its structural similarity to these polymers, consisting solely of repeating disaccharide units of *N*-acetylglucosamine and glucuronic acid (Figure 16.14). Although it has the least complex chemical structure of the glycosaminoglycans, the chains may reach 10^5–10^7 Da. The large mass, polyelectrolyte character, and large volume it occupies in solution contribute to the properties of hyaluronate as a lubricant and shock absorbent. It is ubiquitous in the extracellular matrix and found in synovial fluid, vitreous humor, and umbilical cord.

Chondroitin Sulfates Are the Most Abundant Glycosaminoglycans

The **chondroitin sulfates** are attached to specific serine residues in a protein core through a tetrasaccharide linkage module.

$$\text{GluUA} \xrightarrow[1\to3]{} \text{Gal} \xrightarrow[1\to3]{} \text{Gla} \xrightarrow[1\to4]{} \text{Xyl} \longrightarrow \textit{O}\text{-Ser}$$

Each chain contains 30 to 50 disaccharide units (15–25 kDa), consisting of *N*-acetylgalactosamine and glucuronic acid, which are attached to the linkage module (Figure 16.14). The disaccharides can be sulfated at the C4 or C6 position of *N*-acetylgalactosamine. An average chondroitin sulfate proteoglycan molecule contains about 100 chondroitin sulfate chains attached to the protein core, giving a mass of $1.5–2 \times 10^6$ Da. Proteoglycan preparations are extremely heterogeneous, differing in number and distribution of polysaccharide chains, length of chondroitin sulfate chains, and degree of sulfation. Chondroitin sulfate proteoglycans may aggregate noncovalently with hyaluronate and are prominent components of cartilage, tendons, ligaments, and aorta, as well as brain, kidney, and lung.

Dermatan Sulfate Contains L-Iduronic Acid

Dermatan sulfate differs from chondroitin sulfate in that its predominant uronic acid is L-iduronic acid, although some D-glucuronic acid is also present. The epimerization of D-glucuronic acid to L-iduronic acid occurs after incorporation into the polymer chain and is coupled with the process of sulfation. The glycosidic linkages have the same position and configuration as in chondroitin sulfates, with average polysaccharide chains of $2–5 \times 10^4$ Da. Like heparin,

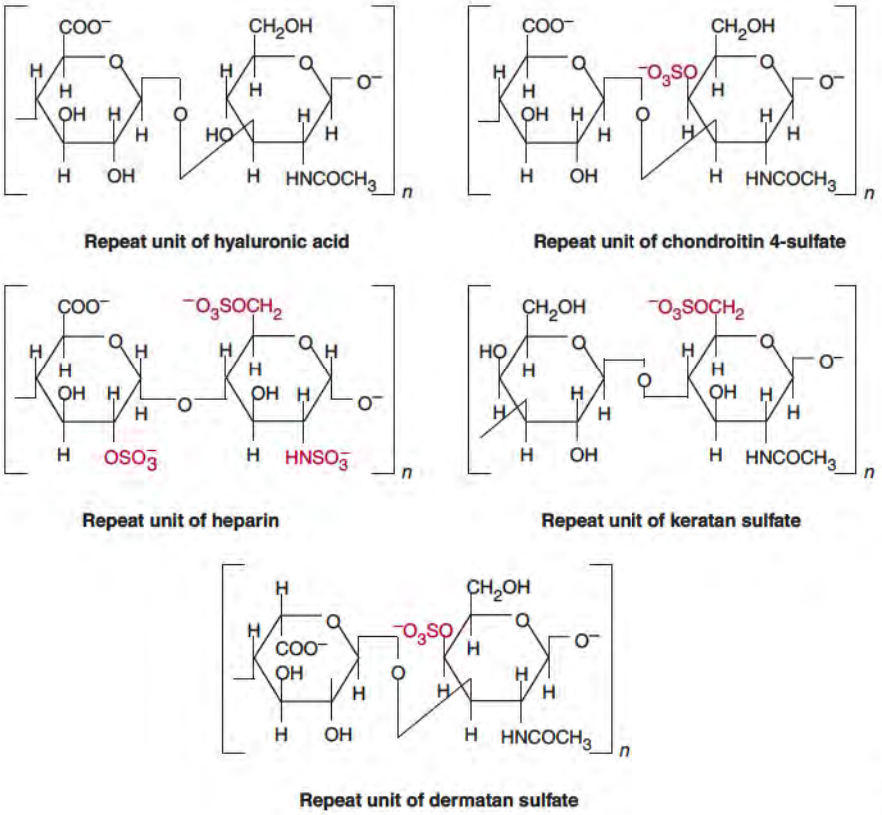

Figure 16.14 Major repeat units of glycosaminoglycan chains.

dermatan sulfate is antithrombic but has only minimal whole-blood anticoagulant and blood lipid-clearing activities. Dermatan sulfate is found in skin, blood vessels, and heart valves.

Heparin and Heparan Sulfate Differ from Other Glycosaminoglycans

Glucosamine and D-glucuronic acid or L-iduronic acid form the characteristic disaccharide repeat unit in **heparin** (Figure 16.14). In contrast to most other glycosaminoglycans, heparin contains β-glycosidic linkages. Almost all glucosamine residues contain sulfamide linkages, while a small number of glucosamine residues are *N*-acetylated. The sulfate content of heparin approaches 2.5 sulfate residues per disaccharide unit in preparations with the highest biological activity. In addition to *N*-sulfate and *O*-sulfate on C6 of glucosamine, heparin may contain sulfate on C3 of the hexosamine and C2 of the uronic acid. Unlike other glycosaminoglycans, heparin is an intracellular component of mast cells, and functions predominantly as an anticoagulant and lipid-clearing agent (Clin. Corr. 16.12).

Heparan sulfate contains a similar disaccharide repeat unit as heparin but has more *N*-acetyl groups, fewer *N*-sulfate groups, and a lower content of *O*-sulfate groups. Heparan sulfate as a component of proteoglycans may be extracellular or an integral and ubiquitous component of the cell surface in many tissues including blood vessel walls and brain, and may function as a coreceptor for certain growth factors.

Keratan Sulfate Exists in Two Forms

Keratan sulfate is composed principally of the disaccharide unit of *N*-acetylglucosamine and galactose, and contains no uronic acid (Figure 16.14). Sulfate content is variable, as ester sulfate on C6 of galactose and hexosamine. Two types of keratan sulfate differ in carbohydrate content and tissue distribution. Both also contain mannose, fucose, sialic acid, and *N*-acetylgalactosamine. Keratan sulfate I, from cornea, is linked to protein by an *N*-acetylglucosamine-asparaginyl bond, typical of glycoproteins. Keratan sulfate II, from cartilage, is linked through *N*-acetylgalactosamine to serine or threonine. Skeletal

CLINICAL CORRELATION 16.12

Heparin Is an Anticoagulant

Heparin is a naturally occurring sulfated glycosaminoglycan that is used to reduce the clotting tendency of patients. Both *in vivo* and *in vitro*, heparin prevents the activation of clotting factors by binding with an inhibitor of the coagulation process. The inhibitor is antithrombin III, a plasma protein inhibitor of serine proteases. In the absence of heparin, antithrombin III slowly (10–30 min) combines with several clotting factors, yielding complexes devoid of proteolytic activity; in the presence of heparin, inactive complexes are formed within a few seconds. Antithrombin III contains an arginine residue that combines with the active site serine of factors Xa and IXa; thus, the inhibition is stoichiometric. Heterozygous antithrombin III deficiency results in increased risk of thrombosis in the veins and resistance to the action of heparin.

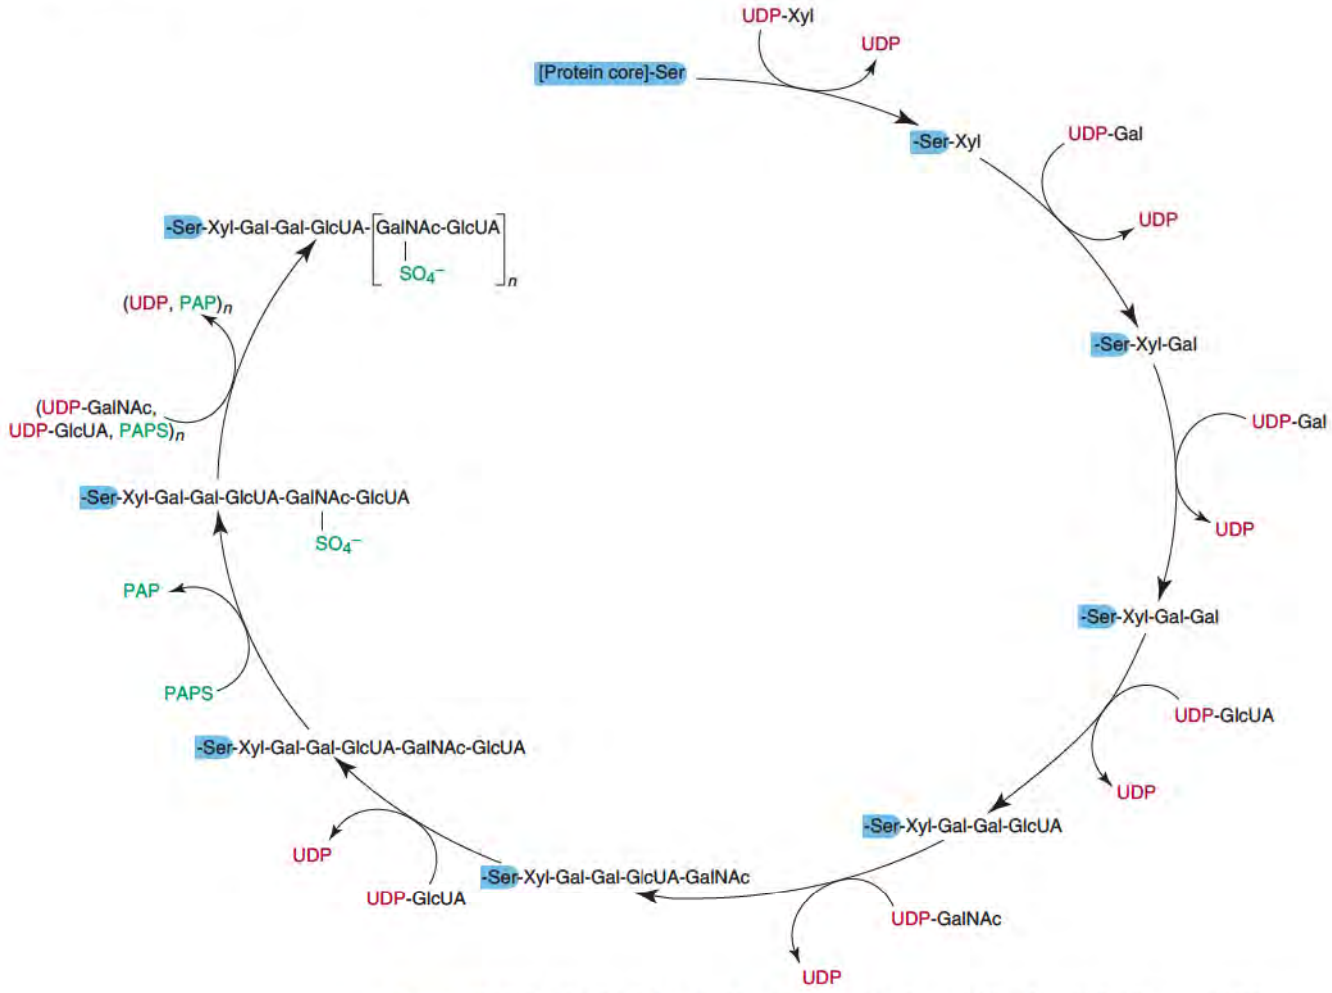

Figure 16.15 Synthesis of chondroitin sulfate proteoglycan. Xyl, xylose; Gal, galactose; GlcUA, glucuronic acid; GalNAc, *N*-acetylgalactosamine; PAPS, phosphoadenosine phosphosulfate.

keratan sulfates are often covalently attached to the same core protein as the chondroitin sulfate chains.

Biosynthesis of Chondroitin Sulfate Is Typical of Glycosaminoglycan Formation

The glycosaminoglycans are assembled by sequential action of glycosyltransferases, which transfer a monosaccharide from a nucleotide-linked derivative to an appropriate acceptor, either the nonreducing end of another sugar or a polypeptide. The biosynthesis of the chondroitin sulfates is most thoroughly understood (Figure 16.15).

Formation of the core protein is the first step, followed by the action of six glycosyltransferase reactions. Strict substrate specificity is required for completion of the unique tetrasaccharide linkage region. Polymerization then results from repeated *N*-acetylgalactosaminyltransferase and glucuronosyltransferase reactions to form the characteristic disaccharide units. Sulfation of *N*-acetylgalactosamine at the C4 or C6 position occurs with chain elongation. The sulfate donor, as in other biological systems, is **3′-phosphoadenosine 5′-phosphosulfate (PAPS)**, which is formed from ATP and sulfate in two steps catalyzed by the bifunctional PAPS synthetase (Figure 16.16). The importance of sulfation is highlighted by the preponderance of chondrodystrophic conditions in animals and humans caused by deficiencies in the sulfation process (Clin. Corr. 16.13).

Synthesis of other glycosaminoglycans requires additional transferase reactions specific for the appropriate sugars and linkages. Completion often involves *O*-sulfation,

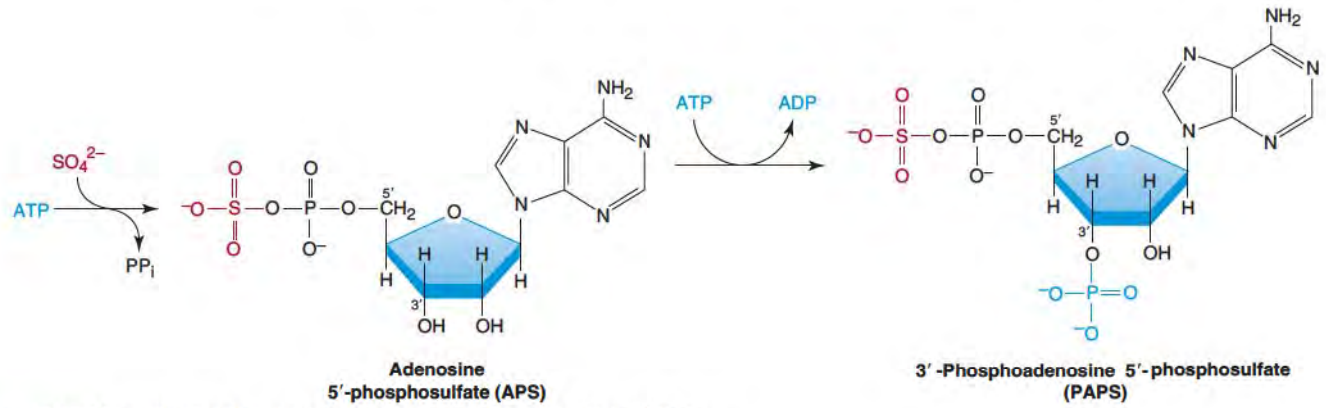

Figure 16.16 Biosynthesis of 3′-phosphoadenosine 5′-phosphosulfate (PAPS).

epimerization, acetylation, or *N*-sulfation. Synthesis of both proteoglycans and glycoproteins is regulated by the same mechanism at the level of hexosamine synthesis. The fructose 6-phosphate-glutamine transamidase reaction (see Figure 16.4, p. 652) is subject to feedback inhibition by UDP-*N*-acetylglucosamine, which is in equilibrium with UDP-*N*-acetylgalactosamine. Similarly, the concentrations of UDP-xylose and UDP-glucuronic acid are stringently controlled by UDP-xylose inhibition of the UDP-glucose dehydrogenase-catalyzed conversion of UDP-glucose to UDP-glucuronic acid (see Figure 16.4). Since xylose is the first sugar added during synthesis of chondroitin sulfate, dermatan sulfate, heparin, and heparan sulfate, the earliest effect of decreased core protein synthesis would be accumulation of UDP-xylose, which aids in maintaining a balance between synthesis of protein and glycosaminoglycans.

Proteoglycans, like glycoproteins and glycolipids are degraded by the sequential action of proteases and glycosidases, **deacetylases** and **sulfatases**. Much of the information about metabolism and degradation of proteoglycans has been derived from the study of the **mucopolysaccharidoses** (Clin. Corr. 16.14). These genetic disorders are characterized by accumulation in tissues and excretion in urine of hetero-oligosaccharide products derived from incomplete breakdown of proteoglycans, due to a deficiency of one or more **lysosomal hydrolases**.

Although proteoglycans continue to be defined on the basis of the glycosaminoglycan chains they contain, new ones have been described largely on the basis of functional proper-

CLINICAL CORRELATION 16.13

Chondrodystrophies due to Sulfation Defects

Sulfation is an essential modification of glycosaminoglycans in the various proteoglycan families. The sulfation process involves transport of inorganic sulfate into the cell via plasma membrane transporters, activation by transformation into phosphoadenosylphosphosulfate (PAPS) via a two-step process catalyzed by PAPS synthetase in the cytosol, then either direct utilization by cytosolic sulfotransferases or transport of PAPS from the cytosol to the Golgi complex for utilization by a host of lumenal sulfotransferases. Three autosomal recessive disorders, diastrophic dysplasia (DTD), atelosteogenesis type II (AOII), and achondrogenesis type 1B (ACG-1B), result from mutations in the DTDST gene which encodes a sulfate transporter. Patients with DTD exhibit disproportionate short stature and generalized joint dysplasia, but usually have a normal lifespan; ACG-1B is characterized by extremely short extremities and trunk; AOII is a perinatally lethal chondrodysplasia. Genetic disorders due to defects in synthesis of PAPS by the bifunctional sulfurylase/kinase (PAPS synthetase) have been identified in both animals and humans. The brachymorphic mouse exhibits a severe growth disorder resulting in extremely short trunk and limbs and small skull. In humans, spondyloepimetaphyseal dysplasia (Pakistani type) is characterized by short and bowed lower limbs, enlarged knee joints, and early onset of degenerative joint disease. These phenotypes clearly highlight the importance of this posttranslational modification to the functioning of proteoglycans, especially in development and maintenance of the skeletal system.

CLINICAL CORRELATION 16.14

Mucopolysaccharidoses

Human genetic disorders characterized by excessive accumulation and excretion of the oligosaccharides of proteoglycans comprise the mucopolysaccharidoses. They result from deficiency of one or more lysosomal hydrolases that are responsible for the degradation of dermatan and/or heparan sulfate. Hurler syndrome and Sanfilippo syndrome are autosomal recessive conditions, whereas Hunter disease is X-linked. Both Hurler and Hunter syndromes are characterized by skeletal abnormalities and mental retardation, which in severe cases may result in early death. In contrast, the physical defects in the Sanfilippo syndrome are relatively mild, whereas the mental retardation is severe. Collectively, the incidence of the mucopolysaccharidoses is 1 per 30,000 births. Multiple sulfatase deficiency (MSD) is characterized by decreased activity of all known sulfatases. Recent evidence suggests that a co- or postranslational modification of a cysteine to 2-amino 3-oxopropionic acid is essential for sulfatase activity, and that a lack of this modification results in MSD. These disorders are amenable to prenatal diagnosis, since the pattern of metabolism exhibited by affected cells obtained from amniotic fluid is strikingly different from normal.

Enzyme Defects in the Mucopolysaccharidoses

Syndrome	*Accumulated Products*[a]	*Deficient Enzyme*[b]
Hunter	Heparan sulfate Dermatan sulfate	Iduronate sulfatase (1)
Hurler—Scheie	Heparan sulfate Dermatan sulfate	α-L-Iduronidase (2)
Maroteaux—Lamy	Dermatan sulfate	*N*-Acetylgalactosamine sulfatase (3)
Mucolipidosis VII	Heparan sulfate Dermatan sulfate	β-Glucuronidase (4)
Sanfilippo type A	Heparan sulfate	Heparan sulfamidase (6)
Sanfilippo type B	Heparan sulfate	*N*-Acetylglucosaminidase (9)

ties or location. **Aggrecan** and **versican** are the predominant extracellular species; **syndecan**, **CD44**, and **thrombomodulin** are integral membrane proteins; **neurocan**, **brevican**, **cerebrocan,** and **phosphacan** are largely restricted to the nervous system. Many proteoglycans (i.e., aggrecan, **syndecan**, and **betaglycan**) carry more than one type of glycosaminoglycan chain, and their sizes and relative amounts may change with development, age, or disease. Many genes encoding the proteoglycan core proteins and biosynthetic enzymes have been cloned, revealing that the relevant proteins belong to families of related origin and possible function.

glucose-6-phosphate dehydrogenase
dehydrogenation
NADPH
pyrophosphorylase
decarboxylation
dolichol phosphate
glycosyl transferase
oxidation
sialic acid
glycosidase
reduction
ribulose-5-phosphate
glycoprotein
transamidation
glucuronic acid
glycosamine glycan
glycosylation
chondroitin sulfate
proteoglycan
epimerization
dermatan sulfate
oligosaccharide
heparan sulfate
nucleotide sugar
heparin
carbohydrate
hyaluronate
mucopolysaccharide
aggrecan

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. All of the following interconversions of monosaccharides (or derivatives) require a nucleotide linked sugar intermediate except
- **A.** galactose 1-phosphate to glucose 1-phosphate.
- **B.** glucose 6-phosphate to mannose 6-phosphate.
- **C.** glucose to glucuronic acid.
- **D.** glucuronic acid to xylose.
- **E.** glucosamine 6-phosphate to *N*-acetylneuraminic acid (a sialic acid).

2. All of the following are true about glucuronic acid except
- **A.** it is a charged molecule at physiological pH.
- **B.** as a UDP derivative, it can be decarboxylated to a component used in proteoglycan synthesis.
- **C.** it is a precursor of ascorbic acid in humans.
- **D.** its formation from glucose is under feedback control by a UDP-linked intermediate.
- **E.** it can ultimately be converted to xylulose 5-phosphate and thus enter the pentose phosphate pathway.

3. NADPH/$NADP^+$ is maintained at a high level in cells primarily by
- **A.** lactate dehydrogenase.
- **B.** the combined actions of glucose 6-phosphate dehydrogenase and gluconolactonase.
- **C.** the action of the electron transport chain.
- **D.** exchange with NAD^+/NADH.
- **E.** the combined actions of transketolase and transaldolase.

4. Fucose and sialic acid
- **A.** are both derivatives of UDP-*N*-acetylglucosamine.
- **B.** are the parts of the carbohydrate chain that are covalently linked to the protein.
- **C.** can be found in the core structure of certain O-linked glycoproteins.
- **D.** are transferred to a carbohydrate chain when it is attached to dolichol phosphate.
- **E.** are the repeating unit of proteoglycans.

5. Glycosaminoglycans
- **A.** are the carbohydrate portion of glycoproteins.
- **B.** contain large segments of a repeating unit typically consisting of a hexosamine and a uronic acid.
- **C.** always contain sulfate.
- **D.** exist in only two forms.
- **E.** are bound to protein by ionic interaction.

6. All of the following are true of proteoglycans except
- **A.** specificity is determined, in part, by the action of glycosyltransferases.
- **B.** synthesis is regulated, in part, by UDP-xylose inhibition of the conversion of UDP-glucose to UDP-glucuronic acid.
- **C.** synthesis involves sulfation of carbohydrate residues by PAPS.
- **D.** synthesis of core protein is balanced with synthesis of the polysaccharide moieties.
- **E.** degradation is catalyzed in the cytosol by nonspecific glycosidases.

Questions 7 and 8: Galactosemia is an inability to transform galactose into glucose and can lead to such problems as cataract formation, growth failure, mental retardation, or eventual death from liver damage. Galactose is reduced to galactitol, which initiates cataract formation. Accumulation of galactose 1-phosphate, the most serious condition, leads to liver failure.

7. The most severe form of galactosemia
- **A.** is a genetic deficiency of a uridylyltransferase that exchanges galactose 1-phosphate for glucose on UDP-glucose.
- **B.** results from a deficiency of an epimerase.
- **C.** is insignificant in infants but a major problem in later life.
- **D.** is a defect in galactokinase.
- **E.** would be expected to interfere with the use of fructose as well as galactose because the deficient enzyme is common to the metabolism of both sugars.

8. UDP-galactose
- **A.** must be formed from galactose 1-phosphate.
- **B.** is usually the first sugar linked to dolichol phosphate.
- **C.** is used in the synthesis of chondroitin sulfate.
- **D.** could not lead to the formation of sugar derivatives like glucuronic acid or xylose.
- **E.** is the direct precursor of *N*-acetylgalactosamine.

Questions 9 and 10: A 6 month old infant presented with hypoglycemia, vomiting, diarrhea, protein-loss enteropathy, and hepatic fibrosis. Measurement of the glycosylation state of endogenous serum transferrin revealed Type Ib CDG (congenital disorders of glycosylation), which is a defect in phosphomannose isomerase activity.

9. The role of phosphomannose isomerase is the interconversion of
- **A.** mannose 6-phosphate and mannose 1-phosphate.
- **B.** glucose 6-phosphate and mannose 6-phosphate.
- **C.** fructose 6-phosphate and mannose 6-phosphate.
- **D.** fructose 1-phosphate and mannose 1-phosphate.
- **E.** glucose 6-phosphate and mannose 1-phosphate.

10. In Type Ic CDG, a defect in an enzyme transferring a glucosyl residue to a high-mannose dolichol pyrophosphate precursor, the carbohydrate structure would be part of a(n)
- **A.** *N*-linked glycoprotein.
- **B.** *O*-linked glycoprotein.
- **C.** proteoglycan.
- **D.** glycosaminoglycan.
- **E.** complex lipid.

Questions 11 and 12: An infant presented with multiple skeletal abnormalities, with the most prominent ones being a short trunk and short limbs. Urine was free of partially degraded oligosaccharides or oligosaccharides of proteoglycans. The blood sulfate concentration and extracellular acid hydrolase activity were normal.

11. The disorder described would most likely be caused by a defect in
- **A.** the ability to generate mannose 6-phosphate.
- **B.** lysosomal glycosidase activity.
- **C.** the gene that codes for a sulfate transporter.
- **D.** PAPS synthetase.
- **E.** a sulfatase.

12. Sulfation is an important component of the synthesis of
- **A.** most proteoglycans.
- **B.** hyaluronate.
- **C.** most glycoproteins.
- **D.** conjugated bilirubin.
- **E.** all of the above.

Problems

13. What is the role of transaldolase and transketolase in the metabolism of glucose?

14. Essential fructosuria is a defect in fructokinase whereas fructose intolerance is a defect in fructose 1-phosphate aldolase. Which of these two diseases leads to severe hypoglycemia after ingestion of fructose, and why?

Answers

1. B The glucose and mannose phosphates are both in equilibrium with fructose 6-phosphate by phosphohexose isomerases. A: Occurs via an epimerase at the UDP-galactose level. C and D: This oxidation of glucose is catalyzed by UDP-glucose dehydrogenase and the product can be decarboxylated to UDP-xylose. E: Again, an epimerization occurs on the nucleotide intermediate.

2. C Man does not make ascorbic acid. A: The charged acid group enhances water solubility, which is a major physiological role for glucuronic acid, for example, bilirubin metabolism. B and D: Decarboxylation of UDP-glucuronic acid gives UDP-xylose, which is a potent inhibitor of the oxidation of UDP-glucose to the acid. E: The reduction of *d*-glucuronic acid to *l*-gulonic acid leads to ascorbate as well as xylulose 5-phosphate for the pentose phosphate pathway.

3. B Although the glucose 6-phosphate dehydrogenase reaction, specific for NADP, is reversible, hydrolysis of the lactone assures that the overall equilibrium lies far in the direction of NADPH. A and C: These use NAD, not NADP. D: This does not occur. E: These enzymes are part of the pentose phosphate pathway but do not use NADP.

4. C Core structure also contains galactose and *N*-acetylgalactosamine. A: Only sialic acid does. Fucose comes from CDP-mannose. B: Usually found at the periphery of the carbohydrate. D: Core structure of *N*-linked carbohydrates contains mannose and *N*-acetylglucosamine. E: Repeating unit is hexosamine and uronic acids.

5. B This is a major distinction from glycoproteins, which, by definition, do not have a serial repeating unit. A: These are the carbohydrate of proteoglycans. C: Most do, but hyaluronate does not. D: There are at least six different classes. E: Carbohydrates are bound by covalent links.

6. E Degradation is lysosomal; deficiencies of one or more lysosomal hydrolases lead to accumulation of proteoglycans in the mucopolysaccharidoses. A: Strict substrate specificity of the enzymes is important in determining the type and quantity of proteoglycans synthesized. Formation of specific protein acceptors for the carbohydrate is also important. B and D: Both xylose and glucuronic acid levels are controlled by this; xylose is the first sugar added in the synthesis of four of the six types and would accumulate if core protein synthesis were decreased. C: This is necessary for the formation of most proteoglycans.

7. A B: The epimerase is normal. C: Galactose is an important sugar for infants. D: In this disease, the galactokinase is normal but is deficient

in the mild form of the disease. E: Fructose metabolism does not use the uridylyltransferase that is deficient in galactosemia.

8. **C** The initial carbohydrate chain built on the serine –OH group contains two galactoses plus an *N*-acetylgalactosamine, supplied as the UDP-derivatives. A: It can also be formed by epimerization of UDP-glucose. B: This is an *N*-acetylglucosamine. D: Since it can be epimerized to UDP-glucose, it can lead to these products. E: This is one of the more complex interconversions that proceeds through nucleotide-bound derivatives of glucose and rhamnose.
9. **C** This is similar to the glucose 6-phosphate-fructose 6-phosphate interconversion. A: Mutases catalyze a 1-6 phosphate shift. B, D, and E: These conversions do not occur directly.
10. **A** A carbohydrate chain assembled on dolichol phosphate is characteristic of N-linked glycoproteins. B, C, and D: Synthesis of O-linked glycoproteins involves the sequential addition to the *N*-acetylgalactosamine linked to serine or threonine. E: Dolichol phosphate is a lipid but is eliminated when the carbohydrate chain is added to the protein.
11. **D** These structural abnormalities are associated with defects in sulfation of the proteoglycans. A: This would lead to an inability to target acid hydrolase to the lysosome and thus increase the extracellular concentration. B and E: These are lysosomal enzymes whose deficiency would lead to partially degraded oligosaccharides in urine. C: Lack of a transporter would lead to elevated serum levels of sulfate.
12. **A** B: Hyaluronate is one glycosaminoglycan which is not sulfated. C: Glycoproteins don't contain sulfate. D: Bilirubin is conjugated with glucuronic acid.
13. 3 Pentose phosphates (ribose 5-phosphatehosphate + 2 xylulose 5-phosphate) are converted to 2 fructose 6-phosphate and glyceraldehyde 3-phosphate by transaldolase and transketolase via a series of 2-carbon and 3-carbon transfers. These reactions are reversible.
14. Lack of fructokinase causes accumulation of fructose which is excreted. Lack of the aldolase results in increased fructose 1-phosphate, which sequesters cellular inorganic phosphate, inhibiting the cells ability to generate ATP.

Key Concepts

- Triacylglycerols are hydrophobic molecules that are the major fuel store in all organisms. In mammals, most triacylglycerol is found in adipose tissue.
- There is net deposition of fat as triacylglycerol in adipose tissue in the fed state, whereas adipose tissue breaks down the triacylglycerol to provide fuel for other tissues during fasting.
- Fatty acids are synthesized mainly in the liver by the sequential addition of two-carbon units, using acetyl CoA derived from dietary glucose and other fuels.
- Fatty acids can be modified by chain elongation and the addition of double bonds to produce a family of molecules. In mammals, some polyunsaturated fatty acids can be made only from essential fatty acid precursors in the diet.
- Most tissues can assemble triacylglycerols from acyl CoAs and glycerol 3-phosphate.
- Fatty acids are converted to acetyl CoA by β-oxidation and then used as fuel in many tissues.
- During prolonged fasting, the ketone bodies, acetoacetate and β-hydroxybutyrate are synthesized from acetyl CoA in the liver. The use of ketone bodies as fuel by the brain and other tissues is an important adaptation to prolonged fasting.
- The synthesis and breakdown of fatty acids is regulated to promote energy storage in the fed state and energy mobilization in the fasted state. In addition, the mobilization of fatty acids from stored triacylglycerol is regulated to meet cellular energy needs.

17.1 • INTRODUCTION

Lipids are **hydrophobic** molecules, meaning that they are not soluble in water and tend to self-associate in separate lipid phases. Most lipids contain or are derived from **fatty acids** (Figure 17.1). Lipids have many important biological functions. **Triacylglycerols** (Figure 17.2) are the major fuel store in the body. Other lipids, including **phospholipids**, **glycolipids**, and **cholesterol**, are crucial constituents of biological membranes; the unique surface active properties of these molecules allow them to form the membrane backbone, separating and defining aqueous compartments within cells. Surface active lipids have other important functions, including maintenance of alveolar integrity in the lungs and solubilization of nonpolar substances in body fluids. Finally, some lipids are important signaling molecules. Fatty acids, **steroid hormones**, and the **eicosanoids**, including **prostaglandins**, are important in communication between cells. Other lipids have signaling functions within cells.

The metabolism of fatty acids and triacylglycerols is so important that imbalances and deficiencies in these processes can have serious pathological consequences in humans. Disease states related to dysfunctions in lipid metabolism include obesity, diabetes mellitus, hypertrigclyceridemia, and ketoacidosis. There are also human genetic diseases that affect fatty acid metabolism, including Refsum disease and deficiencies in carnitine and in fatty acid oxidation.

The Appendix describes the nomenclature and chemistry of lipids, and a discussion of the digestion and absorption of fats is presented in Chapter 25.

17.2 • CHEMICAL NATURE OF FATTY ACIDS AND ACYLGLYCEROLS

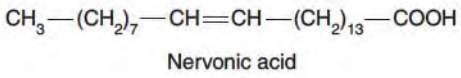
Fatty Acids Are Alkyl Chains Terminating in a Carboxyl Group

Fatty acids (see Figure 17.1) consist of an **alkyl chain** with a terminal carboxyl group. The basic formula of a completely saturated species is $CH_3(CH_2)_nCOOH$. Nearly all fatty acids in humans have an even number of carbon atoms, although some organisms synthesize molecules with an odd number. Humans can use the latter for energy, but they are marginally incorporated into complex lipids. Unsaturated fatty acids occur commonly, with up to six double bonds per chain. If there is more than one double bond per molecule, they are separated by a **methylene** (—CH_2—) **group**. The double bonds are almost always in the cis configuration, which induces a kink in the fatty acid chain, preventing orderly packing of the chains in lipid phases. By inducing disorder, double bonds lower the melting temperature and increase the fluidity of the phases.

Most fatty acids in humans have 16–20 carbon atoms, but C_{14} molecules are found linked to proteins and very long fatty acids are found in complex lipids in the nervous system.

These include nervonic acid (22:1) and docosahexaenoic acid, a C_{22} acid that has six double bonds (Figure 17.3). Some fatty acids with an α-OH group are found as constituents of membrane lipids. **Branched-chain fatty acids**, which have methyl groups at one or more positions along the chain, are also found in some animals, including humans. These contribute specific physical properties to some secretory and structural molecules. For instance, large amounts of branched-chain fatty acids, particularly isovaleric acid (Figure 17.4), occur in lipids of echo-locating structures in marine mammals.

The most abundant fatty acids in humans are shown in Table 17.1. The symbols show the number of carbon atoms and, after the colon, the number of double bonds. Carbon atoms are numbered starting with the carboxyl carbon. The bond locations are shown in parentheses, using the number of the carbon atom on the carboxyl side of the bond.



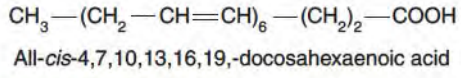


Figure 17.3 Very long-chain fatty acids.

Most Fatty Acids in Humans Occur as Triacylglycerols

Fatty acids are stored primarily as esters of glycerol (Figures 17.2 and 17.5). Most fatty acids in humans are found in **triacylglycerols**, in which all three hydroxyl groups of glycerol are esterified with fatty acids. Compounds with one (**monoacylglycerols**) or two (**diacylglycerols**) esterified fatty acids occur in relatively minor amounts, largely as metabolic intermediates in the synthesis and degradation of glycerol-containing lipids. The trivial names, mono-, di- and triglycerides, are also used for these compounds.

Most triacylglycerols have different fatty acids esterified to the three positions of glycerol. The distribution of fatty acids is influenced by many factors, including diet

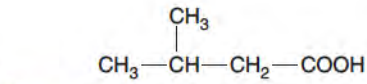

Figure 17.4 Isovaleric acid.

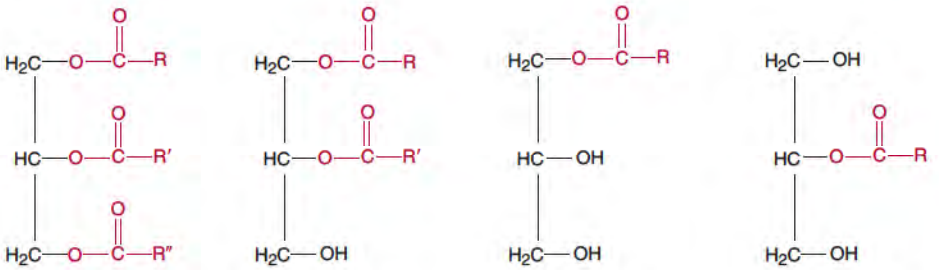

Figure 17.5 Acylglycerols.

TABLE 17.1 • Fatty Acids of Importance to Humans

Name	*Numerical Formula*	*Functions in Humans*
Formic acid	1	
Acetic acid	2:0	
Propionic acid	3:0	Produced by metabolism of odd-chain fatty acids as well as isoleucine, valine, and methionine
Butyric acid	4:0	Milk triacylglycerols contain short chain fatty acids
Myristic acid	14:0	Covalently linked to some proteins
Palmitic acid	16:0	Product of fatty acid synthase
Palmitoleic acid	16:1(9)	Fatty acids with 16–18 carbons comprise the bulk of the fatty acids in triacylglycerols and complex lipids
Stearic acid	18:0	
Oleic acid	18:1(9)	
Linoleic acid	18:2(9, 12)	Essential fatty acid
Linolenic acid	18:3(9, 12, 15)	Essential fatty acid
Arachidonic acid	20:4(5, 8, 11, 14)	Precursor of prostaglandins and other eicosanoids
Lignoceric acid	24:0	
Nervonic acid	24:1(15)	Enriched in sphingolipids

CLINICAL CORRELATION 17.1

Obesity

Obesity has become a worldwide epidemic. It has been estimated that in 2004, 25% of the population in the United States was obese, a figure that is projected to increase to 40% by 2020. Equally distressing figures have been noted for countries with rapidly growing economies such as China and India. The definition of obesity is arbitrary and is based on estimates of ideal body weight (IBW), that is, body weight that is associated with the lowest morbidity and mortality. Overweight is defined as weight up to 20% above IBW, and obesity is weight that is 20% (or greater) above IBW. Body Mass Index (BMI) is another commonly used measure of obesity. It is calculated by dividing weight (in kilograms) by height^2 (in meters squared). An individual with a BMI of 25 or greater is overweight, and of 30 or greater is considered obese. The anatomical location of fat deposition is a good indicator of the risk of morbidity and mortality from obesity; a central distribution of body fat (abdominal adipose tissue) is a greater health risk than a more peripheral distribution of fat (subcutaneous adipose tissue).

Obesity is part of what has been termed Metabolic Syndrome, a collection of symptoms that include central obesity, high blood pressure, high triacylglycerols and low levels of high density lipoprotein in the blood, as well as insulin resistance. As many as 47 million Americans have this syndrome. Individuals with Metabolic Syndrome are at high risk for diabetes and cardiovascular disease. The biochemical link between obesity and diabetes is discussed in Clin. Corr. 17.2. Because of these health risks, the control of obesity is a major public health goal.

The causes of obesity and the underlying reasons for its dramatic increase in human populations are complex. Endocrine disorders such as hypothyroidism or Cushing disease (an overproduction of corticosteroids) are rare, as are mutations in genes coding hormones involved in the control of food intake, such as leptin or its receptor. It seems more likely that the genetic disposition of an individual, together with the environment (food choices, level of exercise), result in obesity. A change in lifestyle is clearly a major element in the obesity epidemic. An increased consumption of foods high in fat and carbohydrate, together with a decrease in exercise is the major cause of weight gain and body fat deposition in populations throughout the world. Thus, obesity is not a single disorder but a heterogeneous group of conditions with multiple causes.

Unfortunately, obesity is a condition that is rarely curable; its treatment remains a persistent medical problem. The standard procedure of reducing caloric intake and increasing energy expenditure is ineffective in obese individuals since, to be effective, it must be continued indefinitely to ensure a reduced body weight. Markedly obese individuals often resort to surgical procedures to remove unwanted fat or reduce the stomach to prevent hunger and food absorption. Several pharmacological interventions have been used for the treatment of obesity. These include the use of compounds, such as β-phenylamine that selectively inhibits the reuptake of norepinephrine, serotonin, and dopamine. This compound reduces food intake and increases thermogenesis. Another approach is to prevent fat absorption using orlistat, which blocks pancreatic lipase, thereby decreasing triacylglycerol digestion. The thermogenic (increases the generation of heat) compound ephedrine has been shown to increase oxygen consumption by 10% in humans, when combined with caffeine. However, a major portion of the weight loss noted with this combination of drugs is due to decreased food intake. Potentially important new approaches to the treatment of obesity involve the development of compounds that regulate satiety. Gastrointestinal peptides such as cholecystokinin and glucagon-like peptide have long been known to reduce food intake. In addition, antagonists of the cannabinoid receptor in the brain reduce appetite. Small molecules that act by binding to these receptors are candidates for drugs that could be used to control appetite.

Hirsch, J., Salens, L. B., and Aronne, L. J. Obesity. In Becker, K. L. (Ed), *Principles and Practice of Endocrinology and Metabolism,* 3d ed. New York, Lippincott, Williams and Wilkins, 2001, 1239; and Freidmann, J. M. Obesity in the new millennium. *Nature* 404: 632, 2000.

and the anatomical location of the stored molecule. In humans, most fatty acids are either saturated or contain one double bond, with oleic acid (18:1) being the most common. Although triacylglycerols are readily catabolized, they are comparatively inert chemically. The highly unsaturated fatty acids in triacylglycerols are much more susceptible to nonenzymatic oxidation.

The Hydrophobicity of Triacylglycerols Is Important for Their Functions

Triacylglycerols and other complex lipids have limited solubility in water because the long hydrocarbon chains of the constituent fatty acids do not form hydrogen bonds. Consequently, they tend to associate with each other or with other hydrophobic groups, such as sterols and the side chains of hydrophobic amino acids. This insolubility in water is essential for the storage of triacylglycerols and for the assembly of biological membranes.

Triacylglycerols are a much more efficient form of energy storage than glycogen. On a weight basis, triacylglycerols yield nearly 2½ times more ATP on complete oxidation than

CLINICAL CORRELATION 17.2

The Key Role of Fatty Acid Metabolism in Type 2 Diabetes: A Tribute to J. Denis McGarry

The late Denis McGarry, a long-time contributor to this book, wrote a prescient article in 1992 entitled "What if Minkowski had been ageustic? An alternative angle on diabetes." Oskar Minkowski (1858–1931) and Josef von Mering were the first to recognize that the pancreas produces a substance that regulates the level of blood glucose; their research ultimately led to the isolation of insulin from β cells of the pancreas. The concept of diabetes as a disease of carbohydrate metabolism began with the ancient observations that diabetic urine is sweet. Folklore tells us that Dr. Minkowski put his finger into the urine of a diabetic patient, tasted it, and noted that it was as "sweet honey." To this day, diabetes is widely considered to be due to an imbalance in carbohydrate metabolism. Dr. McGarry raised the humorous supposition that if Minkowski had been ageustic (i.e., he could not taste), but could smell the acetone in the urine, diabetes would have been classified as a disease of lipid rather than carbohydrate metabolism. This is an important insight into Type 2 (noninsulin-dependent) diabetes, which is associated with obesity and resistance to insulin.

Because most of the human energy reserve is triacylglycerol this fuel is extremely important, particularly during fasting. After a meal, glucose is rapidly removed from the blood and either used for energy or stored as glycogen; within hours humans switch to the oxidation of fatty acids as the major source of energy, with ketone bodies becoming important during prolonged fasting. After 3 days of fasting, even the brain metabolizes ketone bodies. The metabolism of fat over the limited glucose supply is referred to as *fuel sparing*. Fatty acids play an important role in this process by inhibiting glucose utilization in skeletal muscle. In 1963, Phillip Randle and colleagues proposed what is now known as the Randle hypothesis, which states that fatty acid oxidation blocks glucose metabolism by inhibiting key regulatory enzymes involved in glucose utilization, including phosphofructokinase and pyruvate dehydrogenase complex (see Chapter 15) and inhibits glycogen synthesis in skeletal muscle. Fatty acids also markedly reduce the uptake of glucose from the blood by blocking the recruitment of GLUT 4 from the endoplasmic reticulum to the cell surface. This is due in part to the activation of specific isoforms of protein kinase C, as well as the transcription factor NF-κB, by acyl CoAs generated by fatty acid metabolism.

Although the fuel sparing effect of fatty acids is of clear survival advantage, there is also a disadvantage in obesity, which is frequently characterized by a high fatty acid concentration in the blood. This reduces glucose uptake and metabolism by skeletal muscle, resulting in an increase in the fasting levels of blood glucose and a concomitant increase in insulin secretion. The resulting condition is termed *insulin resistance* (elevated levels of blood glucose and insulin). During the early stages of insulin resistance, pancreatic β cells produce enough insulin to regulate blood glucose. However, prolonged overproduction of insulin can cause failure of the β cells, resulting in Type 2 diabetes. While this progression does not occur in all obese patients, insulin resistance evolves to diabetes in ~40% of patients over 5–10 years. Currently over 220 million people worldwide have Type 2 diabetes and the number is predicted to increase dramatically over the next 20 years. More alarmingly, Type 2 diabetes has replaced Type 1 diabetes as the predominant form of this disease among children. Prevention and treatment of Type 2 diabetes is clearly a major medical priority; in many cases insulin resistance is reversible with weight loss and increased exercise, particularly in the early stages.

In his article, Dennis McGarry noted that the re-esterification of fatty acids to triacylglycerol is a critical factor in regulating their concentration in the blood. This prediction is amply supported by the current, widespread clinical use of the antidiabetic thiazolidinedione drugs, which act at the nuclear receptor, PPARγ2. These drugs lower plasma-free fatty acids, in part by increasing the rate of fatty acid esterification to triacylglycerol in white adipose tissue, thereby removing fatty acids from the blood. Dr. McGarry was clearly ahead of his time in predicting the importance of the regulation of fatty acid metabolism in the control of diabetes.

McGarry, J. D. What if Minkowski had been ageustic? An alternative angle on diabetes. *Science* 285: 766, 1992; Roden, M. How FFA inhibits glucose utilization in human skeletal muscle. *News Physiol. Sci.* 19: 92, 2004; Randle, P. J. Regulatory interactions between lipids and carbohydrates: the glucose fatty acid cycle after 35 years. *Diabetes Metabol. Rev.* 14: 263, 1998; and Zimmet, P. Alberti, K. G. M. M., and Shaw, J. Global and social implications of the diabetes epidemic. *Nature* 414: 782, 2001.

glycogen. In addition, triacylglycerols are stored without associated water, whereas glycogen is hydrophilic and binds about twice its weight of water. Therefore, the energy yield per gram of stored triacylglycerol is about 4 times that of hydrated glycogen. Humans store much more fuel as triacylglycerol than as glycogen. The average 70-kg human stores about 250 g of glycogen in liver and muscle. This represents about 1000 kcal of energy, which is less than one day's energy requirement. By contrast, the same individual stores ~16 kg of triacylglycerol, which provides sufficient energy to survive several weeks of starvation. Unlike stores of glycogen and amino acids, which are limited, triacylglycerol stores, can greatly expand, depending on caloric intake. This makes triacylglycerol an excellent fuel store, but it can also lead to obesity and, in some cases, diabetes (Clin. Corrs. 17.1 and 17.2). Adipose tissue is a significant source of hormones that regulate appetite, and subcutaneous fat is also important in temperature regulation because it provides a layer of insulation.

17.3 • INTERORGAN TRANSPORT OF FATTY ACIDS AND THEIR PRIMARY PRODUCTS

In all mammals, the transport and storage of fatty acids is regulated by dietary status. Triacylglycerol is stored in the fed state, with net deposition in adipose tissue. During fasting, triacylglycerol in adipose tissue is hydrolyzed and the products are distributed throughout the body to be used for energy production. As fasting progresses, the liver converts fatty acids to the **ketone bodies, acetoacetate**, and **β-hydroxybutyrate**, which are released into the blood and become a major source of energy for many tissues. These processes are summarized in Figure 17.6.

The transport of lipids presents unique problems because these molecules (especially triacylglycerols, cholesterol and its esters) are insoluble in water. Consequently, lipids are transported through the bloodstream in plasma lipoproteins or bound to proteins. In addition, the transport of triacylglycerols across membranes usually involves breakdown to smaller constituents by lipases.

Lipid Transport in the Fed State

Triacylglycerols in the diet are digested in the stomach and small intestine by **gastric** and **pancreatic lipases** (p. 1052). The principal products are 2-monoacylglycerols and **free fatty acids**, which are absorbed by the epithelial cells that line the small intestine. These cells assemble the absorbed fatty acids and monoacylglycerols into triacylglycerols (p. 688),

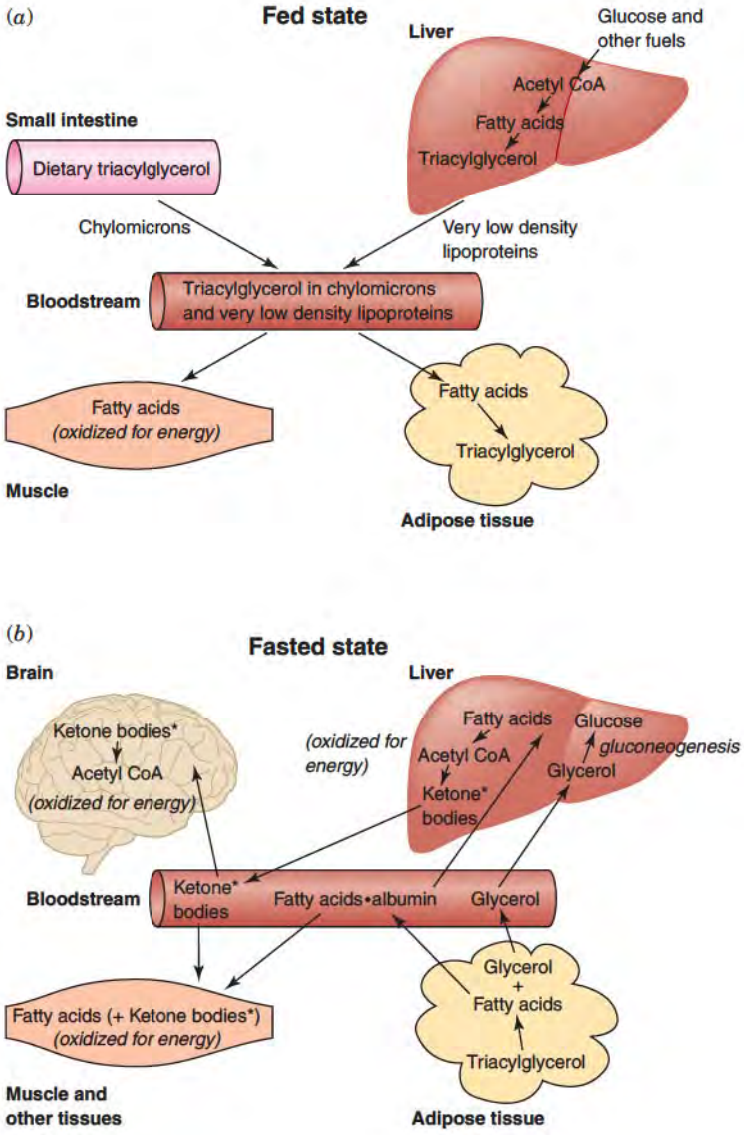

Figure 17.6 Interorgan transport of fatty acids. (*a*) In the fed state, there is net deposition of triacylglycerol in adipose tissue. The sources are dietary fat and fatty acids synthesized in the liver from excess carbohydrate and amino acids. (*b*) In the fasted state, triacylglycerols are hydrolyzed and free fatty acids and glycerol are released into the blood.
*During fasting, the liver synthesizes ketone bodies, which become a major fuel in the blood as fasting progresses.

which are then packaged into **chylomicrons**, a triacylglycerol-rich plasma lipoprotein (p. 1051). Chylomicrons are secreted into lymph and then circulate in the bloodstream.

The liver is another source of triacylglycerols in the fed state. Fatty acids are synthesized in this tissue from excess carbohydrate and amino acids. These fatty acids are assembled into triacylglycerols and packaged into **very low-density lipoprotein (VLDL)**, a second triacylglycerol-rich lipoprotein, which is secreted into the bloodstream (p. 724).

The triacylglycerols in chylomicrons and VLDL are hydrolyzed by **lipoprotein lipase**, located on the surface of capillary endothelial cells in tissues such as adipose tissue and skeletal muscle. The apoprotein ApoC-II, which is found in chylomicrons and VLDL, activates the process by binding the lipoproteins to the enzyme. The products of lipoprotein lipase action are free fatty acids and glycerol. The free fatty acids are utilized in the tissue where hydrolysis occurs. The glycerol is transported through the bloodstream and taken up by the liver where it is used in glycolysis or gluconeogenesis.

Lipoprotein lipase is present at high levels in adipose tissue, cardiac muscle, and skeletal muscle, allowing these tissues to utilize triacylglycerols from lipoproteins. In adipose tissue, the products of lipoprotein lipase are taken up and assembled into triacylglycerols, allowing net deposition of fuel (p. 688). In muscle, the fatty acid products of lipase action are taken up and used to generate energy, although some triacylglycerol synthesis occurs in this tissue.

Lipid Transport in the Fasted State

The triacylglycerols stored in adipose tissue are mobilized for use as fuel in the fasted state. This process is initiated by **hormone-sensitive lipase**, which is located within adipocytes. This enzyme is activated when it is phosphorylated by cAMP-dependent protein kinase A. Conversely, insulin inhibits the activity of this enzyme by inducing its dephosphorylation. The protein, **perilipin**, which coats the surface of fat droplets, is also important in this regulation. When perilipin is not phosphorylated, it blocks lipase access to the triacylglycerol. When perilipin is phosphorylated by protein kinase A, hormone-sensitive lipase translocates to the surface of the fat droplet and hydrolyzes triacylglycerols. The principal product of this enzyme is monoacylglycerol and free fatty acids. Other enzymes complete the hydrolysis. A summary of the regulation of triacylglycerol metabolism is presented in Table 17.2. This regulation results in the net mobilization of fatty acids during fasting and net deposition after a meal. The balance of triacylglycerol synthesis and hydrolysis helps to assure adequate energy stores and avoid obesity (see Clin. Corrs 17.1 and 17.2). Other lipases, including **adipose triglyceride lipase**, may also play a role in the degradation of triacylglycerols. These may contribute to slow unregulated **lipolysis**.

Other lipases rapidly complete the hydrolysis, releasing fatty acids and glycerol into the blood. The fatty acids are referred to as *free fatty acids* although they circulate bound to serum albumin. Each albumin molecule can bind ~10 fatty acids, so its binding capacity is very high. Free fatty acids bound to albumin, however, are a relatively small fraction of the total lipid in plasma when one considers the presence of the lipids in the plasma lipoproteins (p. 724). However, these free fatty acids turn over rapidly, so they represent a significant fraction of the lipid flux through the bloodstream.

The hydrolysis of triacylglycerols present in adipose tissue and in plasma lipoproteins also produces free glycerol. This glycerol is used by the liver, which contains high levels of glycerol kinase, an enzyme that synthesizes glycerol 3-phosphate from glycerol and ATP

TABLE 17.2 • Regulation of Triacylglycerol Metabolism

Protein	*Effect*	*Regulatory Agent*
	Triacylglycerol Mobilization	
Hormone-sensitive lipase and perilipin	Activation by PKA-mediated phosphorylation	Glucagon, epinephrine, ACTH
	Inhibition by dephosphorylation	Insulin
Lipoprotein lipase	Increased enzyme synthesis	Insulin
	Triacylglycerol Synthesis	
Phosphatidate phosphatase	Increased enzyme synthesis	Steroid hormones

(see Figure 15.39, p. 625). Glycerol is metabolized sparingly in other tissues due to low levels of this enzyme. Hepatic glycerol 3-phosphate dehydrogenase converts glycerol 3-phosphate to dihydroxyacetone phosphate, which enters the glycolytic pathway in the fed state. In the fasted state, it is converted to glucose via gluconeogenesis. During prolonged fasting, when much of the body's energy is derived from stored fat, the glycerol produced by the hydrolysis of triacylglycerol in adipose tissue is an important substrate for gluconeogenesis in the liver.

17.4 • SYNTHESIS OF FATTY ACIDS: LIPOGENESIS

Glucose Is the Major Precursor for Fatty Acid Synthesis

Dietary carbohydrate in excess of that needed for energy production and glycogen synthesis is converted to fatty acids in the liver during the fed state in mammals. Glucose provides the carbon for fatty acid synthesis (via acetyl CoA) as well as the reducing equivalents (NADPH) required for this process. Other substrates, such as amino acids, can also contribute to lipogenesis.

Pathway of Fatty Acid Biosynthesis

The synthesis of fatty acids occurs in the cytosol using acetyl CoA produced from glucose or from other precursors (i.e., the carbon skeletons of amino acids). The saturated C_{16} acid, palmitic acid, is synthesized first, and all other fatty acids are made by its modification. Fatty acids are synthesized by sequential addition of two-carbon units from acetyl CoA to the activated carboxyl end of a growing chain by **fatty acid synthase**. In bacteria, fatty acid synthase is a complex of several proteins, whereas in mammalian cells it is a single multifunctional protein.

Formation of Malonyl CoA Is the Commitment Step of Fatty Acid Synthesis

Synthesis of fatty acids from acetyl CoA requires the activated intermediate, malonyl CoA, which is made by carboxylation of acetyl CoA by acetyl-CoA carboxylase (Figure 17.7). The reaction requires ATP and bicarbonate as the source of CO_2. In the first step, CO_2 is linked to a biotin moiety on the enzyme, using energy derived from ATP hydrolysis; the CO_2 is then transferred to acetyl CoA. This reaction is similar to the carboxylation of pyruvate to oxaloacetate by pyruvate carboxylase (p. 622).

Acetyl-CoA carboxylase catalyzes the rate-limiting step in fatty acid synthesis. This enzyme exists in an inactive, protomeric state and, when activated, as linear polymers. The mammalian enzyme is activated by citrate or isocitrate. This represents feed-forward activation of fatty acid synthesis because citrate is exported from the mitochondria to generate cytosolic acetyl-CoA for fatty acid synthesis (see the section on the citrate cleavage pathway on p. 684). Acetyl-CoA carboxylase is also inhibited by long-chain acyl CoAs, resulting in feedback inhibition of fatty acid synthesis by the end product of the pathway. Phosphorylation of acetyl-CoA carboxylase by both cyclic-AMP-dependent protein kinase A and AMP-dependent protein kinases inhibit this enzyme. The importance of this regulation is discussed on page 702.

Reaction Sequence for the Synthesis of Palmitic Acid

The first step catalyzed in fatty acid synthesis is the transfer of the primer molecule, either an acetyl or butyryl group from CoA to a 4′-phosphopantetheine moiety on **acyl carrier protein** (ACP), a protein constituent of the multienzyme complex (Figure 17.8, Reaction 1). The phosphopantetheine unit is identical with that in CoA; both are derived from the

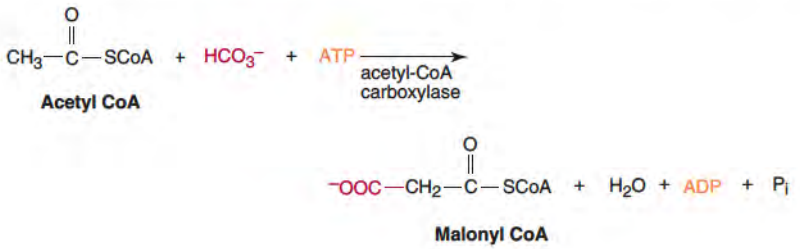

Figure 17.7 **Acetyl-CoA carboxylase reaction.**

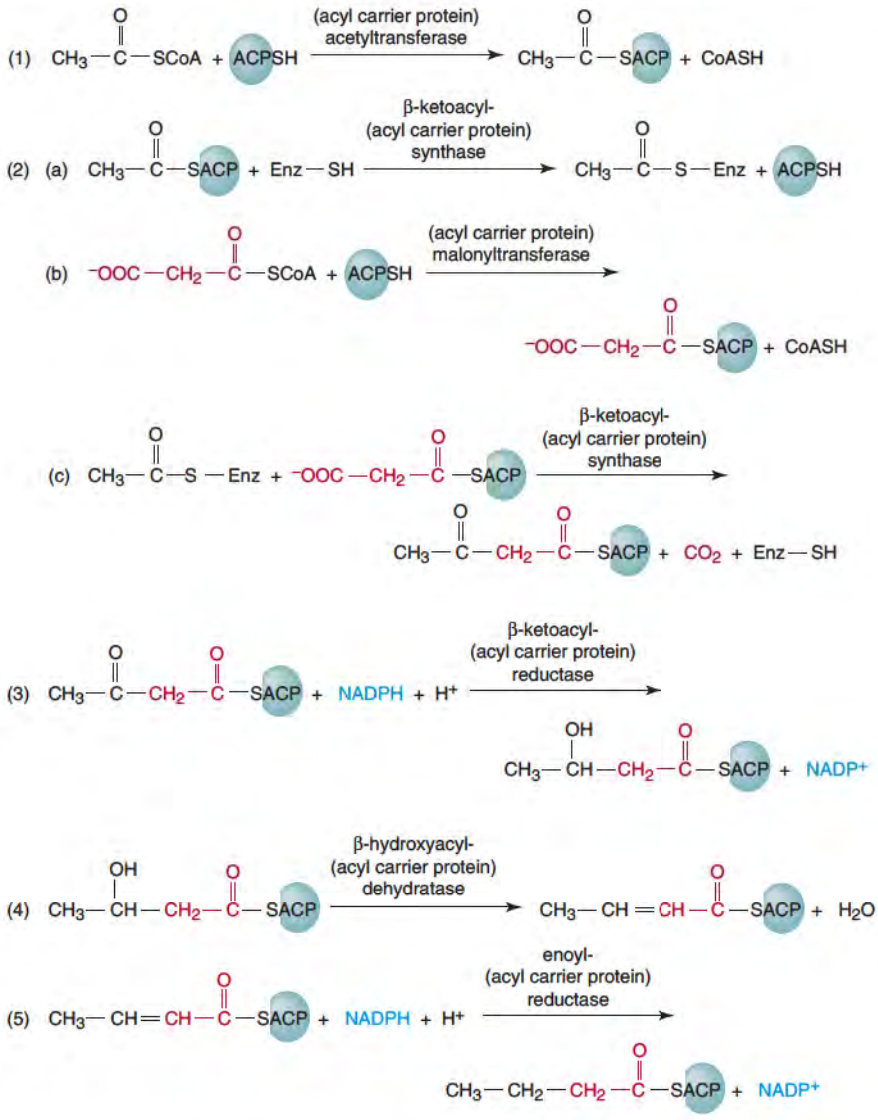

Figure 17.8 Pathway of fatty acid synthesis.

vitamin, pantothenic acid. In bacteria ACP is a small protein, whereas in mammals it is a domain of fatty acid synthase. Six or seven two-carbon units are added to the enzyme complex (depending on whether acetyl CoA or butyryl CoA is the primer) in a repetitive sequence of reactions until the palmitate molecule is completed. The reaction sequence, starting with an acetyl CoA primer and leading to butyryl-ACP, is presented in Figure 17.8.

A round of fatty acid elongation is initiated by the addition of two carbon atoms to the chain in a three-step process. First the fatty acid chain is transferred from the 4′-phosphopantetheine moiety of ACP to a cysteine sulfhydryl group of β-ketoacyl-ACP synthase (Reaction 2a). The -SH group of ACP then accepts a malonyl unit from malonyl CoA (Reaction 2b). Then the condensation step links the growing acyl chain to C2 of the malonyl group, with the loss of CO_2 (Reaction 2c). This is the same CO_2 that was added by acetyl-CoA carboxylase, so the carbon atoms in palmitate are derived entirely from acetyl CoA. The acyl product is β-ketoacyl-ACP. This intermediate is reduced to β-hydroxyacyl-ACP using NADPH as electron donor (Reaction 3). β-Hydroxyacyl-ACP is dehydrated to an enoyl-ACP (Reaction 4) and then reduced to a saturated acyl CoA, using a second molecule of NADPH as reductant (Reaction 5). The growing fatty acid proceeds through six more reaction cycles to produce palmitoyl-ACP, which then is acted on by a thioesterase to produce free palmitic acid (Figure 17.9). The specificity of this enzyme determines the chain length of the fatty acid product. Note that at this stage, the sulfhydryl groups of ACP and synthase are both free, so that another cycle of fatty acid synthesis can begin. The released product is converted to palmitoyl CoA, preparing it for modification or incorporation into complex lipids.

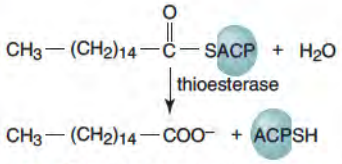

Figure 17.9 Release of palmitic acid from fatty acid synthase by thioesterase.

Mammalian Fatty Acid Synthase Is a Multifunctional Polypeptide

The reactions outlined above are the basic sequence for fatty acid synthesis in all organisms. The enzyme complex, fatty acid synthase, catalyzes all these reactions, but its structure and properties vary considerably. In *Escherichia coli,* the complex is composed of separate enzymes. By contrast, mammalian fatty acid synthase is composed of two identical subunits each of which is a multienzyme polypeptide that contains all of the catalytic activities. There are also variations in the enzyme between mammalian species and tissues.

The growing fatty acid chain is always bound to the multifunctional protein and is transferred sequentially between the 4′-phosphopantetheine group of ACP, which is a domain of the protein, and the cysteine sulfhydryl group of β-ketoacyl-ACP synthase, during the condensation reaction (Reaction 2, Figures 17.8 (p. 681) and 17.10).

The levels of fatty acid synthase in tissues are controlled by the rate of its synthesis and degradation. As shown in Table 17.3, insulin increases the rate of fatty acid synthesis by stimulating transcription of the fatty acid synthase gene, thereby increasing enzyme levels

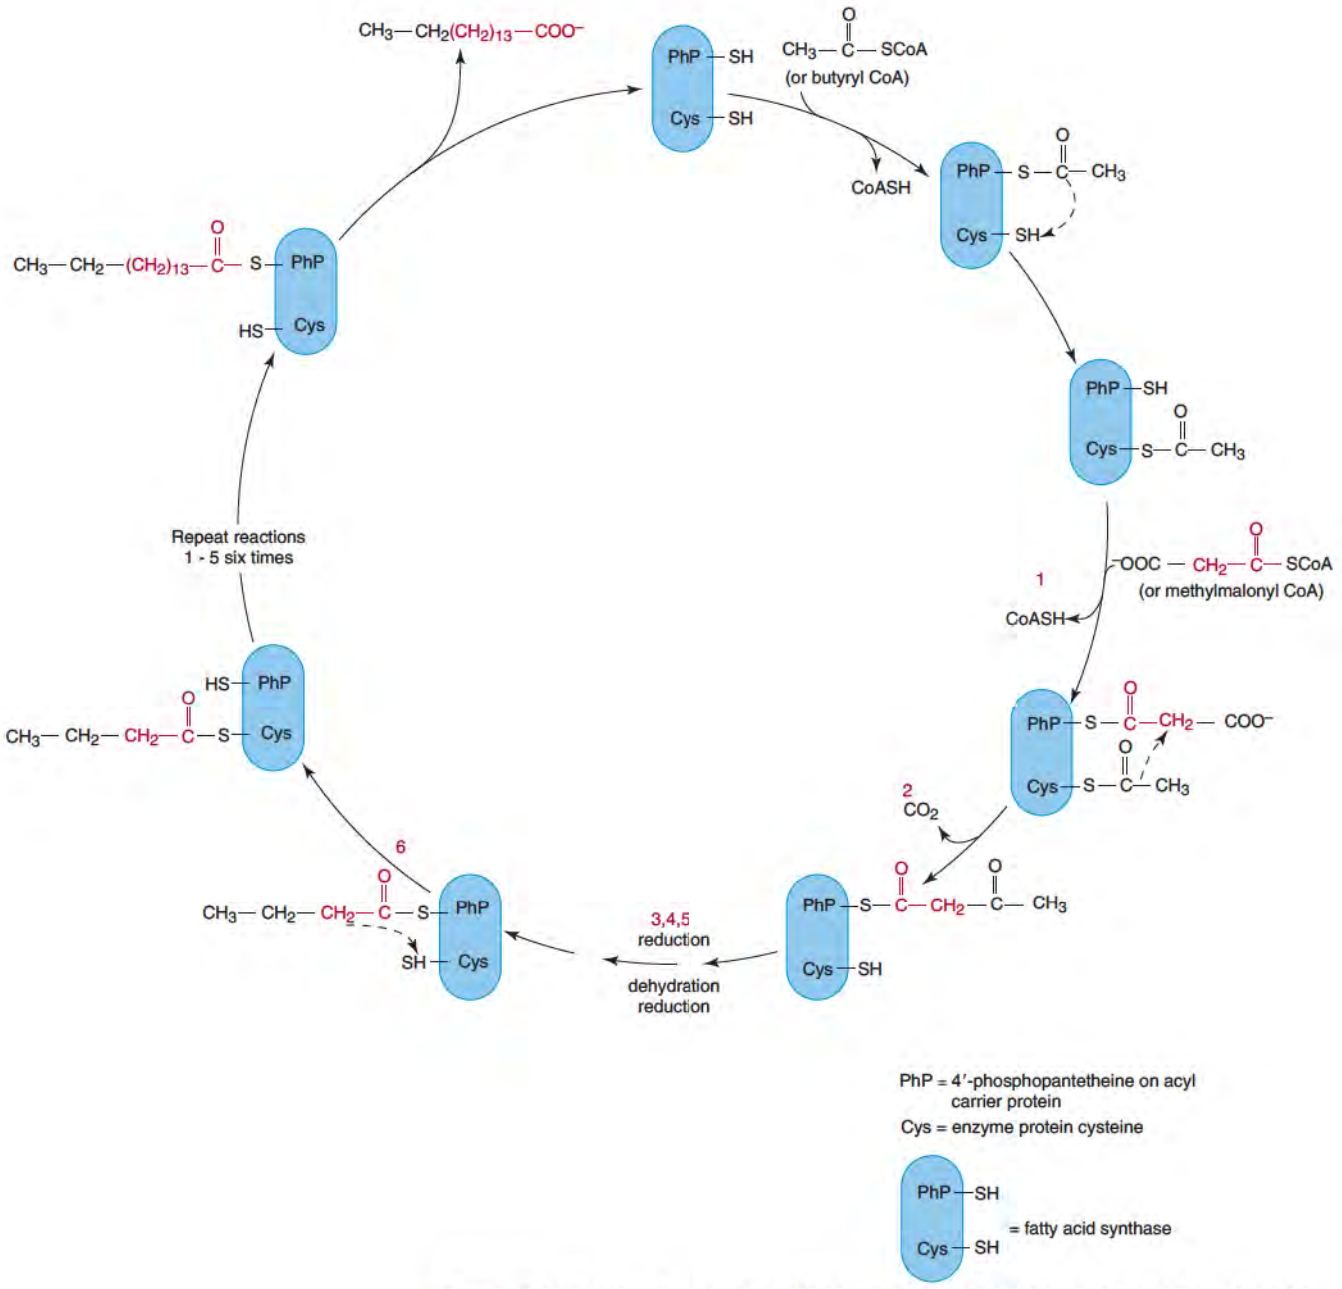

Figure 17.10 Proposed mechanism of fatty acid elongation by mammalian fatty acid synthase.

TABLE 17.3 • Regulation of Fatty Acid Synthesis

Enzyme		*Effect*	*Regulatory Agent*
		Palmitate Synthesis	
Acetyl-CoA carboxylase (ACC)	Short term	Allosteric activation	Citrate, isocitrate
		Allosteric inhibition	C16–C18 acyl CoAs
		Inhibition via PKA phosphorylation of ACC	Glucagon and epinephrine
		Inhibition via AMPK-mediated phosphorylation of ACC	AMP
		Activation by dephosphorylation of ACC	Insulin
	Long term	Increased enzyme synthesis	Thyroid hormone, high carbohydrate diet, insulin
		Decreased enzyme synthesis	Fasting, high fat diet, via low insulin and high glucagon. Polyunsaturated fatty acids (PUFAs) also inhibit synthesis
Fatty acid synthase	Long term	Increased enzyme synthesis	High carbohydrate diet via insulin
		Decreased enzyme synthesis	Fasting, high fat diet, via low insulin and high glucagon. PUFAs also inhibit synthesis
		Biosynthesis of Fatty Acids Other than Palmitate	
Fatty acid synthase		Increased synthesis of branched-chain fatty acids	Increased methylmalonyl CoA/malonyl CoA
		Synthesis of short-chain fatty acids	Expression of specific thioesterase in mammary gland

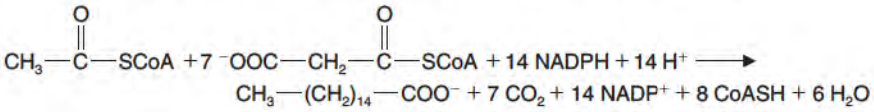
		Decreased enzyme synthesis	Dietary PUFAs

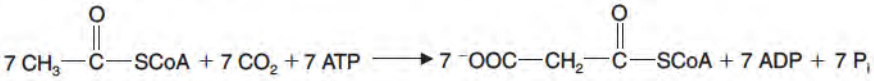
in the liver and other tissues. The factors that are involved in the regulation of lipogenesis in mammals are presented on page 684.

Stoichiometry of Fatty Acid Synthesis

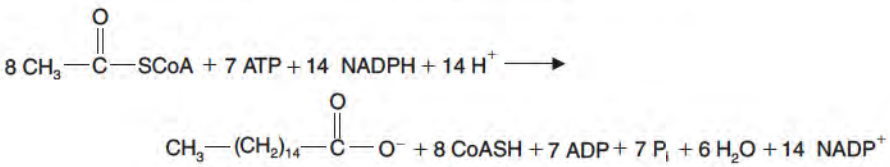
With acetyl CoA as the primer for palmitate synthesis, the overall reaction is



To describe the overall conversion of acetyl CoA to palmitate, the ATP used in formation of malonyl CoA must be included.



Then the stoichiometry for conversion of acetyl CoA to palmitate is



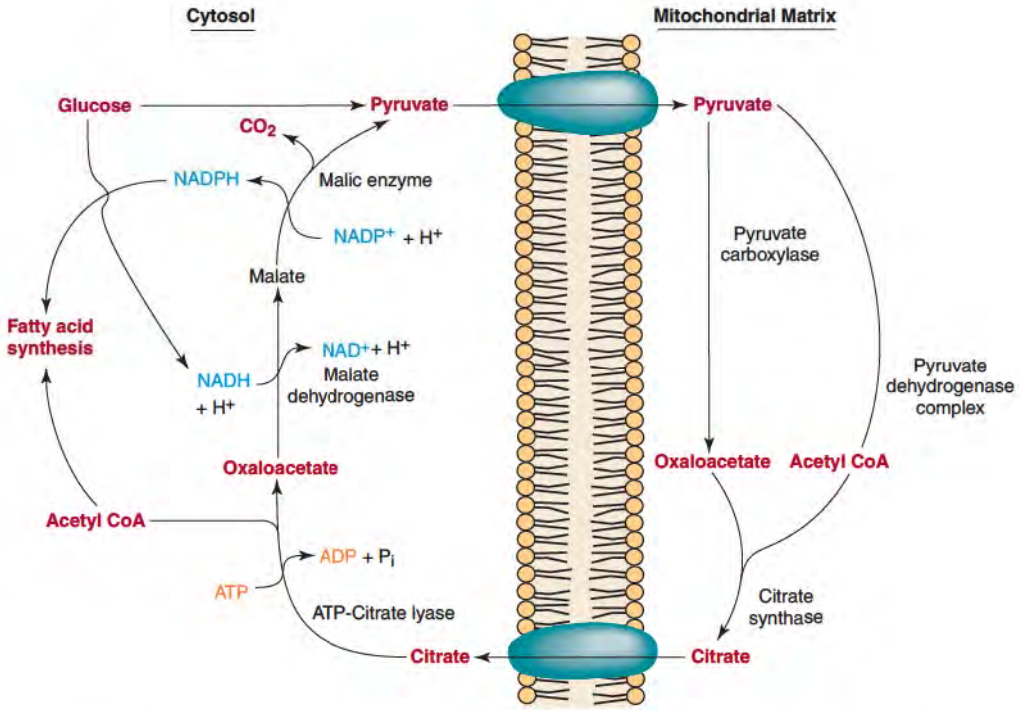


Figure 17.11 Transfer of acetyl CoA from mitochondria to cytosol for fatty acid biosynthesis by the citrate cleavage pathway.

The Citrate Cleavage Pathway Provides Acetyl CoA and NADPH for Lipogenesis in the Cytosol

Glucose breakdown in the liver via glycolysis results in the production of pyruvate, which is converted to acetyl CoA in the mitochondria by pyruvate dehydrogenase complex. However, the synthesis of fatty acids is a cytosolic process and acetyl CoA is not readily transported across the inner mitochondrial membrane. The **citrate cleavage pathway** overcomes this problem. Citrate, formed by citrate synthase in the tricarboxylic acid cycle, is transported across the mitochondrial inner membrane via the tricarboxylate transporter (see Figure 14.49, p. 578). The citrate is then cleaved in the cytosol by **ATP citrate lyase** (also called **citrate cleavage enzyme**) to form acetyl CoA and oxaloacetate (Figure 17.11).

$$\text{citrate} + \text{ATP} + \text{CoA} \rightarrow \text{acetyl CoA} + \text{oxaloacetate} + \text{ADP} + P_i$$

This reaction is not a reversal of citrate synthase, since it requires the hydrolysis of ATP. As mentioned previously, citrate has a second role in fatty acid synthesis as an allosteric activator of acetyl-CoA carboxylase, the rate-limiting enzyme in lipogenesis.

The oxaloacetate generated by citrate cleavage in the cytosol is not readily transported back into the mitochondria. It is instead reduced to malate by the cytosolic isoform of **NAD malate dehydrogenase**. The malate then undergoes oxidative decarboxylation to pyruvate, catalyzed by **NADP malate dehydrogenase** (also called **malic enzyme**). The pyruvate enters the mitochondria for further metabolism. The removal of citrate from the mitochondria (**cataplerosis**) must be accompanied by its replacement (**anaplerosis**) in order to maintain tricarboxylic acid cycle flux. This is achieved by the conversion of pyruvate to oxaloacetate by **pyruvate carboxylase** (p. 622), the major anaplerotic enzyme in mitochondria.

The conversion of oxaloacetate to pyruvate by the citrate cleavage pathway transfers a pair of electrons from NADH to generate NADPH that is used for fatty acid synthesis. The source of the NADH for this process is the glyceraldehyde-3-phosphate dehydrogenase reaction in the glycolytic pathway. The metabolism of glucose thus provides both the carbon atoms and the reducing equivalents required for lipogenesis.

The production of the reducing equivalents used in fatty acid synthesis can be summarized as follows: The citrate cleavage pathway transfers a pair of electrons from NADH to NADPH for each acetyl CoA transferred from mitochondria to cytosol. The transfer of the eight acetyl CoAs that are used for the synthesis of one molecule of palmitate supplies eight NADPHs. Since palmitate synthesis requires 14 NADPHs per mol, the other six NADPHs are supplied by the pentose phosphate pathway, which is also present in the cytosol. The

actual stoichiometry of this process is more complicated because transport of citrate and other di- and tricarboxylic acids across the inner mitochondrial membrane occurs by one-for-one exchanges. The flow rates are probably controlled by a composite of the concentration gradients of several of these exchange systems.

Modification of Fatty Acids

Humans can synthesize the other fatty acids they require from palmitate, except for some polyunsaturated fatty acids (see Table 17.1, p. 675). Fatty acids are modified as the CoA derivatives by three processes: elongation, desaturation, and hydroxylation.

Elongation Reactions

Fatty acid elongation in mammals occurs in either the endoplasmic reticulum or the mitochondria. These processes are slightly different in the two locations. In the endoplasmic reticulum, fatty acyl CoAs are elongated by reactions similar to the ones catalyzed by cytosolic fatty acid synthase; malonyl CoA is the source of two-carbon units and NADPH provides the reducing power. The preferred elongation substrate is palmitoyl CoA, which is converted almost exclusively to stearate (18:0) in most tissues. The brain, however, contains one or more additional elongation systems, which synthesize longer-chain acids (up to C_{24}) that are required for membrane lipids. These elongation systems also use malonyl CoA.

Fatty acid elongation in mitochondria uses acetyl CoA, and both NADH and NADPH as electron donors (Figure 17.12). This system operates by reversal of the pathway of fatty acid β-oxidation (p. 692) with the exception that NADPH-linked enoyl-CoA reductase (last step of elongation) replaces FAD-linked acyl-CoA dehydrogenase (first step in β-oxidation). This process has little activity with acyl CoA substrates of 16 carbons or longer; it serves primarily to elongate shorter molecules.

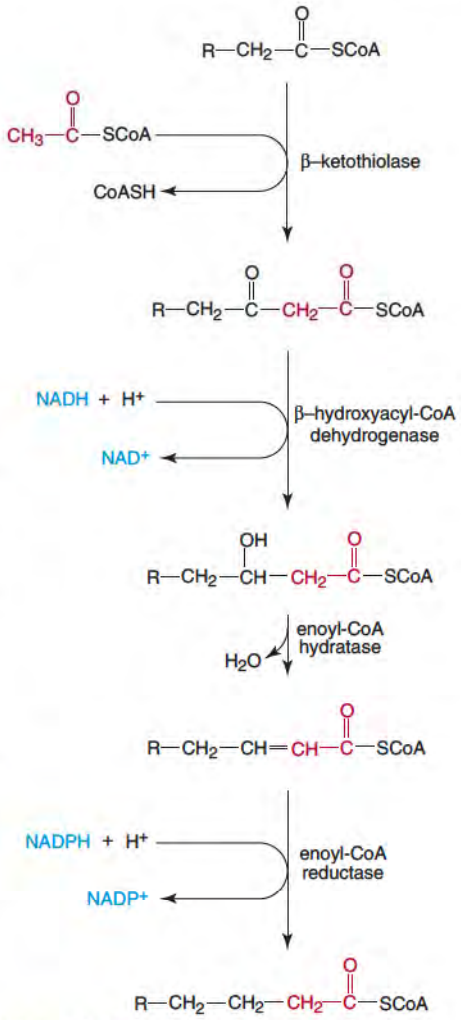

Figure 17.12 Pathway of fatty acid elongation in mitochondria.

Formation of Monoenoic Acids by Stearoyl-CoA Desaturase

In vertebrates, **fatty acid desaturation** occurs in the endoplasmic reticulum, and the reactions and enzymes that introduce cis double bonds are significantly different from the acyl-CoA dehydrogenases of mitochondrial β-oxidation. Desaturation is carried out by **monooxygenases**, which have fatty acyl CoA, NADH and O_2 as substrates (p. 695). The three components of the system are the **desaturase enzyme, cytochrome b_5**, and **NADPH-cytochrome b_5 reductase**. The overall reaction is.

$$R{-}CH_2{-}CH_2{-}(CH_2)_7{-}C(=O){-}SCoA + NADPH + H^+ + O_2 \rightarrow$$
$$R{-}CH{=}CH{-}(CH_2)_7{-}C(=O){-}SCoA + NADP^+ + 2H_2O$$

The initial step in the formation of unsaturated fatty acids is the formation of the Δ^9 double bond by **stearoyl-CoA desaturase** in palmitic or stearic acid to produce palmitoleic or oleic acid, respectively. The synthesis of unsaturated fatty acids is important for regulating the fluidity of triacylglycerols and membrane phospholipids. It is also required for the synthesis of cholesterol esters in the liver and waxy secretions in the skin, which preferentially use newly synthesized, rather than dietary fatty acids. Expression of stearoyl-CoA desaturase is highly regulated by both dietary and hormonal mechanisms. Insulin, triiodothyronine, hydrocortisone, and dietary cholesterol increase gene transcription and thus the levels of stearoyl-CoA desaturase in the liver, whereas dietary polyunsaturated fatty acids have the opposite effect.

Formation and Modification of Polyunsaturated Fatty Acids

Polyunsaturated fatty acids, particularly arachidonic acid (20:4), are precursors of important signaling molecules: prostaglandins, thromboxanes, and leukotrienes (p. 737). Polyunsaturated fatty acids are also required for the synthesis of complex lipids, particularly in the nervous system. These fatty acids can also undergo nonenzymatic oxidation reactions, creating products that damage cellular constituents and may have pathological effects.

In mammals, double bonds can be added only to the proximal half of fatty acyl CoAs; they cannot be added beyond C9. Consequently, linoleic (18:2) and linolenic (18:3) are required polyunsaturated fatty acids in the diet (Figure 17.13). These **essential fatty acids**

$CH_3{-}(CH_2)_3{-}(CH_3{-}CH{=}CH)_n{-}(CH_2)_m{-}COOH$

Basic formula of the linoleic acid series

$CH_3{-}(CH_2{-}CH{=}CH)_n{-}(CH_2)_m{-}COOH$

Basic formula of the linolenic acid series

Figure 17.13 The linoleic and linolenic acid series.

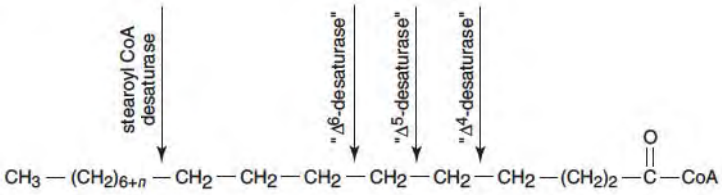

Figure 17.14 Positions in the fatty acid chain where desaturation can occur in the human. In mammals, there must be at least six carbons beyond the bond being desaturated.

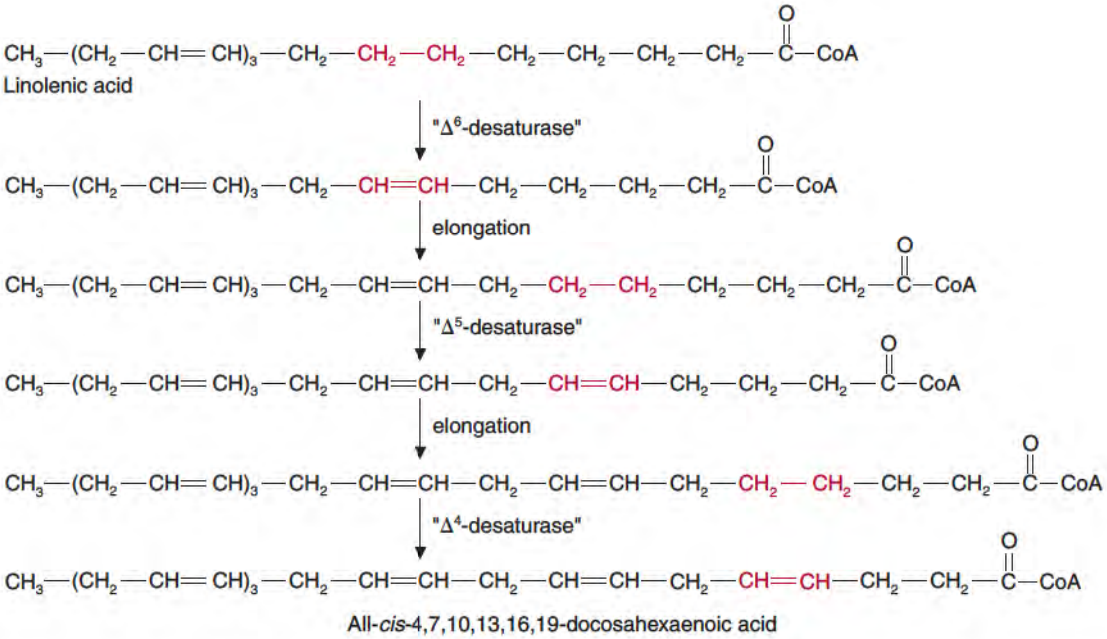
are obtained in the diet from plants and cold-water fish. There are two series of polyunsaturated fatty acids. The distal double bond of linoleic acid is six carbons from the methyl group; it is referred to as n-6 or ω-6. A second series, n-3 or ω-3, has the distal double bond three carbons from the methyl group. One isomer of linolenic acid is part of this series.

The essential fatty acids are modified by elongation and desaturation to form the polyunsaturated fatty acids found in mammals. A variety of polyunsaturated fatty acids are synthesized by humans using desaturases that introduce double bonds at positions 4, 5, or 6 (Figure 17.14). These enzymes act only in the synthesis of polyunsaturated fatty acids because they can use only substrates with a double bond at position 9. This elongation and desaturation occurs in either order. Conversion of linolenic acid to all *cis*-4,7,10,13,16,19-docosahexaenoic acid in the brain is an example of such a reaction sequence.



Formation of Hydroxy Fatty Acids in Nerve Tissue

Two different processes produce **α-hydroxy fatty acids** in vertebrates. One occurs in the mitochondria of many tissues and acts on relatively short-chain fatty acids. The other has been demonstrated only in the nervous system, where it produces long-chain fatty acids hydroxylated on C2 that are required for the formation of some myelin lipids. The enzyme in the brain that catalyzes this reaction is a monooxygenase that requires O_2 and NADH or NADPH and preferentially uses C_{22} and C_{24} fatty acids. This process is closely coordinated with the synthesis of sphingolipids that contain hydroxylated fatty acids (see p. 729).

Fatty Acid Synthase Can Produce Fatty Acids Other than Palmitate

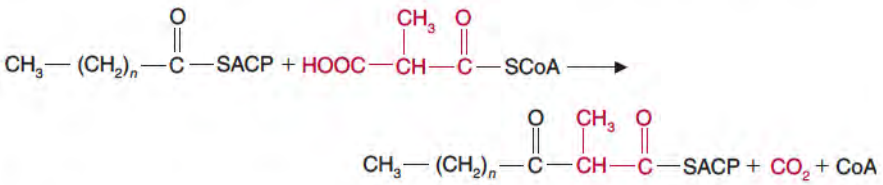
The principal fatty acids synthesized by humans for energy storage are palmitate and its modification products. However, smaller amounts of different fatty acids are synthesized for other purposes. Two examples are the production of the fatty acids shorter than

palmitate in the **mammary gland** and the synthesis of branched-chain fatty acids in some secretory glands.

Milk contains fatty acids with chains that are shorter than palmitate. The relative amounts of the fatty acids produced by the mammary gland vary with species and with the physiological state of the animal. In ruminants, the pathway of fatty acid synthesis, which normally produces palmitate, is modified to synthesize fatty acids as short as C_4. This is accomplished by the expression of soluble **thioesterases**, which cleave the shorter chains from fatty acid synthase. Human milk contains no fatty acids with chains shorter than 10 carbons.

There are relatively few branched-chain fatty acids in vertebrates. Until recently, their metabolism has been studied mostly in bacteria such as Mycobacteria, where they are present in a greater variety and amount. Simple, branched-chain fatty acids are synthesized by tissues of vertebrates for specific purposes, such as the production of waxes in sebaceous glands and avian preen glands, and the elaboration of structures in echo-locating systems of porpoises.

Most of the branched-chain fatty acids in vertebrates are methylated derivatives of saturated, straight-chain acids that are synthesized by fatty acid synthase. When **methylmalonyl CoA** is used as a substrate instead of malonyl CoA, a methyl side chain is inserted into the fatty acid by the following reaction:



Regular reduction steps then follow. These reactions occur in many tissues at a rate several orders of magnitude lower than the utilization of malonyl CoA in fatty acid synthesis. The proportion of branched-chain fatty acids that are synthesized is largely governed by the relative availability of the two precursors. An increase in branching can occur by decreasing the ratio of malonyl CoA to methylmalonyl CoA. A malonyl-CoA decarboxylase that is responsible for this decrease occurs in many tissues. It has been suggested that an increased concentration of methylmalonyl CoA, which occurs in vitamin B_{12} deficiency, can lead to excessive production of branched-chain fatty acids.

Fatty Acyl CoAs May Be Reduced to Fatty Alcohols

Many phospholipids contain fatty acid chains in ether linkage, rather than ester linkage. The synthetic precursors of these ether-linked chains are fatty alcohols (Figure 17.15) rather than fatty acids. These alcohols are formed in vertebrates by a two-step, NADPH-linked reduction of fatty acyl CoAs in the endoplasmic reticulum. In tissues that produce relatively large amounts of ether-containing lipids, the concurrent production of fatty acids and fatty alcohols is closely coordinated.

Figure 17.15 Fatty alcohol.

17.5 • STORAGE OF FATTY ACIDS AS TRIACYLGLYCEROL

Most mammalian tissues convert fatty acids to triacylglycerols by a common sequence of reactions, but liver, adipose, and muscle tissue carry out this process to the greatest extent. Adipose tissue is a specialized organ for synthesis, storage, and hydrolysis of triacylglycerol and is the main site of long-term energy storage. Triacylglycerols are stored in the cytosol as liquid droplets surrounded by a monolayer of membrane lipids and the protein perilipin. These droplets are not a dead-end store; there is continuous synthesis and breakdown of triacylglycerol in adipose tissue. Some storage also occurs in skeletal and cardiac muscle, but only for local consumption. Triacylglycerol synthesis in liver is primarily for the production of

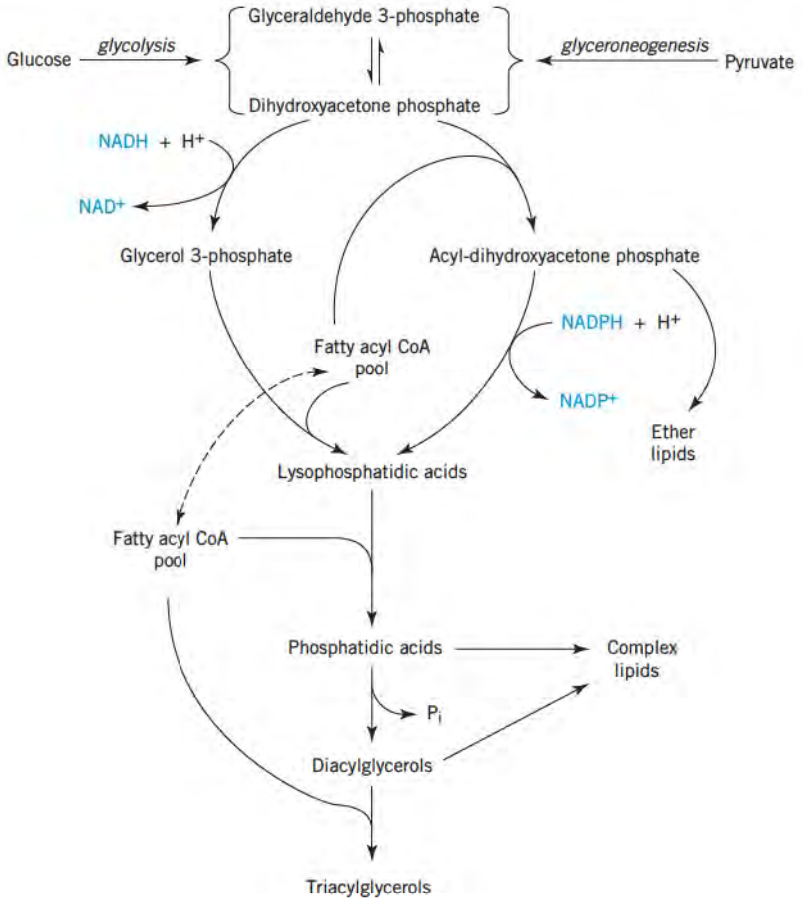


Figure 17.16 Pathways of triacylglycerol synthesis. Some of these intermediates are used as precursors for the synthesis of membrane lipids.

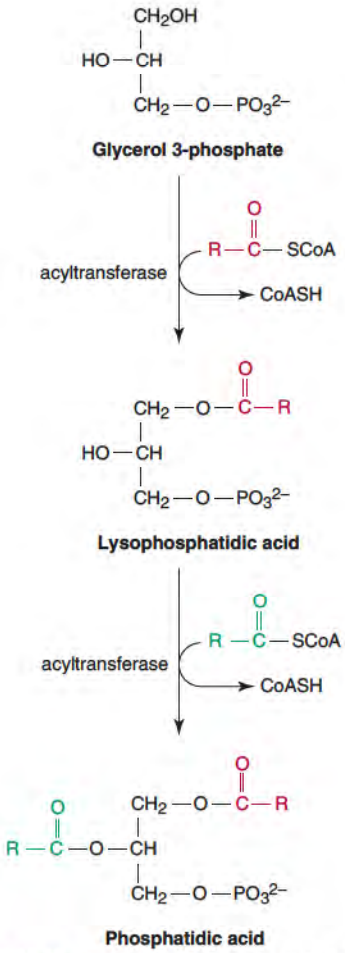

Figure 17.17 Synthesis of phosphatidic acid from glycerol 3-phosphate and fatty acyl CoAs.

plasma lipoproteins, rather than for energy storage. The fatty acids for this process may come from the diet, from adipose tissue via the blood, or from *de novo* synthesis, primarily from the catabolism of dietary glucose.

Triacylglycerols Are Synthesized from Fatty Acyl CoAs and Glycerol 3-Phosphate

Triacylglycerols are synthesized in most tissues from fatty acyl CoAs and a glycerol precursor, **glycerol 3-phosphate** (Figure 17.16). Glycerol 3-phosphate is derived from several sources. In most tissues, it is synthesized by the reduction of dihydroxyacetone phosphate. In the fed state, the dihydroxyacetone phosphate is derived from glucose via glycolysis; in the fasted state in adipose tissue and liver, glycerol 3-phosphate is derived from **glyceroneogenesis** (p. 689). In the liver, there is an additional source of glycerol 3-phosphate; glycerol can be phosphorylated by **glycerol kinase**, which is very active in this tissue.

Fatty acids are activated for further metabolism by conversion to their CoA esters in the following reactions:

$$R{-}C(=O){-}O^- + ATP + CoASH \xrightarrow{\text{acyl-CoA synthetase}} R{-}C(=O){-}SCoA + AMP + PP_i + H_2O$$

This two-step reaction has an acyl adenylate (fatty acyl-AMP) as an intermediate. The overall reaction is driven by the hydrolysis of the pyrophosphate product to two P_i.

The synthesis of triacylglycerols involves the formation of **phosphatidic acid**, which is formed by two sequential acylations of glycerol 3-phosphate to form lysophosphatidic and then phosphatidic acid (Figure 17.17). Phosphatidic acid is used for triacylglycerol synthesis by hydrolysis of the phosphate group by **phosphatidate phosphatase** to yield

diacylglycerol, which is then acylated to triacylglycerol (Figure 17.18). Phosphatidic acid is also a key intermediate in the synthesis of other glycerolipids (p. 712). In an alternative pathway, dihydroxyacetone phosphate is acylated, reduced to lysophosphatidic acid, and then acylated a second time to form phosphatidic acid (see Figure 17.16). Although this is not a major pathway of triacylglycerol synthesis, it is important for the synthesis of membrane lipids with ether-linked alky chains.

Triacylglycerol synthesis follows a different pathway in epithelial cells of the small intestine. These cells take up 2-monoacylglycerols and free fatty acids from the gut, which are the major digestion products of dietary triacylglycerols by pancreatic lipase. An enzyme in the mucosal cells acylates these monoacylglycerols using acyl CoAs as substrates. The resulting diacylglycerols can then be acylated to form triacylglycerols, which are packaged into chylomicrons.

Analysis of human triacylglycerols shows that each position of glycerol is esterified with fatty acids of distinct composition. Saturated fatty acids are found preferentially at position 1 and unsaturated fatty acids at positions 2 and 3. Two main factors that determine the fatty acid composition at each position on glycerol are the specificity of the acyltransferases involved and the relative availability of different fatty acids in the fatty acyl CoA pool.

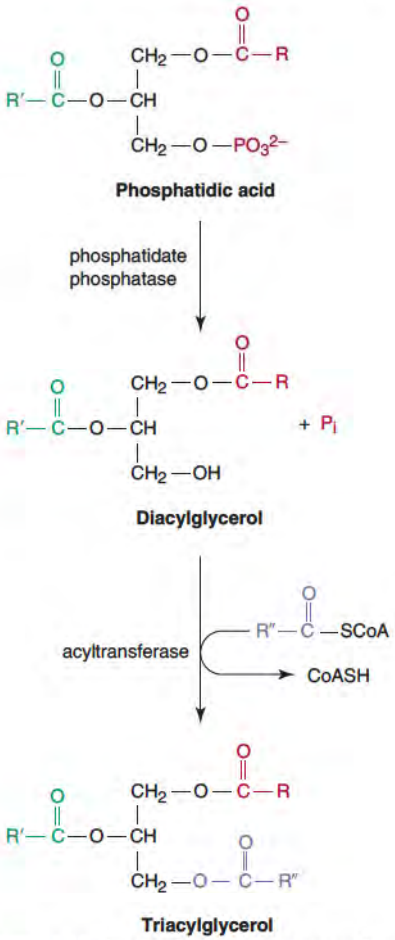

Figure 17.18 Synthesis of triacylglycerol from phosphatidic acid.

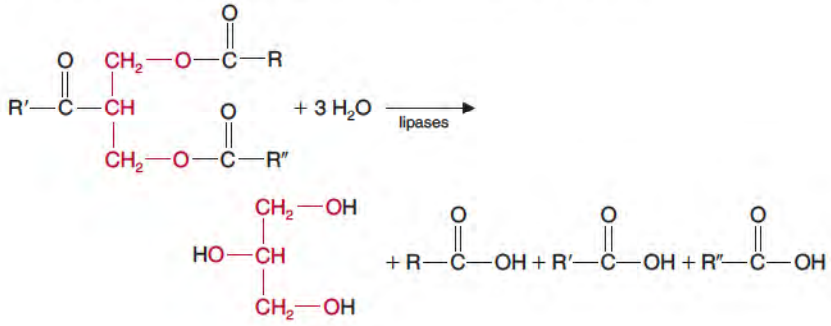
Mobilization of Triacylglycerols Requires Hydrolysis

The first step in mobilizing stored fatty acids for energy production is hydrolysis of triacylglycerol. Several lipases catalyze this reaction and the sequence of hydrolysis of the three acyl chains is determined by the specificities of the lipases involved.



Triacylglycerol Synthesis Occurs during Fasting as Part of a Triacylglycerol–Fatty Acid Cycle Involving Glyceroneogenesis

The release of free fatty acids from adipose tissue is a critical metabolic adaptation to fasting. The quantity of fatty acids released by adipose tissue, however, exceeds the amount used for energy by other tissues. As much as 60% of these fatty acids are redeposited in adipose tissue as triacylglycerols. Both liver and adipose tissue play a major role in this process (Clin. Corr. 17.3). In the fed state, the glycerol 3-phosphate for triacylglycerol synthesis is derived from glucose via glycolysis. During fasting, however, the entry of glucose into adipose tissue is limited because the insulin concentration is low and glucose is being used by other tissues. In this dietary state, glycerol 3-phosphate is synthesized in both the adipose tissue and the liver by glyceroneogenesis. As shown in Figure 17.19, substrates that enter the tricarboxylic acid cycle, such as pyruvate, glutamate, or aspartate, can support net glyceroneogenesis. This pathway is essentially an abbreviated version of gluconeogenesis, in which malate formed in the tricarboxylic acid cycle leaves the mitochondria and is converted to oxaloacetate in the cytosol. Phosphoenolpyruvate carboxykinase then converts oxaloacetate to phosphoenolpyruvate, which is converted to dihydroxyacetone phosphate and then to glycerol 3-phosphate, which is used for triacylglycerol synthesis. The key enzyme in this process is phosphoenolpyruvate carboxykinase; its activity is induced in liver and adipose tissue during fasting.

CLINICAL CORRELATION 17.3

Triacylglycerol/Fatty Acid Cycle

The triacylglycerol that is stored in adipose tissue is hydrolyzed to free fatty acids (FFA) during fasting to provide energy for tissues such as skeletal and cardiac muscle, and indirectly to the brain via ketone bodies. Hormones, most notably insulin, control this process. As the level of insulin falls during fasting, the rate of triacylglycerol hydrolysis (lipolysis) increases, resulting in FFA release from adipose tissue. A surprising aspect of this process is the fate of the FFA; in fasted humans up to 65% of this FFA is re-esterified to triacylglycerol in the liver and other peripheral tissues. In liver the triacylglycerol products are released into the blood as VLDL and sent back to the adipose tissue for deposition as triacylglycerol. This process has been termed the triacylglycerol/fatty acid cycle.

The synthesis of triacylglycerol in mammalian tissues requires glycerol 3-phosphate, which can be derived from dietary glucose via glycolysis in the fed state. During fasting, when low insulin inhibits glucose utilization, the glycerol 3-phosphate for the re-esterification of FFA is generated by glyceroneogenesis, an abbreviated version of gluconeogenesis. In this pathway, pyruvate—or compounds that can generate pyruvate, such as alanine or lactate—is converted to glycerol 3-phosphate via dihydroxyacetone phosphate (Figure 17.19). Recent studies have shown that glyceroneogenesis and not glycolysis is the predominant pathway for the synthesis of glycerol 3-phosphate, even during the fed state. The key enzyme in the pathway of glyceroneogenesis is phosphoenolpyruvate carboxykinase (PEPCK), which is very active in brown and white adipose tissue. If the expression of the PEPCK gene is ablated in the adipose tissue of mice, glyceroneogenesis is inhibited and triacylglycerol storage is reduced. Conversely, overexpression of the PEPCK gene in adipose tissue of transgenic mice increases the rate of glyceroneogenesis, resulting in obesity.

The metabolic logic of the triacylglycerol/fatty acid cycle most likely resides in the importance of fatty acids as a fuel during starvation. In order to ensure that there is sufficient FFA in the blood, more FFA is released from fat cells than is required; what is not used is reesterified to triacylglycerol and redeposited in adipose tissue, at a small energetic cost. The triacylglycerol/fatty acid cycle consumes 3%–6% of the energy in a molecule of triacylglycerol; it is apparently better to have the needed fuel available and pay for it energetically, than to run short at a critical time! The rate of FFA reesterification in the triacylglycerol/fatty acid cycle is a key factor in determining the steady-state concentration of FFA in the blood, a parameter that is directly involved in the etiology of Type 2 diabetes (see Clin. Corr. 17.2, p. 677). The thiazolidinediones, a class of antidiabetic drugs, induce the activity of PEPCK in adipose tissue and increase the rate of FFA reesterification to triacylglycerol via glyceroneogenesis in this tissue, supporting the important role of this process in maintaining lipid homeostasis.

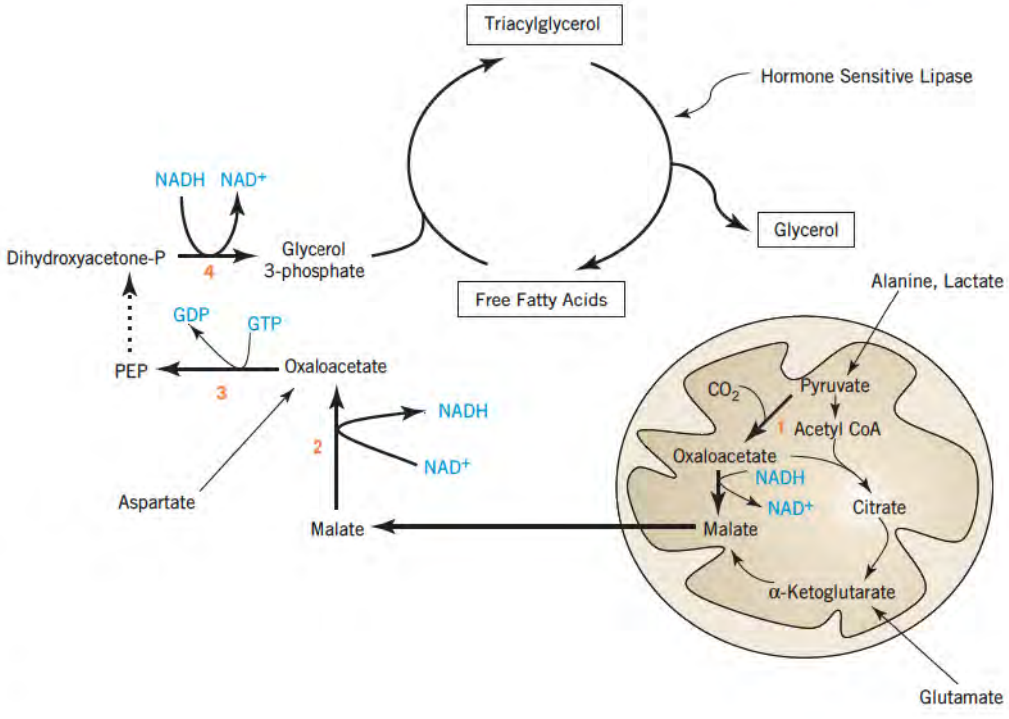

Figure 17.19 The pathway of glyceroneogenesis in the liver and adipose tissue. During fasting, this pathway, which is an abbreviated version of gluconeogenesis, produces glycerol 3-phosphate for triacylglycerol synthesis. The key enzymes of glyceroneogenesis are (1) pyruvate carboxylase, (2) the mitochondrial and cytosolic forms of NAD malate dehydrogenase, (3) phosphoenolpyruvate carboxykinase, and (4) glycerol 3-phosphate dehydrogenase.

17.6 • UTILIZATION OF FATTY ACIDS FOR ENERGY PRODUCTION

Fatty acids in the circulation are taken up by cells and used for energy production, primarily in mitochondria, in a process integrated with energy generation from other sources. Fatty acids are broken down to acetyl CoA in the mitochondria, with the production of NADH and $FADH_2$. These three products are then used in the mitochondrial matrix for energy production via the tricarboxylic acid cycle and oxidative phosphorylation.

The utilization of fatty acids for energy production varies considerably from tissue to tissue and depends to a significant extent on metabolic status, that is, fed or fasted, exercising or resting. Most tissues can use fatty acids as a fuel. Fatty acids are a major energy source in cardiac and skeletal muscle, but the brain does not oxidize fatty acids because they cannot cross the blood–brain barrier. Mammalian red blood cells cannot oxidize fatty acids because they lack mitochondria, the site of fatty acid oxidation. During fasting, the liver converts acetyl CoA, generated by fatty acid oxidation and the breakdown of amino acids, into **ketone bodies**, which become a major fuel after 2–3 days of fasting. Most tissues, including the brain, adapt to fasting by utilizing these ketone bodies.

β-Oxidation of Straight-Chain Fatty Acids Is a Major Energy-Producing Process

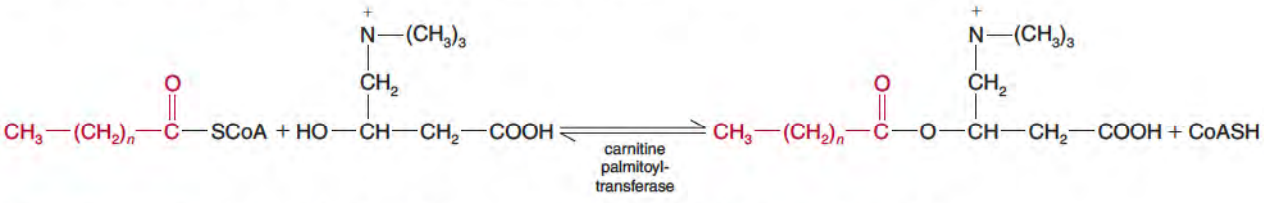
CoA esters of fatty acids are the substrates for oxidation. For the most part, the pathway of fatty acid oxidation is similar, but not identical to, a reversal of the process of fatty acid synthesis. That is, two-carbon fragments are removed sequentially from the carboxyl end of the fatty acid by enzymatic **oxidation, hydration**, and **oxidation** to form a β-keto acid, which is then split by **thiolysis**. The pathway is called **β-oxidation** because carbon 3 (the β-carbon) is oxidized twice prior to cleavage.

Fatty Acids Are Activated by Conversion to Fatty Acyl CoA

The first step in the utilization of a fatty acid is its activation to a fatty acyl CoA. This reaction is catalyzed by enzymes in the endoplasmic reticulum and outer mitochondrial membrane and is the same one used in the synthesis of triacylglycerols. The fatty acyl CoAs are released into the cytosol.

Carnitine Carries Acyl Groups across the Inner Mitochondrial Membrane

Most long chain fatty acyl CoAs are formed outside the mitochondria, but are oxidized in the mitochondrial matrix. The mitochondrial membrane is impermeable to CoA and its derivatives. Fatty acids are transported into the mitochondria using **carnitine (4-trimethylamino-3-hydroxybutyrate)** as a carrier. The process is outlined in Figure 17.20.



The acyl group is transferred from CoA to carnitine by **carnitine palmitoyltransferase I (CPT I)** on the outer mitochondrial membrane. Acyl carnitine and free carnitine are then exchanged across the inner mitochondrial membrane by **carnitine-acylcarnitine translocase**. Finally, the fatty acyl group is transferred back to CoA by **carnitine palmitoyltransferase II (CPT II)** on the matrix side of the inner mitochondrial membrane. This process functions primarily in the transport of fatty acyl CoAs with 12–18 carbons. Genetic abnormalities in this system lead to serious pathological consequences (Clin. Corr. 17.4). By contrast, entry of shorter-chain fatty acids is independent of carnitine; they cross the inner mitochondrial membrane as free fatty acids and become activated to their CoA derivatives in the matrix. CPT I is an important site for the regulation of fatty acid oxidation because its rate controls the

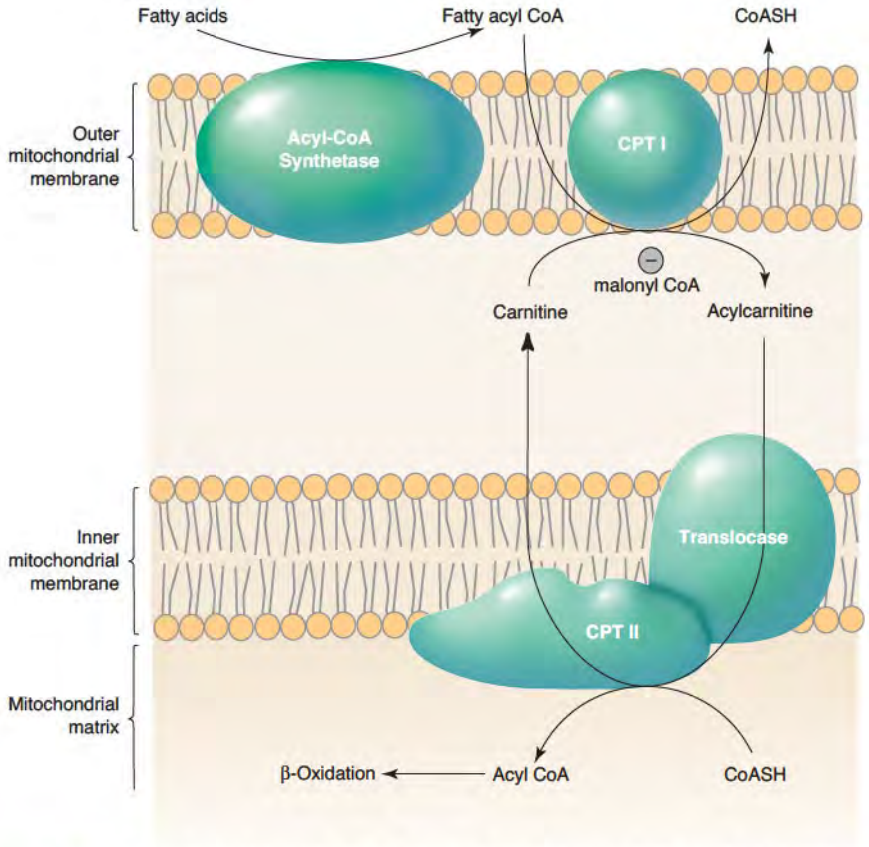


Figure 17.20 Fatty acids are transported into the mitochondria as acylcarnitines for oxidation. Inhibition of carnitine palmitoyltransferase I (CPT I) by malonyl CoA regulates the rate of fatty acid oxidation.

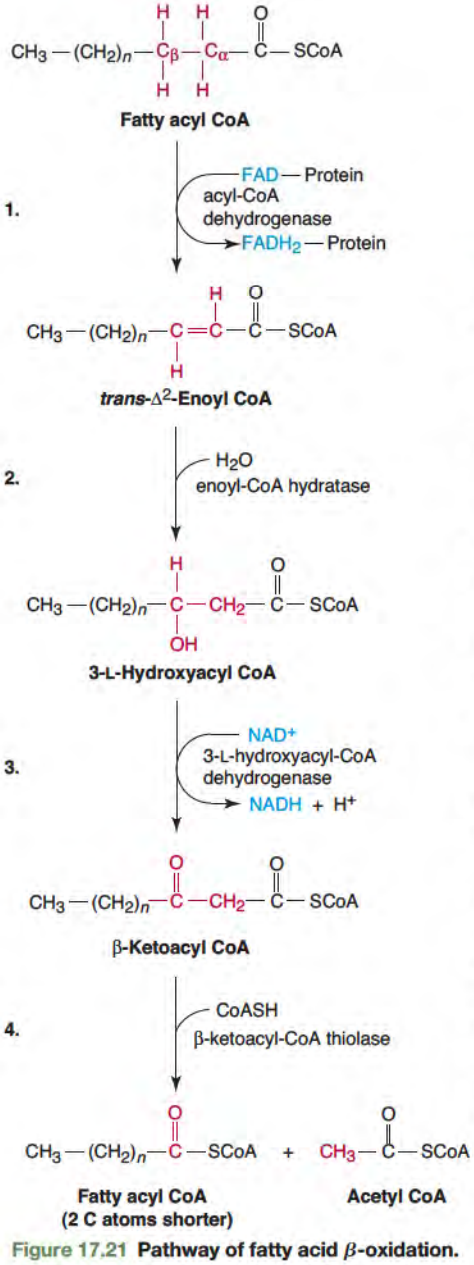

Figure 17.21 Pathway of fatty acid β-oxidation.

entry of fatty acids into the mitochondria and therefore determines the supply of substrate for β-oxidation in the mitochondrial matrix. **Malonyl CoA**, which is the product of acetyl-CoA carboxylase and a key intermediate in fatty acid synthesis (p. 680), is an inhibitor of CPT I.

β-Oxidation Is a Sequence of Four Reactions

β-oxidation is a series of four reactions that act on a fatty acyl Co A to produce an acetyl CoA and a new acyl CoA that is two carbon atoms shorter than the initial substrate (Figure 17.21). Once a fatty acyl CoA is formed at the inner surface of the inner mitochondrial membrane, it can be oxidized by acyl-CoA dehydrogenase, a flavoprotein that uses FAD as the electron acceptor (Reaction 1). The product is an enoyl CoA with a *trans* double bond between the C2 and C3 atoms and enzyme-bound $FADH_2$. As in the tricarboxylic acid cycle, the $FADH_2$ transfers its electrons to enzymes of oxidative phosphorylation, regenerating FAD.

The second step in β-oxidation is hydration of the trans-double bond to a **3-L-hydroxyacyl CoA**, which is oxidized to a **3-ketoacyl CoA** intermediate, with the generation of NADH in the third step. The final step is cleavage of the chain by ketothiolase, generating acetyl CoA and a fatty-acyl CoA that has been shortened by two carbon atoms. This shortened acyl CoA is ready for the next round of oxidation, starting with acyl-CoA dehydrogenase. In most tissues, the acetyl CoA will be used by the tricarboxylic acid cycle and the $FADH_2$ and NADH will be reoxidized by the oxidative phosphorylation pathway with the production of ATP.

Each of the four reactions shown in Figure 17.21 is catalyzed by several different enzymes that have specificity for substrates of different chain lengths. For example, at least four enzymes catalyze the first dehydrogenation step. These are very long-chain, long-chain, medium-chain, and short-chain acyl-CoA dehydrogenases (**VLCAD**, **LCAD**, **MCAD**, and **SCAD**). VLCAD, which oxidizes straight-chain acyl CoAs ranging from C12 to C24, differs from the other family members in that it is membrane associated. MCAD has broad chain length specificity but is most active with C6 and C8 substrates, whereas the order of preference for SCAD is C4 > C6 > C8. LCAD is involved in initiating the oxidation of branched chain fatty acids, for example, 2-methylpalmitoyl CoA.

CLINICAL CORRELATION 17.4

Genetic Deficiencies in Carnitine Transport (OMIM 212140) or Carnitine Palmitoyltransferase (OMIM 600650)

Several diseases result from genetic abnormalities in the transport of long-chain fatty acids across the inner mitochondrial membrane. They stem from deficiencies in the level of carnitine or in the synthesis and transport of acylcarnitines. Mutations can affect carnitine palmitoyl transferases (CPT) or the mitochondrial carnitine-acylcarnitine translocase.

Two categories of carnitine deficiency, primary and secondary, are now recognized. Primary carnitine deficiency is caused by a defect in the high-affinity plasma membrane carnitine transporter in tissues such as muscle, kidney, heart, and fibroblasts (but apparently not in liver where a different transporter is operative). It results in extremely low levels of carnitine in affected tissues and in plasma (because of failure of the kidneys to reabsorb carnitine). The clinical symptoms of carnitine deficiency range from mild, recurrent muscle cramping to severe weakness and death. The very low carnitine level in heart and skeletal muscle seriously compromises long-chain fatty acid oxidation. Dietary carnitine therapy, which raises the plasma concentration of carnitine and forces its entry into tissues in a nonspecific manner, is frequently beneficial. Secondary carnitine deficiency is often associated with inherited defects in the β-oxidation pathway. These disorders frequently cause the accumulation of acylcarnitines, which are excreted in the urine (see Clin. Corr. 17.5, p. 694), thereby depleting the carnitine pool. These acylcarnitines may also impair the uptake of free carnitine by tissues.

There are several different CPT deficiencies. The most common form results from mutations in the CPT II gene that cause a partial loss of enzyme activity. Patients generally experience muscle weakness during prolonged exercise when the muscles rely heavily on fatty acids as an energy source. Myoglobinuria, due to breakdown of muscle tissue, is frequently observed. The disorder is usually referred to as the *muscular* form of CPT II activity deficiency. Mutations causing more severe loss of CPT II activity (90% or greater) can have serious consequences in early infancy. These are usually precipitated by periods of fasting and include hypoketotic hypoglycemia, hyperammonemia, cardiac malfunction, and sometimes death. Similar morbidity and mortality are associated with mutations in the gene for liver CPT I. To date, only a few patients with hepatic CPT I deficiency have been reported, possibly because the disease is frequently lethal. No defects in the muscle isoform of CPT I have been reported.

The first patient with carnitine-acylcarnitine translocase deficiency was described in 1992. Clinical features included intermittent hypoglycemic coma, hyperammonemia, muscle weakness, and cardiomyopathy. The condition proved fatal at age 3 years. Several additional cases with similar symptomatology have since been reported.

These disorders can be treated with a diet that is low in long-chain fatty acids and by avoiding fasting, to minimize conditions where tissues require fatty acid oxidation for energy. The diet can also be supplemented with medium-chain triacylglycerols, because these fatty acids enter the mitochondria by a carnitine-independent mechanism.

Stanley, C. A., Hale, D. E., Berry, G. T., Deleeno, S., et al. A deficiency of carnitine-acylcarnitine translocase in the inner mitochondrial membrane. *N. Engl. J. Med.* 327: 19, 1992; Roe, C. R., and Dong, J. Mitochondrial fatty acid oxidation disorders. In Scriver, C. R., Beaudet, A. L., Sly, W. S., and Valle, D. (Eds.), *The Metabolic and Molecular Bases of Inherited Disease*, 8th ed. New York: McGraw Hill, 2001, II:2297; and Bonnefont, J. P., Demaugre, F., Prip-Buus, C., Saudubray, J., M., et al. Carnitine palmitoyltransferase deficiencies. *Mol. Gen. Metab.* 68: 424, 1999.

A feature unique to the oxidation of long-chain fatty acids is that the enoyl-CoA hydratase, 3-hydroxyacyl-CoA dehydrogenase, and β-ketothiolase steps are all catalyzed by a membrane-bound complex of the three enzymes called **trifunctional protein**. This complex is distinct from the enzymes that catalyze the oxidation of medium and short chain acyl CoAs, all of which are soluble proteins in the mitochondrial matrix. Clin. Corr. 17.5 describes genetic deficiencies of acyl-CoA dehydrogenases.

Energy Yield from the β-Oxidation of Fatty Acids

Each round of β-oxidation produces one acetyl CoA, one $FADH_2$, and one NADH. In the oxidation of palmitoyl CoA, seven cleavages of carbon–carbon bonds take place, with the formation of two acetyl CoAs in the final cleavage. Thus, the β-oxidation of palmitate produces eight acetyl CoA, seven $FADH_2$, and seven NADH. On the basis of current estimates of the yields of ATP in oxidative phosphorylation (p. 572), each $FADH_2$ yields 1.5 ATPs, and each NADH yields 2.5 ATPs when oxidized by the electron transport chain. Therefore, the oxidation of the seven NADH and seven FADH produces 28 ATP. Oxidation of each acetyl CoA through the tricarboxylic acid cycle yields 10 ATP (p. 573), so the eight 2-carbon fragments from a palmitate molecule produce 80 ATP, for a total of 108 ATP. However, two ATP equivalents are used to activate palmitate to palmitoyl CoA (1 ATP is converted to 1 AMP + PP_i). Therefore, each palmitic acid yields 106 ATP/mol on complete oxidation. The importance of fatty acids in supplying the energy needs for human metabolism is discussed on page 849.

CLINICAL CORRELATION 17.5

Genetic Deficiencies in the Acyl-CoA Dehydrogenases

Deficiencies in the acyl-CoA dehydrogenases represent a recently discovered group of inherited disorders that affect the first reaction in the β-oxidation of fatty acids. Patients with mutations that affect enzymes with specificity for different chain length have been described. These include very long-chain acyl-CoA dehydrogenase (VLCAD), long-chain acyl-CoA dehydrogenase (LCAD), medium-chain acyl-CoA dehydrogenase (MCAD), and short-chain acyl-CoA dehydrogenase (SCAD). Patients with these autosomal recessive mutations share many of the same clinical features. The best characterized is MCAD deficiency which, though first recognized in 1982, is among the most common of all inborn errors of metabolism.

MCAD deficiency usually manifests itself within the first 2 years of life. Typical symptoms, which are seen after 12 h or more of fasting, include vomiting, lethargy, and frequently coma, accompanied by hypoketotic hypoglycemia and dicarboxylic aciduria. The absence of ketosis is due to the block in hepatic fatty acid oxidation, which also causes a slowing of gluconeogenesis. This blockade, coupled with impaired fatty acid oxidation in muscle, promotes glucose utilization, leading to profound hypoglycemia. Accumulation of medium-chain acyl CoAs in tissues forces their metabolism through alternative pathways including ω-oxidation and transesterification to glycine or carnitine. Excessive urinary excretion of the reaction products (medium-chain dicarboxylic acids together with medium-chain esters of glycine and carnitine) provide diagnostic clues to this disorder. Many cases previously diagnosed loosely as *Reye-like syndrome* or *sudden infant death syndrome* were in fact due to MCAD deficiency.

Patients with this disorder are treated by avoidance of prolonged fasting and consumption of a high-carbohydrate diet. Supplementing the diet with carnitine replenishes carnitine that is lost by the increased excretion of acylcarnitines. This is consistent with the fact that the metabolic complications of MCAD deficiency are seen only when tissues become heavily dependent on fatty acids as a source of energy.

Comparison of Fatty Acid Synthesis and Oxidation

The pathways of fatty acid synthesis and oxidation are similar. However, like many paired anabolic and catabolic pathways, the synthesis and oxidation of fatty acids are not the reverse of each other. The critical differences between the two pathways are outlined in Table 17.4. They include different cellular locations, different cofactors (NADPH in synthesis and FAD and NAD^+ in oxidation) and the use of ATP to drive malonyl CoA formation for fatty acid synthesis. These differences permit both pathways to proceed in the forward direction because $\Delta G < 0$ for both. The differences also permit independent regulation that prevents futile cycling.

β-Oxidation of Some Fatty Acids Requires Additional Steps

The β-oxidation pathway oxidizes saturated fatty acids with even numbers of carbon atoms to acetyl CoA. However, other fatty acids in the diet, including those with cis double

TABLE 17.4 • Comparison of Schemes for Biosynthesis and β-Oxidation of Palmitate

Parameter	*Biosynthesis*	*β-Oxidation*
Subcellular localization	Primarily cytosolic	Primarily mitochondrial
Phosphopantetheine-containing acyl carrier	Acyl carrier protein	Coenzyme A
Small carbon fragment added or removed	C1 and C2 atoms of malonyl CoA after initial priming	Acetyl CoA
Oxidation–reduction coenzyme	NADPH	FAD when saturated chain dehydrogenated, NAD^+ when hydroxy acid dehydrogenated
Stereochemical configuration of β-hydroxy intermediates	D-β-Hydroxy	L-β-Hydroxy
Energy equivalents yielded or utilized in interconversion of palmitate and acetyl CoA	7 ATP + 14 NADPH = 49 ATP equiv	7 $FADH_2$ + 7 NADH − 2 ATP = 26 ATP equiv

bonds, branched chains, and odd numbers of carbon atoms, require additional steps for their complete oxidation. These steps allow these fatty acids to be used as fuels and prevent their accumulation. Other reactions catalyze the α- and ω-oxidation of fatty acids. **α-Oxidation** occurs at C2 instead of C3 as occurs in the β-oxidation whereas **ω-oxidation** occurs at the methyl end of the fatty acid molecule.

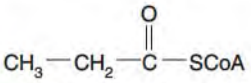

Figure 17.22 **Propionyl CoA.**

Oxidation of Odd-Chain Fatty Acids Produces Propionyl CoA

Fatty acids with an odd number of carbon atoms are oxidized by the β-oxidation pathway. The products of the final cleavage by thiolase are acetyl CoA and **propionyl CoA** (Figure 17.22). Propionyl CoA, which is also produced by the catabolism of isoleucine, valine, and methionine, is metabolized by carboxylation to methylmalonyl CoA and conversion to succinyl CoA (p. 779).

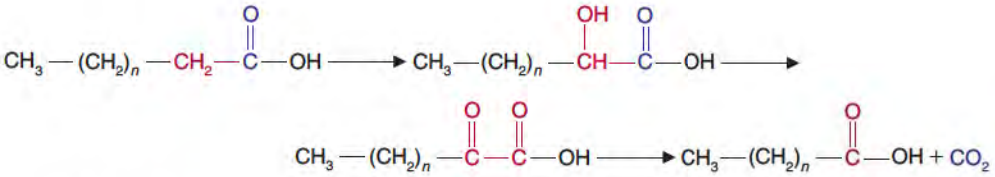
Oxidation of Unsaturated Fatty Acids Requires Additional Enzymes

Unsaturated fatty acids are utilized by β-oxidation, but additional reactions are required to deal with the cis double bonds. Metabolism begins with several rounds of β-oxidation, which generates intermediates that have cis double bonds near the carboxyl carbon. Double bonds beginning at odd- and even-numbered carbon atoms require different strategies. The oxidation of linoleoyl CoA (18:2) (Figure 17.23), illustrates this process. β-oxidation generates an enoyl CoA intermediate with a cis double bond between C3 and C4, instead of the intermediate with a trans bond between C2 and C3 that is required by enoyl-CoA hydratase. **Enoyl-CoA isomerase** changes the cis Δ3 to a *trans*-Δ2-enoyl CoA, which can then be metabolized by β-oxidation.

A second problem occurs when the cis double bond of the acyl CoA intermediate resides between C4 and C5. In this case, the action of acyl-CoA dehydrogenase gives rise to a *trans*-2, *cis*-4-enoyl CoA. This is acted on by 2,4-dienoyl-CoA reductase that produces a *trans*-3-enoyl CoA using reducing equivalents from NADPH. **Enoyl-CoA isomerase** then produces *trans*-2-enoyl CoA, which is a substrate for β-oxidation.

Some Fatty Acids Undergo α-Oxidation

As noted earlier, there are several mechanisms for **hydroxylation of fatty acids**. Some long-chain fatty acids are hydroxylated for sphingolipid synthesis and other shorter-chain fatty acids are hydroxylated on the α carbon in order to start their oxidation. The sequence is as follows:



Some of these hydroxylations occur in the endoplasmic reticulum and mitochondria and involve monooxygenases (P450 family) that require O2 and NADH or NADPH. The α-hydroxylation of fatty acids also occurs in peroxisomes. This is particularly important for the metabolism of branched-chain fatty acids (Clin. Corr. 17.6, p. 697). A branched-chain fatty acid, such as phytanoyl CoA, which is derived from chlorophyll in the diet, is acted on by a hydroxylase in a reaction involving α–ketoglutarate, Fe^{2+}, and ascorbate, with the generation of 2-hydroxyphytanoyl CoA and formyl CoA. The latter is metabolized to CO_2 via formic acid. The 2-hydroxyphytanoyl CoA is then further metabolized to pristanic acid, which undergoes β-oxidation.

ω-Oxidation Gives Rise to Dicarboxylic Acids

ω-Oxidation is another minor pathway for fatty acid oxidation, which occurs in the endoplasmic reticulum of many tissues. In this pathway, hydroxylation takes place on the methyl carbon at the opposite end of the molecule from the carboxyl group or on

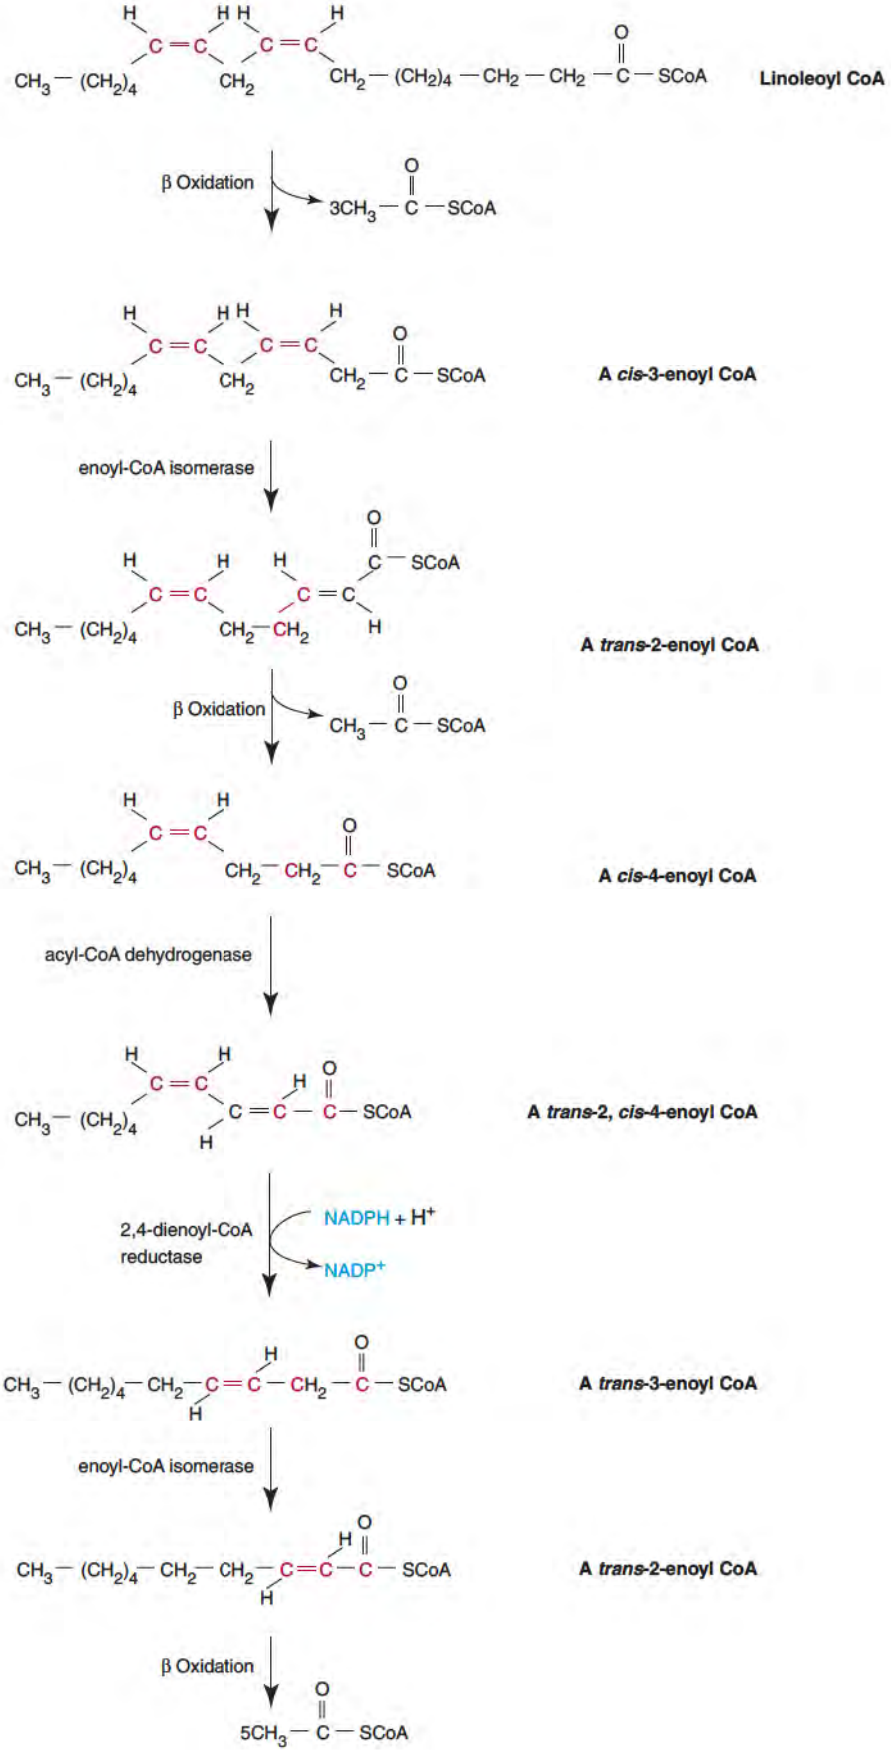


Figure 17.23 **Oxidation of linoleoyl CoA.**

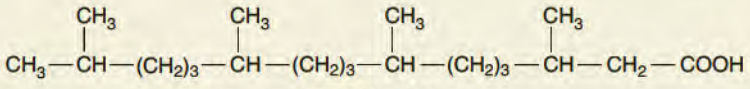
CLINICAL CORRELATION 17.6

Refsum Disease (OMIM 266500)

Although α-oxidation of fatty acids is relatively minor in terms of total energy production, it is significant in the metabolism of branched-chain fatty acids in the diet. A principal example of these is phytanic acid, a metabolic product of phytol, which is a constituent of chlorophyll. Phytanic acid is a significant constituent of milk and animal fats. It cannot be oxidized by β-oxidation because of the presence of the 3-methyl group. It is metabolized by α-hydroxylation followed by dehydrogenation and decarboxylation. β-Oxidation can completely degrade the resulting molecule, producing three molecules of propionyl CoA, three molecules of acetyl CoA, and one molecule of isobutyryl CoA.

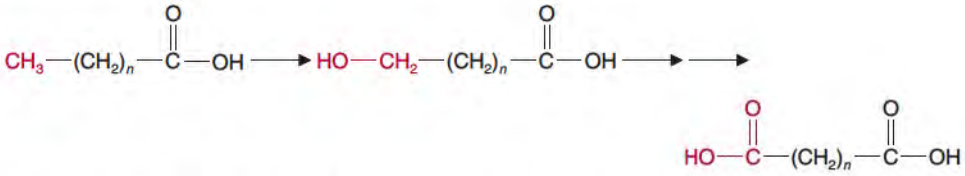
Patients with a rare genetic disease called Refsum disease lack the peroxisomal α-hydroxylating enzyme and accumulate large quantities of phytanic acid in their tissues and sera. This leads to serious neurological problems such as retinitis pigmentosa, peripheral neuropathy, cerebellar ataxia, and nerve deafness. The restriction of dietary dairy and meat products from ruminants results in lowering of plasma phytanic acid and regression of the neurological symptoms.

Wanders, R. J. A., van Grunsven, E. G., and Jansen, G. A. Lipid metabolism in peroxisomes: enzymology, functions and dysfunctions of the fatty acid α- and β-oxidation systems in humans. *Biochem. Soc. Trans.* 28: 141, 2000.



Phytanic acid

the carbon next to the methyl end. It uses a monooxygenase, which requires O_2, and NADPH. Hydroxylated fatty acids can be further oxidized in the cytosol to **dicarboxylic acids** via the sequential action of cytosolic **alcohol** and **aldehyde dehydrogenases**. Medium-chain fatty acids are the principal substrates of this pathway. The overall reactions are



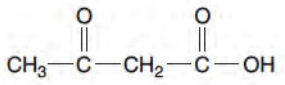
These dicarboxylic acids form CoA esters at either carboxyl group and then undergo β-oxidation to produce shorter-chain dicarboxylic acids such as adipic (C_6) and succinic (C_4) acids. This process also occurs primarily in peroxisomes.

Ketone Bodies Are Formed from Acetyl CoA

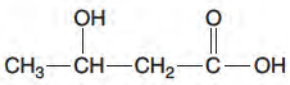
Ketone bodies are water-soluble products of lipid oxidation that are formed in liver and kidney mitochondria during prolonged fasting. The ketone bodies, **acetoacetic acid** and its reduction product **β-hydroxybutyric acid**, are made from acetyl CoA that is produced by fatty acid and amino acid catabolism (Figure 17.24). Ketone bodies are an important adaptation to prolonged fasting; they can be present at high concentrations in the blood (>3 mM) and are an important energy source for many tissues (see Clin. Corr. 17.3, p. 690).

HMG CoA Is an Intermediate in the Synthesis of Acetoacetate from Acetyl CoA

Ketone bodies are formed in the liver (and to a lesser extent in the kidney cortex during prolonged fasting). Their synthesis occurs in the mitochondrial matrix and begins with condensation of two acetyl CoA molecules to form acetoacetyl CoA, in a reaction that is the reverse of the final step of β-oxidation (Figure 17.25). The enzyme involved, **β-ketothiolase**, is an isozyme of the enzyme that functions in β-oxidation. HMG-CoA synthase catalyzes the condensation of acetoacetyl CoA with another molecule of acetyl CoA to form



Acetoacetic acid



β-Hydroxybutyric acid

Figure 17.24 **Structures of ketone bodies.**

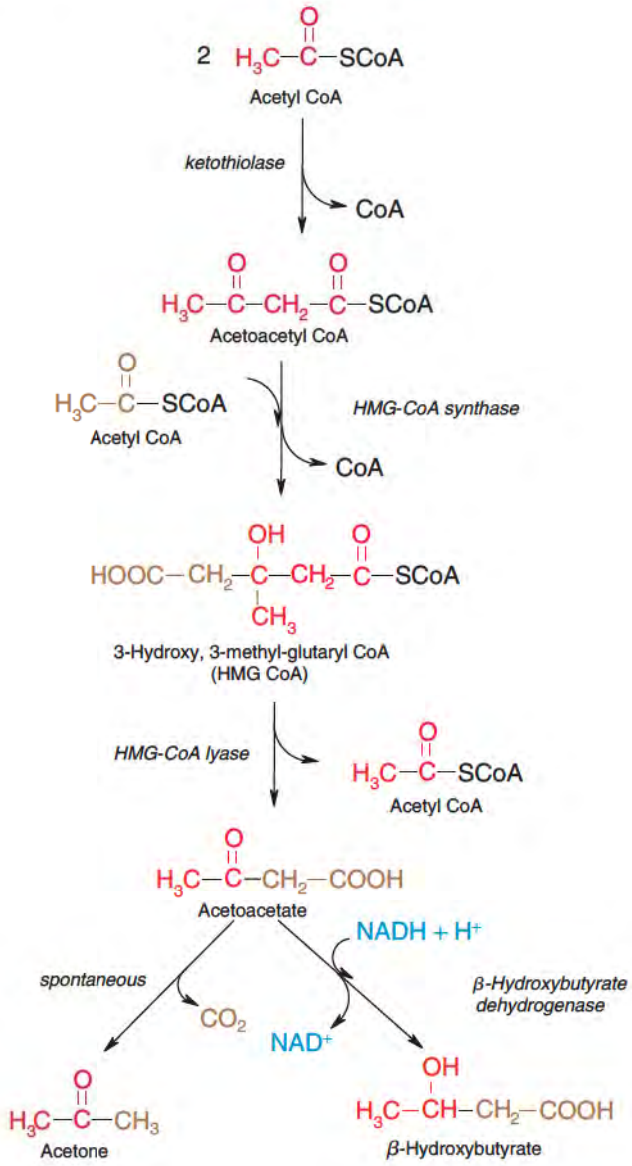


Figure 17.25 Ketone bodies are synthesized from acetyl CoA in hepatic mitochondria.

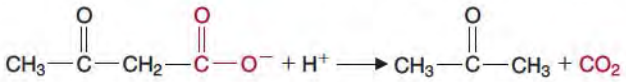
β-hydroxy-β-methylglutaryl coenzyme A (HMG CoA). HMG CoA lyase then cleaves HMG CoA to yield acetoacetic acid and acetyl CoA.

Acetoacetate Forms Both D-β-Hydroxybutyrate and Acetone

Some of the acetoacetate is reduced to D-β-hydroxybutyrate in mitochondria by **D-β-hydroxybutyrate dehydrogenase**. Note that the product of β-hydroxybutyrate dehydrogenase is D-β-hydroxybutyrate, whereas β-hydroxybutyryl CoA formed during β-oxidation is the L isomer. The extent of this reaction depends on the intramitochondrial NAD^+/NADH ratio. Because β-hydroxybutyrate dehydrogenase has high activity in the liver, the concentrations of its substrates and products are maintained close to equilibrium. Thus, the ratio of β-hydroxybutyrate to acetoacetate in the blood reflects the NAD^+/NADH ratio in liver mitochondria. During fasting, this ratio is relatively high because of the NADH generated by fatty acid oxidation, favoring β-hydroxybutyrate formation; in overnight fasted humans, the β-hydroxybutyrate/acetoacetate ratio is ~3:1. β-hydroxybutyrate and acetoacetate are released from liver and kidney for use by other tissues. β-Hydroxybutyrate also exports reducing equivalents from fatty acid oxidation.

Some acetoacetate undergoes spontaneous nonenzymatic decarboxylation to acetone:



Acetone formation is negligible under normal conditions, but at high concentrations of acetoacetate, which can occur in severe diabetic ketoacidosis (Clin. Corr. 17.7), acetone can reach levels high enough to be detectable in the breath.

HMG CoA is also an intermediate in cholesterol synthesis (p. 719). However, the HMG CoA used for ketone body and cholesterol synthesis is present in different metabolic pools. The HMG CoA used for **ketogenesis** is synthesized in hepatic (and renal) mitochondria by an isozyme of HMG-CoA synthase that is expressed at high levels during prolonged fasting. Moreover, HMG-CoA lyase, which converts HMG CoA to acetoacetate and acetyl CoA, is expressed only in hepatic (and renal) mitochondria. In contrast, HMG

CLINICAL CORRELATION 17.7

Ketone Bodies as a Fuel: The Atkins Diet

The current popularity of low-carbohydrate diets for weight loss underscores the importance of the metabolism of ketone bodies as fuels in humans. The best know of these diets was popularized by the late Dr. Robert Atkins in his book *Dr. Atkins' Diet Revolution,* which has sold more than 6 million copies. The Atkins' Diet is high in fat and protein and very low in carbohydrate (less that 20 g/day during the initial phase) and has been highly controversial among the medical establishment because of its high fat content. Individuals on the diet often lose a considerable amount of weight, despite the author's promise that dieters can "stop counting calories and measuring portions." Controlled clinical studies have shown that obese subjects lose more weight on a high-fat/low-carbohydrate diet than on an isocaloric diet with higher levels of carbohydrate. Surprisingly, a marked decrease was noted in the levels of triacylglycerol in the blood of individuals consuming the high-fat/low-carbohydrate diet. As an example, a 2-year trial that compared a low-carbohydrate/high-fat diet (an Atkins-type diet) against a low-fat/high-carbohydrate diet, a Mediterranean-style diet, was performed on 322 subjects, who had an average BMI of 31. Individuals on the high-fat/low-carbohydrate diet lost an average of 10.4 pounds compared with a loss of 6.4 pounds for the group on the high-carbohydrate/low-fat diet. In addition, there was a 20% reduction in the ratio of total cholesterol to HDL cholesterol for the high-fat group and only a 12% reduction in that ratio for the individuals on the high-carbohydrate diet. The authors concluded that the high-fat/low-carbohydrate diet was safe for long-term human consumption and that it provided metabolic benefits; they suggested that it be considered in weight loss programs for obese patients.

Central to the Atkins' Diet is the mobilization of fatty acids from adipose tissue and their conversion by the liver to ketone bodies (β-hydroxybutyrate, acetoacetate, and acetone). An assay of ketone bodies in the urine is the prescribed method of determining metabolic status while on the diet, since even small quantities of dietary carbohydrate will depress ketone body synthesis, largely by inhibiting lipolysis in adipose tissue. As the concentration of ketone bodies rise in the blood, a fraction is excreted in the urine and some via the breath. Could this account for the greater weight loss noted by individuals on the Atkins' Diet? For comparison, after 7 days of fasting, the daily urinary excretion rate of acetoacetate and β-hydroxybutyrate in humans is approximately 110 mmol/day; the excretion rate is even less early in starvation (60 mmol/day after 2 days of starvation). This excretion could contribute to the negative caloric balance and weight loss characteristic of the Atkins' Diet, although the energy loss does not exceed 100 kcal/day. It is most likely, however, that the high fat content of the Atkins Diet reduces appetite and thus food intake. In addition, in the absence of carbohydrate, the diet is monotonous and compliance is a major problem.

In general, ketosis develops when glucose oxidation is suppressed and fat catabolism is accelerated. There are two types of ketosis: the normal ketosis of fasting and the pathological hyperketonemia of diabetic ketoacidosis. No other fuel in the human blood can change so drastically as ketone bodies and still be compatible with life. After an overnight fast, the concentration of ketone bodies is approximately 0.05 mM, but this concentration can rise to 2 mM after 2 days of starvation and to 7 mM after 40 days, a 140-fold change in the concentration. In a seminal study, O. E. Owen and colleagues demonstrated that during prolonged starvation acetoacetate and β-hydroxybutyrate replaced glucose as the predominant fuel for the brain. This reduces the need to synthesize glucose from amino acids derived from muscle and liver protein. Muscle avidly consumes ketone bodies early in starvation but switches to fatty acid oxidation as starvation progresses, thereby sparing ketone bodies for metabolism by the brain. Thus, ketone bodies are a normal fuel for a variety of tissues and are part of a complex pattern of fuel metabolism that occurs during fasting in humans.

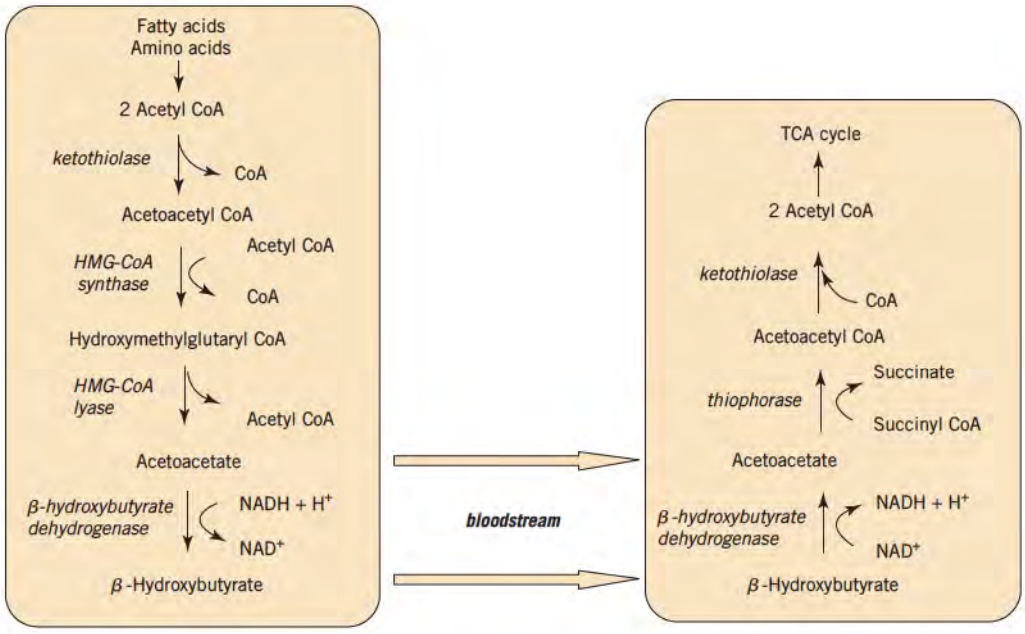

Figure 17.26 Ketone body synthesis and utilization.

CoA for cholesterol synthesis is made at low levels in the cytosol of many tissues by a cytosolic isozyme of HMG-CoA synthase.

Utilization of Ketone Bodies by Nonhepatic Tissues Requires Formation of Acetoacetyl CoA

Acetoacetate and β-hydroxybutyrate produced by the liver are excellent fuels for many nonhepatic tissues, including cardiac muscle, skeletal muscle, and brain, particularly when glucose is in short supply (prolonged fasting) or inefficiently used (insulin deficiency). Under these conditions, these tissues will oxidize free fatty acids, whose blood concentration rises as insulin levels fall. During prolonged fasting, ketone bodies replace glucose as a fuel, particularly in brain, which begins to use ketone bodies after 2–3 days of fasting. This reduces the requirement for glucose production by gluconeogenesis during a prolonged fast, thus "sparing" the muscle protein that contributes amino acids for gluconeogenesis (p. 619). Acetoacetate and β-hydroxybutyrate also serve as precursors for cerebral lipid synthesis during the neonatal period.

Ketone bodies are metabolized in the mitochondria of nonhepatic tissues. β-Hydroxybutyrate dehydrogenase converts β-hydroxybutyrate to acetoacetate by an NAD-linked oxidation in the mitochondrial matrix. Acetoacetate is then converted to its CoA derivative by **acetoacetate:succinyl–CoA transferase** (**thiophorase**), which is present in tissues that use ketone bodies but not in liver. Succinyl CoA serves as the source of the CoA. The reaction is depicted in Figure 17.26. β-Ketothiolase converts the acetoacetyl CoA into two acetyl CoAs, which enter the tricarboxylic acid cycle for energy production.

In summary, the pathways of ketone body synthesis and utilization share several steps. However, there are reactions that are unique to each pathway. The key enzymes of ketone body synthesis, HMG-CoA synthase and HMG-CoA lyase, are expressed in liver (and kidney cortex) but not in other tissues. The key enzyme of ketone body utilization, acetoacetate:succinyl–CoA transferase, is present in many tissues, but not in the liver. These differences ensure that ketone bodies are made in the liver and utilized in other tissues.

Peroxisomal Oxidation of Fatty Acids Serves Many Functions

Although the bulk of fatty acid oxidation occurs in mitochondria, a significant fraction also takes place in the **peroxisomes** of liver, kidney, and other tissues. Peroxisomes are a class of subcellular organelles with distinctive morphological and chemical characteristics

(p. 20). Peroxisomes in the liver contain the enzymes needed for β-oxidation. The mammalian **peroxisomal fatty acid oxidation** pathway is similar to that in plant glyoxysomes, but differs from mitochondrial β-oxidation in three important respects. First, the initial dehydrogenation is accomplished by an oxidase system that uses $\mathbf{O_2}$ and produces $\mathbf{H_2O_2}$ (Figure 17.27). The $\mathbf{H_2O_2}$ is consumed by **catalase**. The remaining steps are the same as in the mitochondrial β-oxidation system. Second, the peroxisomal and mitochondrial enzymes differ in their specificity; the peroxisomal enzymes prefer fatty acids longer than eight carbons. Although rat liver mitochondria carry out the complete oxidation of fatty acyl CoAs to acetyl CoA, β-oxidation in liver peroxisomes will not proceed beyond octanoyl CoA (C_8). Thus, peroxisomes shorten long-chain fatty acids to a point where β-oxidation can be completed in the mitochondria. It is interesting to note that the thiazolidinediones, antidiabetic drugs that reduce peripheral insulin resistance and decrease triacylglycerol levels in patients, cause a marked increase in peroxisomes.

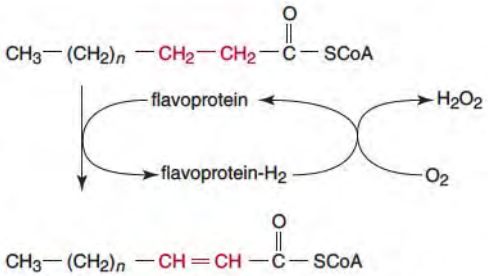

Figure 17.27 Initial step in peroxisomal fatty acid oxidation.

Other peroxisomal reactions include chain shortening of dicarboxylic acids, conversion of cholesterol into bile acids, and formation of ether lipids. Because of these diverse metabolic roles, it is not surprising that the congenital absence of functional peroxisomes, an inherited defect known as Zellweger syndrome, has such devastating effects (see Clin. Corr. 1.7, p. 21).

17.7 • REGULATION OF LIPID METABOLISM

Regulation in the Fed State

The metabolism of lipids in humans is controlled by the dietary status of the individual via a complex set of hormonal signals. After a meal that contains lipid, carbohydrate, and protein, the dietary lipid is deposited as triacylglycerol in adipose tissue. In addition, dietary carbohydrate and amino acids, in excess of that required for energy or for protein synthesis, are converted into fatty acids and deposited in adipose tissue as triacylglycerol. The major anabolic hormone, insulin, is required for both fatty acid synthesis and for the formation of triacylglycerol in adipose tissue. A summary is presented in Tables 17.2, p. 679, and 17.3, p. 683. Insulin acts at two levels; it induces the transcription of genes that code for critical enzymes in the pathways of lipid synthesis and storage (long-term regulation) and it controls processes such as glucose uptake and triacylglycerol hydrolysis (short-term regulation).

Insulin stimulates fatty acid synthesis by increasing the levels of key enzymes, including fatty acid synthase, NADP-malate dehydrogenase (malic enzyme), and acetyl-CoA carboxylase in the liver by inducing the transcription of their genes. Insulin also stimulates the synthesis of glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase, the two enzymes in the oxidative portion of the pentose pathway that generate some of the NADPH that is required for fatty acid synthesis. The short-term effect of insulin on hepatic fatty acid synthesis is exerted by activating a specific **phosphoprotein phosphatase**, which removes phosphate from acetyl-CoA carboxylase, thereby activating this enzyme. Increased flux through glycolysis is also important in providing acetyl CoA for fatty acid synthesis.

In adipose tissue, insulin is required in the fed state for glucose uptake via GLUT 4. The metabolism of this glucose via glycolysis provides glycerol 3-phosphate for the synthesis of triacylglycerol. Insulin also blocks the breakdown of triacylglycerol by inhibiting lipolysis, thereby preventing a futile cycle. As in the liver, insulin exerts its short-term effects by activating phosphoprotein phosphatases. This decreases the phosphorylation of key proteins, including hormone sensitive lipase and perilipin, leading to decreased breakdown of triacylglycerols.

Regulation in the Fasted State

Fasting results in a dramatic alteration in lipid metabolism, with cessation of lipid deposition and reliance on stored triacylglycerol. As the concentration of glucose in the blood

decreases, there is a parallel decrease in the concentration of insulin in the circulation. There is also an increase in epinephrine and glucagon, which increases the level of hepatic cAMP and activates protein kinase A. In adipose tissue, there is increased phosphorylation of hormone sensitive lipase and perilipin, resulting in an increase in triacylglycerol breakdown and the release of free fatty acids and glycerol from this tissue (see Table 17.2, p. 679, for a summary of these controls).

In the liver, these hormonal changes lead to a decrease in fatty acid synthesis, due to reduction in the levels of the key enzymes (see Table 17.3, p. 683). There is also inhibition of the rate-limiting enzyme, acetyl-CoA carboxylase, due to cAMP-dependent phosphorylation of the enzyme. Glycolysis is also inhibited; this decreases the supply of acetyl CoA for lipogenesis. The liver begins to produce ketone bodies as fasting progresses, due to an increase in the rate of fatty acid oxidation caused by increased levels of fatty acids in the blood. During prolonged fasting, about half of the fatty acids that enter the liver are converted to ketone bodies and released into the blood for utilization by tissues such as the muscle, heart, and (after 2 days of fasting) the brain, thereby sparing the use of glucose.

Regulation of Fatty Acid Oxidation

The rate of fatty acid oxidation in mitochondria is controlled by regulating the entry of substrate into this organelle. The key enzyme is carnitine palmitoyltransferase I (CPT I), which synthesizes acyl carnitine from cytosolic acyl CoA (see Figure 17.20, p. 692). In the liver, acetyl-CoA carboxylase is activated in the fed state, because enzyme levels are increased, cyclic-AMP-dependent phosphorylation is low, and the enzyme is activated by citrate. The resulting high concentration of malonyl CoA stimulates fatty acid synthesis, but blocks fatty acid oxidation by inhibiting CPT I. This regulation prevents a futile cycle. Conversely, in the fasted state, the activity of acetyl-CoA carboxylase in the liver is low because enzyme levels are decreased, the enzyme is phosphorylated, and citrate is also decreased. CPT I is active and fatty acid oxidation occurs at a high rate under these conditions because of the low levels of malonyl CoA.

Fatty acid oxidation in muscle is also regulated by malonyl CoA, even though this tissue does not synthesize fatty acids. Muscle contains an isozyme of acetyl-CoA carboxylase, which produces malonyl CoA solely for the regulation of CPT I. The enzyme is activated by citrate and inhibited by phosphorylation. It is phosphorylated by both protein kinase A and an AMP-dependent kinase. Phosphorylation by the former enzyme allows fatty acid oxidation to be regulated by dietary state. In the fed state, the high concentration of insulin results in low levels of phosphorylation. Acetyl-CoA carboxylase produces malonyl CoA, which inhibits CPT I and blocks fatty acid oxidation. Conversely, in the fasted state, the high concentration of cAMP stimulates phosphorylation of acetyl-CoA carboxylase, resulting in its inhibition. As a consequence, CPT I facilitates fatty acid entry into the mitochondria for oxidation. This regulation promotes fatty acid oxidation in the fasted state and inhibits it in the fed state.

The second kinase, which is regulated by AMP, links the rate of fatty acid oxidation to the energy status of the muscle. In resting muscle, AMP levels are low. As a result, the AMP-dependent protein kinase is inactive, acetyl-CoA carboxylase is active, and the malonyl CoA that is generated inhibits CPT I and fatty acid oxidation. In exercising muscle, high levels of AMP activate the protein kinase. The resulting inhibition of acetyl-CoA carboxylase results in low levels of malonyl CoA and the activation of both CPT I and fatty acid oxidation. This regulation allows exercise to stimulate the rate of fatty oxidation through the increased production of AMP.

Fatty Acids as Regulatory Molecules

Fatty acids are themselves regulatory molecules in the liver, muscle, and adipose tissue. In muscle, long-chain acyl CoAs activate protein kinase C, as well as the transcription factors PPARγ and NFκB, which in turn inhibit insulin action by blocking the activation of intermediates in the insulin signaling pathway. These effects of fatty acids have dramatic consequences in the regulation of carbohydrate metabolism in muscle (Clin. Corrs. 17.2 and 17.8).

CLINICAL CORRELATION 17.8

Fatty Acids as Regulatory Molecules

Most textbooks of biochemistry deal extensively with the critical role of fatty acids in energy metabolism and thus stress the pathways of their synthesis, degradation, and modification. However, fatty acids also serve as regulatory molecules, which play a key role in the control of gene transcription, appetite, and hepatic glucose synthesis. Dietary fatty acids regulate gene expression by altering the activity of one of several **p**eroxisome **p**roliferator-**a**ctivated **r**eceptors (PPARs), which are transcription factors in the nuclear receptor family. The importance of the PPARs in the control of energy homeostasis is exemplified by the widespread clinical use of thiazolidinediones, which are PPARγ agonists, for the control of diabetes (see Clin. Corr. 17.1 for a detailed discussion of the role of these transcription factors). Fatty acids activate the PPARs and promote triacylglycerol deposition and glucose utilization by adipocytes. Long-chain fatty acids (LCFA) also act in the brain to regulate appetite via their CoA derivatives. Administration of oleic acid into rat brain ventricles suppresses appetite by lowering the expression of hypothalamic neuropeptides that inhibit appetite (neuropeptide Y and agouti-related protein); the elevated fatty acids in the hypothalamus signal a surfeit of energy. This effect is independent of leptin, a hormone produced in adipose tissue and a key inhibitor of appetite in mammals (see Clin. Corr. 21.1, p. 840). The administration of oleic acid into the brain also markedly decreases hepatic glucose production and the activity of glucose-6-phosphatase, a key enzyme in gluconeogenesis. This effect represents a brain–liver axis, since raising the concentration of oleic acid in the blood does not alter hepatic glucose output. The effect of oleic acid in the brain depends on the activation of K^+ channels by protein kinase C (PKC); several PKC isoforms are activated by fatty acids. Another site of regulation is the upper small intestine. There is evidence in both rodents and humans that fat activates an intestine–brain–liver axis, which signals satiety and controls the synthesis and release of glucose by the liver. The direct administration of fatty acids into the upper intestine increases LCFA CoA levels and suppresses hepatic glucose output. The importance of this axis is established by experiments showing that the effect of LCFA CoA is abolished when innervation of the gut via the vagus nerve is disrupted. Clearly, the view that fatty acids are only a fuel for energy metabolism and a constituent of complex lipids is an oversimplification. These molecules also have complex roles in regulating metabolic adaptations to nutrient availability.

Key Terms

acylglycerols (mono-, di-, and tri-)
fatty acids (saturated, unsaturated, essential, branched chain)
chylomicron
free fatty acids
lipoprotein lipase
pancreatic lipase
very low-density lipoprotein (VLDL)
hormone-sensitive lipase
perilipin
adipose triglyceride lipase
fatty acid synthesis
lipogenesis
lipolysis
coenzyme A (CoA)
fatty acid synthase
malonyl CoA
acyl carrier protein
palmitic acid
ATP citrate lyase
citrate cleavage pathway
anaplerosis/cataplerosis
malic enzyme
fatty acid desaturation
fatty acid elongation
polyunsaturated fatty acids
glycerol 3-phosphate
glycerol kinase
glyceroneogenesis
phosphatidic acid
brown adipose tissue
white adipose tissue
insulin
fatty acid oxidation (β-oxidation)
carnitine/carnitine shuttle
propionyl CoA
ketone bodies
ketogenesis
peroxisomes

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. All of the following statements about acetyl-CoA carboxylase are correct except
- **A.** it catalyzes the rate-limiting step of fatty acid synthesis.
- **B.** it requires biotin.
- **C.** it is inhibited by cAMP-mediated phosphorylation.
- **D.** it is activated by palmitoyl CoA.
- **E.** its content in a cell responds to changes in fat content in the diet.

2. During the synthesis of palmitate in liver cells,
- **A.** the addition of malonyl CoA to fatty acid synthase elongates the growing chain by three carbon atoms.
- **B.** a β-keto residue on the 4′-phosphopantetheine moiety is reduced to a saturated residue by NADPH.
- **C.** palmitoyl CoA is released from the synthase.
- **D.** transfer of the growing chain from ACP to another -SH occurs prior to addition of the next malonyl CoA.
- **E.** the first compound to add to fatty acid synthase is malonyl CoA.

3. In humans, desaturation of fatty acids
- **A.** occurs primarily in mitochondria.
- **B.** is catalyzed by an enzyme system that uses NADPH and a cytochrome.
- **C.** introduces double bonds primarily of *trans* configuration.
- **D.** can occur only after palmitate has been elongated to stearic acid.
- **E.** introduces the first double bond at the methyl end of the molecule.

4. Lipoprotein lipase
- **A.** is an intracellular enzyme.
- **B.** is stimulated by cAMP-mediated phosphorylation.
- **C.** functions to mobilize stored triacylglycerols from adipose tissue.
- **D.** is stimulated by one of the apoproteins present in VLDL.
- **E.** produces free fatty acids and a monoacylglycerol.

5. α-Oxidation
- **A.** is important in the metabolism of branched chain fatty acids.
- **B.** metabolizes a fatty acid completely to acetyl CoA.
- **C.** produces hydrogen peroxide.
- **D.** prevents the fatty acid from producing energy.
- **E.** requires NADPH.

6. Another minor pathway of fatty acid oxidation is ω-oxidation, which results in a hydroxylation. ω-Oxidation
- **A.** occurs in mitochondria.
- **B.** introduces the –OH on the carbon adjacent to the carboxyl group.
- **C.** oxidizes primarily very long-chain fatty acids.
- **D.** oxidizes the terminal methyl group.
- **E.** produces dicarboxylic acids in the initial oxidation.

Questions 7 and 8: Following a severe cold which caused a loss of appetite, a 1-year-old boy was hospitalized with hypoglycemia, hyperammonemia, muscle weakness, and cardiac irregularities. These symptoms were consistent with a defect in the carnitine transport system. Dietary carnitine

therapy was tried unsuccessfully, but a diet low in long-chain fatty acids and supplemented with medium-chain triacylglycerols was beneficial.

7. Carnitine transport of fatty acids from the cytosol to the mitochondria involves all of the following except
- **A.** hydrolysis of ATP.
- **B.** the exchange of acylcarnitine and free carnitine across the inner mitochondrial membrane.
- **C.** two carnitine palmitoyl transferases (CPT I and CPT II) located on different mitochondrial membranes.
- **D.** release of CoASH from fatty acyl CoA in the cytosol.
- **E.** consumption of mitochondrial CoASH.

8. The child was diagnosed with carnitine-acylcarnitine translocase deficiency. The dietary treatment was beneficial because
- **A.** the child could get all required energy from carbohydrate.
- **B.** the deficiency was in the peroxisomal system so carnitine would not be helpful.
- **C.** medium-chain fatty acids (8–10 carbons) enter the mitochondria before being converted to their CoA derivatives.
- **D.** medium-chain triacylglycerols contain mostly hydroxylated fatty acids.
- **E.** medium-chain fatty acids such as C_8 and C_{10} are readily converted into glucose by the liver.

Questions 9 and 10: Medium-chain acyl-CoA dehydrogenase deficiency (MCAD), a defect in β-oxidation, usually produces symptoms within the first 2 years of life after a period of fasting. Typical symptoms include vomiting, lethargy, and hypoketotic hypoglycemia. Excessive urinary secretion of medium-chain dicarboxylic acids and medium-chain esters of glycine and carnitine help to establish the diagnosis.

9. β-Oxidation of fatty acids
- **A.** generates ATP only if acetyl CoA is subsequently oxidized.
- **B.** is usually suppressed during starvation.
- **C.** uses only even-chain, saturated fatty acids as substrates.
- **D.** uses $NADP^+$.
- **E.** occurs by a repeated sequence of four reactions.

10. The lack of ketone bodies in the presence of low blood glucose in this case is unusual since ketone body concentrations usually increase with fasting-induced hypoglycemia. Ketone bodies
- **A.** are formed by removal of CoA from the corresponding intermediate of β-oxidation.
- **B.** are synthesized from cytoplasmic β-hydroxy-β-methyl glutaryl coenzyme A (HMG-CoA).
- **C.** are synthesized primarily in muscle tissue.
- **D.** include both β-hydroxybutyrate and acetoacetate, the ratio reflecting the intramitochondrial $[NADH]/[NAD^+]$ ratio in liver.
- **E.** form when β-oxidation is interrupted.

Questions 11 and 12: One of the problems associated with obesity is the increased risk of Type 2 diabetes. High fatty acid concentration in the blood reduces glucose uptake and metabolism by skeletal muscle, increasing levels of blood glucose and insulin secretion (insulin resistance). Prolonged overproduction of insulin can cause failure of the β cells of the pancreas and Type 2 diabetes. This occurs in ~40% of obese individuals over 5–10 years. One way of regulating the concentration of fatty acids in blood is their reesterification into triacylglycerols. One type of antidiabetic drug (thiazolidinedione) acts on a nuclear receptor (PPARγ2) facilitating the rate of fatty acid esterification in white adipose tissue.

11. All of the following events are usually involved in the synthesis of triacylglycerols in adipose tissue except
- **A.** addition of a fatty acyl CoA to a diacylglycerol.
- **B.** addition of a fatty acyl CoA to a lysophosphatide.
- **C.** a reaction catalyzed by glycerol kinase.
- **D.** hydrolysis of phosphatidic acid by a phosphatase.
- **E.** reduction of dihydroxyacetone phosphate.

12. Glycerol-3-phosphate for triacylglycerol synthesis
- **A.** is always formed by reduction of dihydroxyacetone phosphate.
- **B.** can be formed in liver by glyceroneogenesis but not in adipose tissue.
- **C.** derives its carbons primarily from amino acids in the fed state.
- **D.** can be synthesized only in the presence of phosphoenolpyruvate carboxykinase.
- **E.** is derived primarily from glucose via glycolysis in the fed state.

Problems

13. How does β-oxidation of an unsaturated fatty acid deal with the naturally occurring *cis* double bond when the first step of β-oxidation produces a *trans* enoyl CoA intermediate?

14. How does oxidation of a 17-carbon fatty acid (from plants) lead to the production of propionyl CoA? Be specific in your answer.

Answers

1. D It is activated by citrate and inhibited by long-chain fatty acyl CoAs. C: Since cAMP increases at times when energy is needed, it is consistent that a process that uses energy would be inhibited. E: Long-term control is related to enzyme synthesis and responds appropriately to dietary changes.

2. B A: Splitting CO_2 from malonyl CoA is the driving force for the condensation reaction so the chain grows two carbon atoms at a time. C: In mammals, palmitate is released as the free acid; the conversion to the CoA ester is by a different enzyme. D: It is important to realize that only ACP binds the incoming malonyl CoA so it must be freed before another addition can be made. E: Acetyl CoA adds first to form the foundation for the rest of the chain.

3. **B** A: Desaturation occurs in the endoplasmic reticulum. C: Naturally occurring fatty acids are *cis*. D: Elongation and unsaturation can occur in any order. E: If this were true, we could make linoleic acid.
4. **D** ApoC-II binds the lipoprotein to the enzyme. A–C: These are characteristics of hormone-sensitive lipase. E: This is pancreatic lipase.
5. **A** The presence of a methyl group precludes the β-oxidation process at that point. B: Once past the methyl group, β-oxidation can proceed. C: The reaction is by a hydroxylase that adds an –OH. D: During the α-oxidation phases, energy is produced. E: This hydroxylase uses ascorbate as reducing agent.
6. **D** This is why it is called ω-oxidation. A: Occurs in endoplasmic reticulum. B: This is α-oxidation. C: Medium-chain fatty acids are preferred substrates. E: The hydroxyl group requires alcohol and aldehyde dehydrogenases to convert it to the acid.
7. **A** The exchanges of the acyl group between CoA and carnitine do not require additional energy. B: This is catalyzed by carnitine-acylcarnitine translocase. C: CPT I is on the outer membrane, and CPT II is on the matrix side of the inner membrane. D and E: Only the acyl portion of the molecule is transported; the CoASH molecules remain in their respective compartments.
8. **C** Because medium-chain fatty acids cross the mitochondrial membrane directly, they do not require the carnitine system. A: This is never true. B: Peroxisomal oxidation does not require carnitine, but this is not a peroxisomal system. D: Hydroxylated fatty acids are not a common constituent of triacylglycerols. E: Liver cannot synthesize glucose from fatty acids with an even number of carbon atoms.
9. **E** A and D: It is important to realize that β-oxidation, itself, generates $FADH_2$ and NADH, which can be reoxidized to generate ATP. B: Fatty acid oxidation is usually enhanced during fasting. C: β-Oxidation is a general process requiring only minor modifications to oxidize nearly any fatty acid in the cell.
10. **D** A and E: β-Oxidation proceeds to completion; ketone bodies are formed by a separate process. B and C: Ketone bodies are formed, but not used, in liver mitochondria; cytosolic HMG CoA is a precursor of cholesterol. Ketone bodies are not readily synthesized by muscle.
11. **C** This does not occur to any significant extent in adipose tissue. A, B, and D: The sequential addition of fatty acyl CoAs to glycerol 3-phosphate forms lysophosphatidic acid, then phosphatidic acid whose phosphate is removed before the addition of the third fatty acyl residue. E: This is the formation of α-glycerol phosphate in adipose.
12. **E** This is the primary pathway in liver and adipose tissue. A: Liver can form it from glycerol because it has glycerol kinase. B: Both tissues have this pathway. C and D: These are substrates for gluconeogenesis in the fasted state and require phosphoenolpyruvate carboxykinase.
13. When several rounds of β-oxidation produce an intermediate with a *cis* double bond between C3 and C4, enoyl-CoA isomerase changes the *cis* Δ^3 to a *trans* Δ^2 enoyl CoA and β-oxidation continues. If another *cis* double bond is encountered between C4 and C5, first the normal dehydrogenase, then a reductase with NADPH, followed by the enoyl-CoA isomerase act on the molecule to produce a *trans* 2-enoyl CoA. β-Oxidation continues.
14. β-Oxidation proceeds normally, but the final thiolase cleavage yields acetyl CoA and propionyl CoA. Propionyl CoA is not a substrate for SCAD (short-chain acyl-CoA dehydrogenase) so β-oxidation terminates.

Key Concepts

- Most cells synthesize the major glycerophospholipids and sphingolipids from dietary components and metabolic intermediates. Both are major components of cell membranes.
- Glycerophospholipids have other functions including as components of pulmonary surfactant. Phosphatidylcholine has a role in the HDL-dependent process that carries cholesterol from peripheral tissues to the liver, and inositol-containing phospholipids serve as second messengers and as attachment sites for proteins on the cell surface.
- Cholesterol is synthesized from acetyl CoA in a multistep process in which the synthesis of mevalonate, catalyzed by HMG-CoA reductase, is the rate-limiting, regulated step. The reductase is the target of the statin class of cholesterol-lowering drugs. Cholesterol is the precursor for the synthesis of bile acids and steroid hormones such as testosterone, estrogen, glucocorticoids, and mineralocorticoids.
- Plasma lipoproteins, including HDL, LDL, chylomicrons, VLDL, and a variety of accessory proteins, transport cholesterol and triacylglycerols in blood. Cholesteryl ester transferase has an important role in the process. LDL and LDL-receptors are the major regulatory elements that control the levels of cholesterol in plasma and tissues.
- There are several classes of sphingolipids, including sphingomyelin, cerebrosides, globosides, gangliosides, and sulfatides. Degradation of sphingolipids involves lysosomal enzymes: A genetic deficiency of one or more of these enzymes results in the accumulation of incompletely catabolized sphingolipids and mucopolysaccharides in tissues.
- Arachidonic acid is the precursor of lipid hormones that include prostaglandins, leukotrienes, and lipoxins that mediate various inflammatory phenomena. The key enzymes in these pathways are cyclooxygenase and lipoxygenases.

18.1 • INTRODUCTION

Lipid is a general term that describes substances that are relatively water insoluble and extractable by nonpolar solvents. Complex lipids of humans fall into two broad categories: (1) neutral, nonpolar lipids, such as triacylglycerols and cholesteryl esters, and (2) polar lipids, such as phospholipids and glycolipids. The polar lipids are amphipathic, containing a hydrophobic and hydrophilic region in the same molecule. The hydrophobic and hydrophilic regions in glycerophospholipids are bridged by a glycerol moiety and in sphingomyelin and glycosphingolipids by sphingosine. Triacylglycerol is found primarily in storage sites in adipose tissue, whereas polar lipids occur primarily in cellular membranes.

Complex lipids have many roles. Besides their function in the structure of membranes, some glycerophospholipids are required for the activity of membrane enzymes and inositol-containing phospholipids serve as precursors of signaling molecules Glycosphingolipids have a role in cell–cell recognition, phagocytosis, contact inhibition, and rejection of transplanted tissues and organs. Antigenic determinants of blood groups are primarily glycolipid in nature. Cholesterol is important in atherosclerosis and various sphingolipids accumulate in genetic disorders called sphingolipidoses.

The nomenclature and chemistry of lipids is presented in the Appendix.

18.2 • PHOSPHOLIPIDS

Two major classes of acylglycerolipids are triacylglycerols and glycerophospholipids which have as their core the C_3 polyol, glycerol. Two primary alcohol groups of glycerol are not stereochemically identical, and in the case of phospholipids, it is usually the same hydroxyl group esterified to the phosphate residue. The stereospecific numbering system designates different hydroxyl groups. In this system, when the structure of glycerol is drawn in the Fischer projection with the C2 hydroxyl group projecting to the left of the page, the carbon atoms are numbered as shown in Figure 18.1. When the stereospecific numbering (sn) system is employed, the prefix *sn-* is used before the name of the compound. Glycerophospholipids usually contain a sn-glycerol 3-phosphate moiety. Although each contains the glycerol moiety as a fundamental structural element, neutral triacylglycerols and charged ionic phospholipids have very different physical properties and functions.

Phospholipids Contain Phosphatidic Acid Linked to a Base

Phospholipids are polar, ionic lipids composed of 1,2-diacylglycerol and a phosphodiester bridge that links the glycerol backbone to some base, usually a nitrogenous one, such as choline, serine, or ethanolamine (Figures 18.2 and 18.3). The most abundant phospholipids in human tissues are phosphatidylcholine (also called lecithin), phosphatidylethanolamine, and phosphatidylserine (Figure 18.4). At physiologic pH, phosphatidylcholine and phosphatidylethanolamine have no net charge and exist as dipolar zwitterions, whereas phosphatidylserine has a net charge of –1, causing it to be an acidic phospholipid. Phosphatidylethanolamine (PE) is related to phosphatidylcholine in that trimethylation of PE produces lecithin. Most phospholipids contain more than one kind of fatty acid per molecule, so that a given class of phospholipids from any tissue actually represents a family of molecular species. Phosphatidylcholine (PC) contains mostly palmitic acid (16:0) or stearic acid (18:0) in the sn-1 position and primarily unsaturated 18 carbon fatty acids oleic, linoleic, or α-linolenic in the sn-2 position. Phosphatidylethanolamine has the same saturated fatty acids as PC at the sn-1 position but contains more of the long-chain polyunsaturated fatty acids, namely, linoleic acid [18:2(9,12)], arachidonic acid [20:4(5,8,11,14)], and docosahexaenoic acid [22:6(4,7,10,13,16,19)], at the sn-2 position.

Phosphatidylinositol, an acidic phospholipid that occurs in mammalian membranes (Figure 18.5), is rather unusual because it often contains almost exclusively stearic acid (18:0) in the sn-1 position and arachidonic acid in the sn-2 position.

Another phospholipid composed of a polyol polar head group is phosphatidylglycerol (Figure 18.5), which occurs in relatively large amounts in mitochondrial membranes and pulmonary surfactant and is a precursor of cardiolipin. Phosphatidylglycerol and phosphatidylinositol both carry a formal charge of –1 at neutral pH and are therefore acidic lipids.

Cardiolipin, a very acidic (charge –2) phospholipid, is composed of two molecules of phosphatidic acid linked together covalently through a molecule of glycerol (Figure 18.6). It occurs primarily in the inner membrane of mitochondria of metabolically active tissues (e.g., heart muscle) and in bacterial membranes. Cardiolipin is present in the membrane of *Treponema palladium* and is the antigen detected in the Wasserman test for syphilis. Barth syndrome is a rare X-linked mitochondrial disorder caused by a defect in the TAZ gene, which encodes the protein taffazin which is required for cardiolipin synthesis. Patients with this inherited disorder exhibit cardiomyopathy, skeletal myopathy, and abnormal mitochondria.

Phospholipids mentioned so far contain only *O*-acyl residues attached to glycerol. *O*-(1-alkenyl) substituents occur at C1 of the sn-glycerol in phosphoglycerides in combination with an *O*-acyl residue esterified to the C2 position; compounds in this class are known as plasmalogens (Figure 18.7) or plasmenyl lipids. Relatively large amounts of ethanolamine plasmalogen (also called plasmenylethanolamine) occur in myelin with lesser amounts in heart muscle where **choline plasmalogen** is abundant. The alkenyl moiety is usually 16:0, 18:0 or 18:1(9).

An unusual phospholipid called **platelet activating factor** (**PAF**) (Figure 18.8) is a major mediator of hypersensitivity, acute inflammatory reactions, allergic responses, and anaphylactic shock. In hypersensitive individuals, cells of the polymorphonuclear (PMN) leukocyte family (basophils, neutrophils, and eosinophils), macrophages, and monocytes are coated with IgE molecules that are specific for a particular antigen (e.g., ragweed pollen and bee venom). Subsequent reexposure to the antigen and formation of antigen–IgE complexes on the surface of the aforementioned inflammatory cells provokes synthesis and release of PAF. Platelet activating factor contains an *O*-alkyl moiety at sn-1 and an acetyl residue instead of a long-chain fatty acid in position 2 of the glycerol moiety. PAF is not stored; it is synthesized and released when PMN cells are stimulated. Platelet aggregation, cardiovascular and pulmonary changes, edema, hypotension, and PMN cell chemotaxis are affected by PAF. Inactivation of PAF involves hydrolysis of the acetyl moiety followed by reacylation with a long-chain fatty acid to form an ether-type membrane phospholipid.

Phospholipids in Membranes Serve a Variety of Roles

Although present in body fluids such as plasma and bile, phospholipids are present in highest concentration in cellular membranes where they serve as structural and functional components. Nearly one-half the mass of the erythrocyte membrane is composed

CLINICAL CORRELATION 18.1

Clearance of Red Blood Cells: Role of Phosphatidylserine

The phospholipids of the plasma membrane of cells, including red blood cells, are distributed asymmetrically: The outer leaflet that faces the extracellular space contains the choline lipids phosphatidylcholine and sphingomyelin, whereas the inner leaflet facing the cytoplasm contains phosphatidylethanolamine and negatively charged phospholipids, including phosphatidylserine. Macrophages contain phosphatidylserine receptors that bind, internalize, and degrade phosphatidylserine-displaying cells. Normal aging of red cells is associated with the exposure of phosphatidylserine on the surface of the plasma membrane, which signals cells of the macrophage system to remove them from the circulation.

There is evidence that the anemia and shortened life span of red cells in certain pathologic conditions such as lead intoxication and uremia in patients with renal failure could be due to increased red cell phosphatidylserine exposure. An enzyme called semblase transports phosphatidylserine from the inner leaflet of the plasma membrane to the outer leaflet. Semblase is inactive in healthy cells; however, this calcium-sensitive enzyme becomes active when cells are exposed to stressors (e.g., osmotic shock, ATP depletion, exposure to reactive oxygen species) that increase the intracellular calcium concentration.

Kempe, S. K., Lang, P.A., Eisele, K., et al. Stimulation of erythrocyte phosphatidylserine exposure by lead ions. *Am. J. Cell Physiol.* 288:C396, 2005.

of various phospholipids (p. 458). They also activate certain enzymes; as an example, β-hydroxybutyrate dehydrogenase, in the inner membrane of mitochondria (p. 698), has an absolute requirement for phosphatidylcholine; phosphatidylserine and phosphatidylethanolamine cannot substitute. Phosphatidylserine apparently has a role in clearance of red cells (Clin. Corr. 18.1). Phosphatidylcholine also plays a central role in the process of reverse cholesterol transport.

Dipalmitoyllecithin Is Necessary for Normal Lung Function

Normal lung function depends on a constant supply of dipalmitoyllecithin in which the molecule contains palmitic acid (16:0) residues in the sn-1 and sn-2 positions. More than 80% of the phospholipid in the extracellular fluid layer that lines alveoli of normal lungs is dipalmitoyllecithin. This surfactant produced by type II epithelial cells prevents atelectasis at the end of the expiration phase of breathing (Figure 18.9). It decreases the surface tension of the fluid layer of the lung. Lecithin molecules that do not contain two residues of palmitic acid are not effective in the lowering of surface tension. Surfactant also contains phosphatidylglycerol, phosphatidylinositol, cholesterol, and 18- and 36-kDa proteins (designated surfactant proteins), which contribute significantly to the lowering of the surface tension. Surfactant proteins alter the molecular structure of the phospholipid film secreted by type II pneumocytes in such a way as to stabilize the film and maintain its flexibility. Most of the cholesterol in surfactant is derived from plasma lipoproteins, but the phospholipids are synthesized by type II cells. Before the 28th week of gestation, fetal lung synthesizes primarily sphingomyelin. Normally, at this time, glycogen that has been stored in epithelial type II cells is converted to fatty acids and then to dipalmitoyllecithin. During lung maturation there is a good correlation between the increase in intracellular lamellar inclusion bodies that represent phosphatidylcholine storage organelles, called lamellar bodies, and the decrease in glycogen content of these cells. At the 24th week of gestation, the type II granular pneumocytes appear in the alveolar epithelium and start to produce lamellar bodies. Their number increases until the 32nd week when surfactant appears in the lung and amniotic fluid. In the few weeks before term, screening tests on amniotic fluid can detect newborns that are at risk for respiratory distress syndrome (RDS) (Clin. Corr. 18.2). These are useful in timing elective deliveries, in determining if the mother should receive antenatal corticosteroid therapy to accelerate maturation of the fetal lung, or in applying preventive therapy to the newborn infant. Dexamethasone has been used in neonates with chronic lung disease (bronchopulmonary dysplasia). While corticosteroid therapy may be effective in some cases in improving lung function, in others it causes periventricular abnormalities in the brain. Exogenous human surfactant administered by means of intratracheal instillation is used widely to treat RDS.

Respiratory failure due to surfactant insufficiency also occurs in adults whose type II cells have been destroyed as an adverse side effect of immunosuppressive medications or chemotherapeutic drug (e.g., bleomycin).

The detergent properties of phospholipids, especially phosphatidylcholine, are important in bile to aid in solubilizing cholesterol. An impaired production and secretion of phospholipids into bile can lead to formation of cholesterol stones and bile pigment gallstones. Membrane phospholipids are a reservoir for lipid mediators that regulate many metabolic pathways and processes. Phospholipases catalyze the release of these mediators.

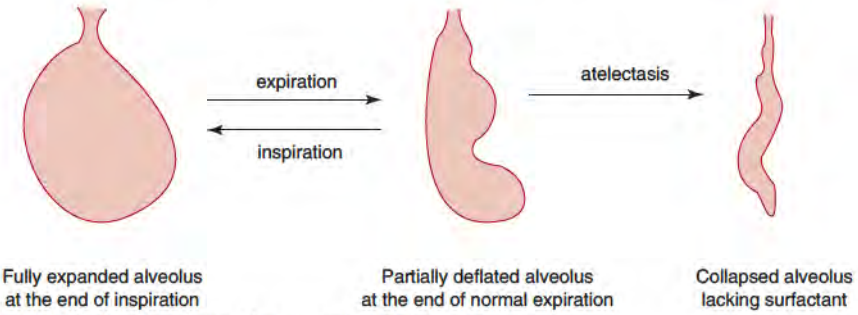

Figure 18.9 Role of surfactant in preventing atelectasis.

CLINICAL CORRELATION 18.2

Respiratory Distress Syndrome

Respiratory distress syndrome (RDS) is a major cause of neonatal morbidity and mortality in many countries. It accounts for about 15%–20% of all neonatal deaths in Western countries and somewhat less in developing countries. The disease affects only premature babies, and the incidence varies directly with the degree of prematurity. Premature babies develop RDS because of immaturity of their lungs from deficiency of pulmonary surfactant. The maturity of the fetal lung can be assessed from the lecithin/sphingomyelin (L/S) ratio in amniotic fluid. The mean L/S ratio in normal pregnancies increases gradually with gestation until about 31 or 32 weeks when the slope rises sharply. The ratio of 2.0 is characteristic of term birth, and it is achieved at the gestational age of about 34 weeks. At pulmonary maturity, the critical L/S ratio is 2.0 or greater. The risk of developing RDS when the L/S ratio is 1.5–1.9 is about 40%, and for less than 1.5 about 75%. Although the L/S ratio is still widely used to predict the risk of RDS, the results are unreliable if the amniotic fluid has been contaminated by blood or meconium. Determination of saturated palmitoyl phosphatidylcholine (SPC), phosphatidylglycerol, and phosphatidylinositol is also predictive of the risk of RDS. Replacement therapy using surfactant from human and animal lungs is effective in the prevention and treatment of RDS.

Gynecol.* 57:295, 1981.

Phosphatidylinositol and phosphatidylcholine are sources of arachidonic acid for synthesis of prostaglandins, thromboxanes, leukotrienes, and related compounds.

Inositides Are Important in Membrane Function

Inositol-containing phospholipids (inositides), especially phosphatidylinositol 4,5-bisphosphate (PIP_2) (Figure 18.10), play a central role in signal transduction systems. When certain hormones bind to their receptors (p. 507), PIP_2 in the inner leaflet of the plasma membrane is hydrolysed by phosphoinositidase C (PIC) into inositol 1,4,5-trisphosphate (IP_3), which triggers release of Ca^{2+} from the endoplasmic reticulum, and 1,2-diacylglycerol (DAG), which increases the activity of protein kinase C (PKC) (Figure 18.11). Removal of the 5-phosphate of IP_3 abolishes the signal and the intracellular Ca^{2+} concentration declines. The 1,2-diacylglycerol is converted to phosphatidic acid by diacylglycerol kinase (Figure

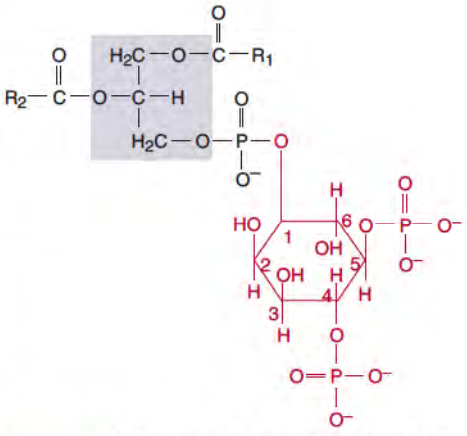

Figure 18.10 **Structure of phosphatidylinositol 4,5-bisphosphate (PIP_2 or PtdIns (4,5)P_2).**

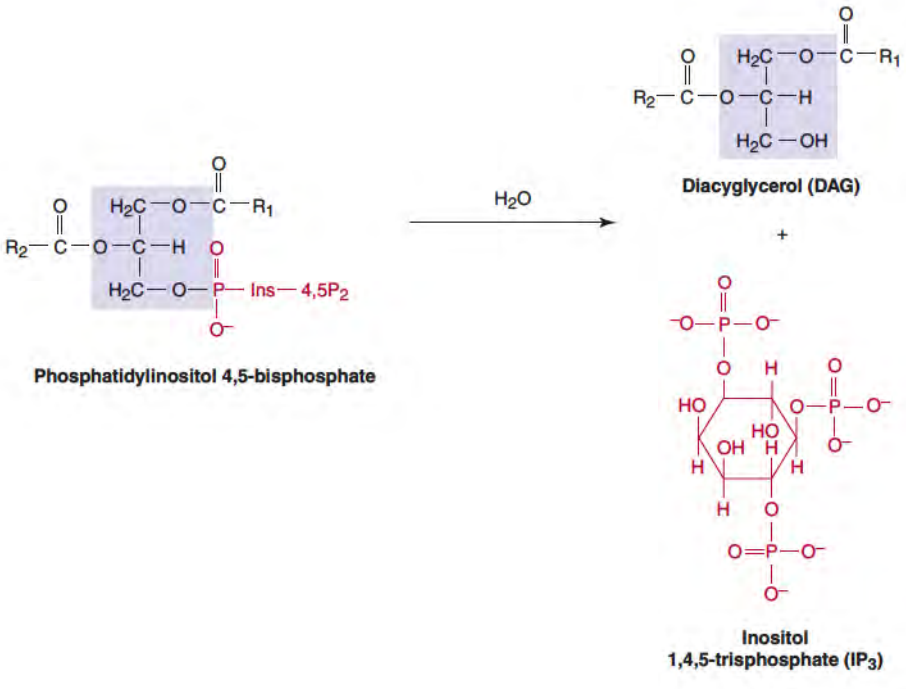

Figure 18.11 **Generation of 1,2-diacylglycerol and inositol 1,4,5-trisphosphate by action of phospholipase C on phosphatidylinositol 4,5-bisphosphate.**

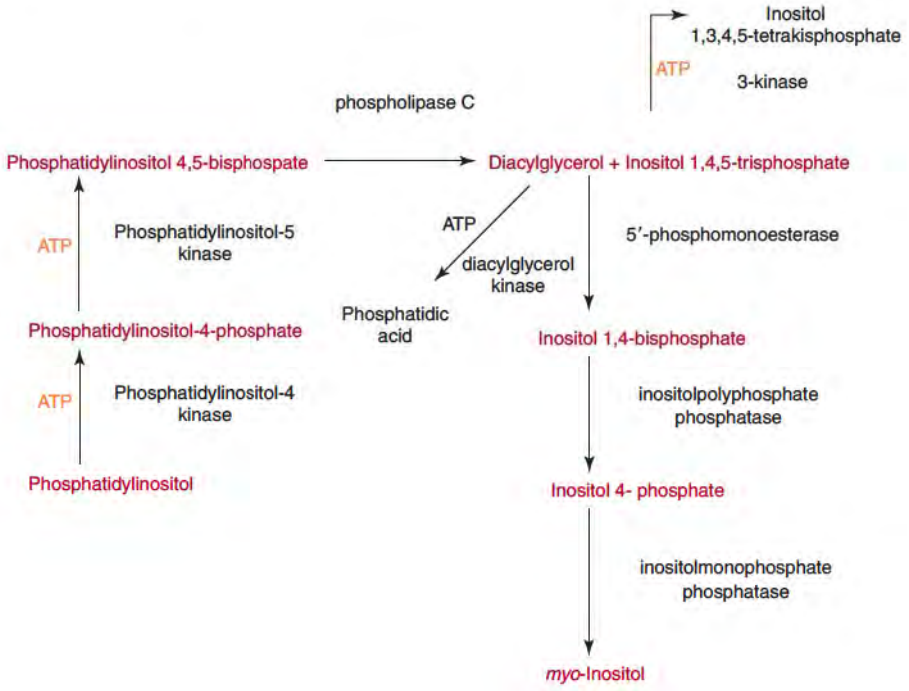

Figure 18.12 Pathways for the synthesis and removal of intracellular inositol 1,4,5-trisphosphate and diacylglycerol.

18.12). Phosphatidic acid, a product of phospholipase D action on phospholipids, has been implicated as a second messenger.

These pathways of inositol phosphate metabolism serve in: (1) removal and inactivation of IP_3, (2) conservation of inositol, and (3) synthesis of polyphosphates such as inositol pentakisphosphate ($InsP_5$) and inositol hexakisphosphate ($InsP_6$) whose functions have not been determined. IP_3 is metabolized by 5-phosphomonoesterase to inositol 1,4-bisphosphate and by a 3-kinase that forms inositol 1,3,4,5-tetrakisphosphate. A family of phosphatases converts $Ins(1,4)P_2$ to myo-inositol (Figure 18.12), which then enters the phospholipid pool.

Besides being a component of membranes and source of arachidonic acid for prostaglandin and leukotriene synthesis (p. 743), phosphatidylinositol serves to anchor (GPI anchor) certain glycoproteins to the external surface (p. 471). A major medical problem concerns trypanosomal parasites (e.g., *Trypanosoma brucei,* which causes sleeping sickness). This parasite has resisted immunological approaches to treatment by changing its surface antigens. The external surface of the plasma membrane is coated with a protein called variable surface glycoprotein (VSG) linked to the membrane through a phosphatidylinositol anchor. C-type phospholipase on the cell surface permits the shedding of the anchored protein allowing trypanosomes to discard surface antigens, thus changing their coat and escaping antibodies of the host's immune system.

Biosynthesis of Phospholipids

Phosphatidic Acid Is Synthesized from α-Glycerophosphate and Fatty Acyl CoA

l-α-Phosphatidic acid (commonly called phosphatidic acid) and 1,2-diacyl-sn-glycerol are intermediates common to the pathways of phospholipid and triacylglycerol synthesis (Figure 18.13; p. 713). All cells synthesize phospholipids to some degree (except mature erythrocytes), whereas triacylglycerol biosynthesis occurs only in liver, adipose tissue, and intestine. In most tissues, the pathway for phosphatidic acid synthesis begins with α-glycerol 3-phosphate (sn-glycerol 3-phosphate). The most general source of α-glycerol 3-phosphate, particularly in adipose tissue, is from reduction of the glycolytic intermediate, dihydroxyacetone phosphate by glycerol 3-phosphate dehydrogenase.

$$\text{Dihydroxyacetone phosphate} + \text{NADH} + \text{H}^+ \leftrightharpoons \text{glycerol 3-phosphate} + \text{NAD}^+$$

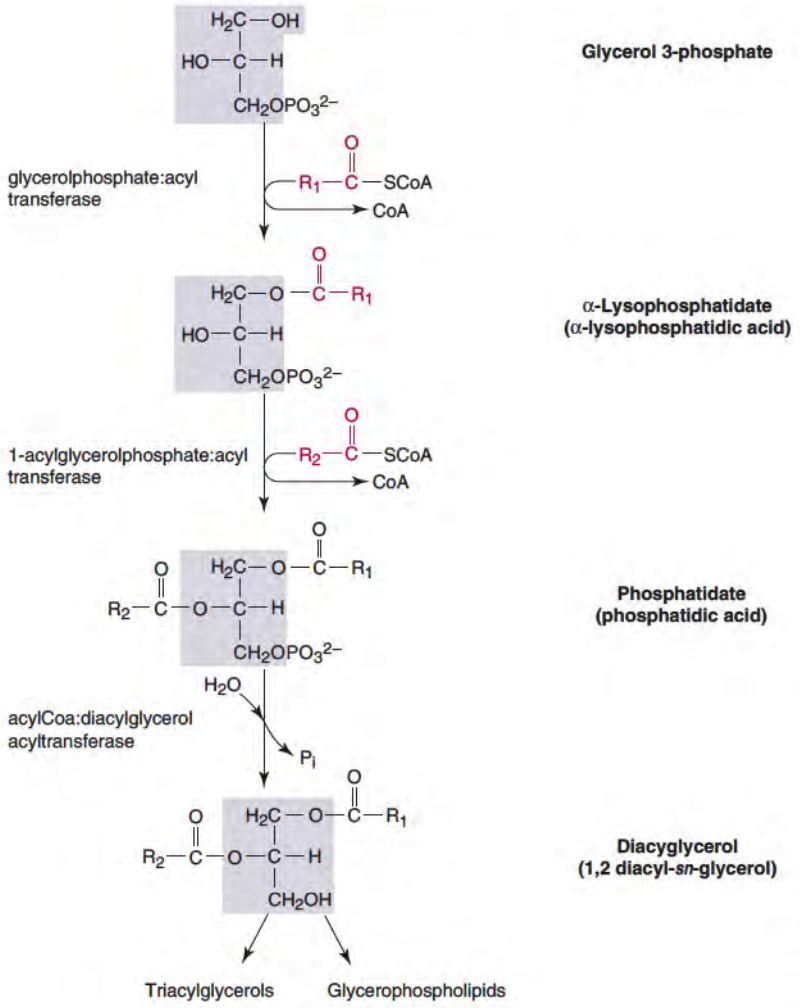

Figure 18.13 Phosphatidic acid biosynthesis from glycerol 3-phosphate and the role of phosphatidic acid phosphatase in synthesis of phospholipids and triacylglycerols. R_1 and R_2 represent long-chain fatty acids.

Liver and kidney derive glycerol 3-phosphate by means of the **glycerol kinase** reaction:

$$\text{Glycerol} + \text{ATP} \xrightarrow{Mg^{+2}} \text{glycerol 3-phosphate} + \text{ADP}$$

Phosphatidic acid synthesis starts with **glycerol 3-phosphate:acyltransferase** attaching predominantly saturated fatty acids or oleic acid to glycerol 3-phosphate to produce 1-acylglycerol phosphate or α-lysophosphatidic acid. 1-Acylglycerol phosphate:acyltransferase then acylates the sn-2 position, usually with an unsaturated fatty acid to produce phosphatidic acid (Figure 18.13). The donors of acyl groups are the CoA derivatives of the appropriate fatty acids.

The specificity of these acyltransferases does not always match the fatty acid asymmetry of the membrane phospholipids of a particular cell. Remodeling reactions, discussed in the following section, modify the composition at C1 and C2 of the glycerol phosphate backbone. Cytosolic **phosphatidic acid phosphatase** hydrolyzes phosphatidic acid generated on the endoplasmic reticulum, thereby yielding 1,2-diacyl-sn-glycerol that serves as the branch point in triacylglycerol and phospholipid synthesis (Figure 18.13).

Phospholipids Are Synthesized by Addition of a Base to Phosphatidic Acid

The major pathway for synthesis of phosphatidylcholine involves sequential conversion of choline to phosphocholine, **CDP-choline**, and phosphatidylcholine. Free choline, a dietary requirement for most mammals including humans, is phosphorylated by choline kinase (Figure 18.14). **Phosphocholine cytidylyltransferase** converts phosphocholine to CDP-choline. Inorganic pyrophosphate (PP_i) is a product of this reaction. The phosphocholine moiety is then transferred to C3 of 1,2-diacylglycerol by

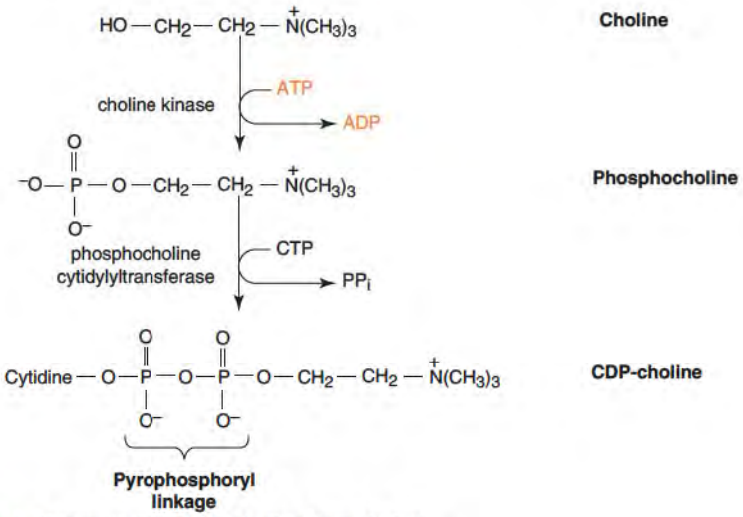

Figure 18.14 **Biosynthesis of CDP-choline from choline.**

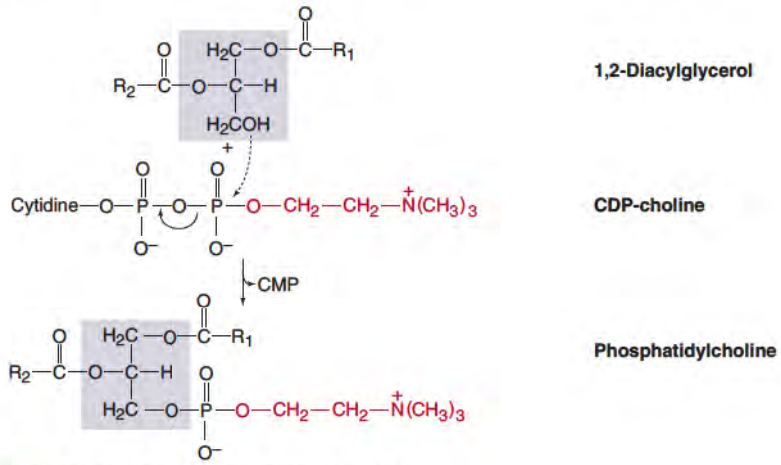

Figure 18.15 **Choline phosphotransferase reaction.**

choline phosphotransferase (Figure 18.15). This is the principal pathway for synthesis of dipalmitoyllecithin in lung.

The rate-limiting step for phosphatidylcholine synthesis is the cytidylyltransferase reaction (see Figure 18.14). This enzyme is regulated by translocation between cytosol and endoplasmic reticulum. The cytosolic form is inactive; binding of the enzyme to the ER membrane activates it. Translocation of cytidyl transferase from cytosol to endoplasmic reticulum is regulated by cAMP and fatty acyl CoA. Reversible phosphorylation of the enzyme by a cAMP-dependent protein kinase releases it from the membrane, rendering it inactive. Dephosphorylation causes it to bind to the ER membrane and become active. Fatty acyl CoAs promote its binding to the endoplasmic reticulum. In liver most of the phosphatidylcholine is formed by repeated methylation of phosphatidylethanolamine. Phosphatidylethanolamine *N*-methyltransferase of the ER transfers methyl groups in sequence from *S*-adenosylmethionine (AdoMet) (Figure 18.16).

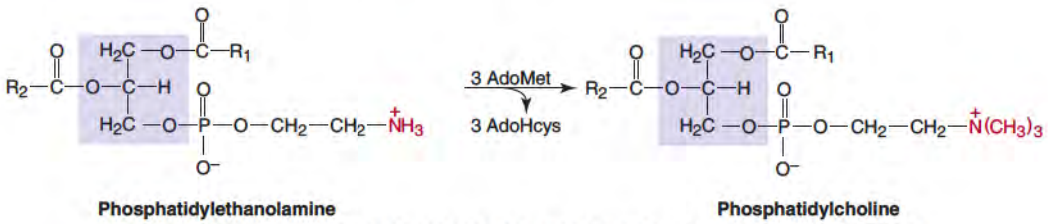

Figure 18.16 **Biosynthesis of phosphatidylcholine from phosphatidylethanolamine and *S*-adenosylmethionine (AdoMet); *S*-adenosylhomocysteine (AdoCys).**

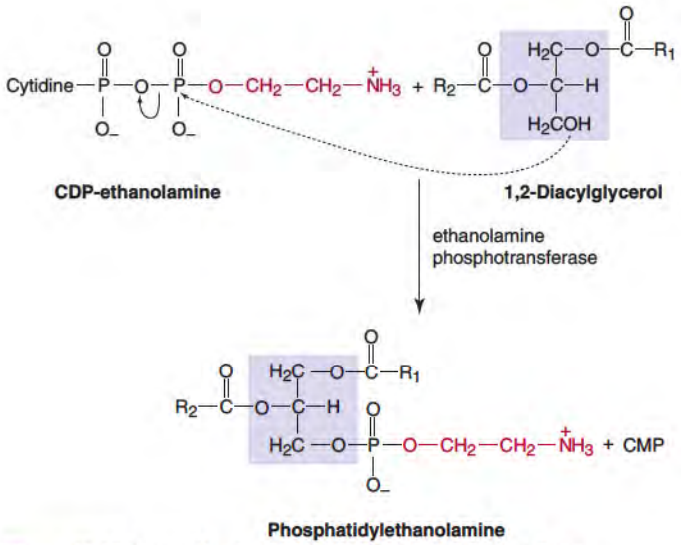

Figure 18.17 **Biosynthesis of phosphatidylethanolamine from CDP-ethanolamine and diacylglycerol.**

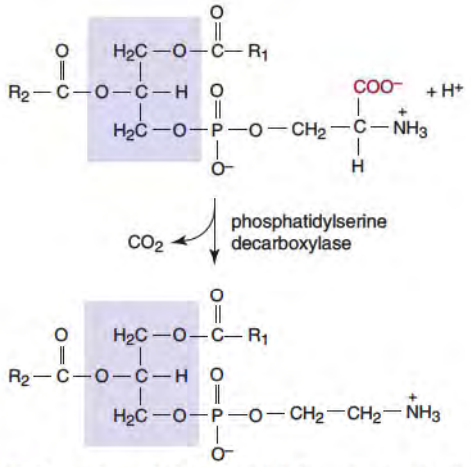

Figure 18.18 **Formation of phosphatidylethanolamine by the decarboxylation of phosphatidylserine.**

Phosphatidylethanolamine synthesis in liver and brain involves ethanolamine phosphotransferase of the endoplasmic reticulum (Figure 18.17). CDP-ethanolamine is formed by ethanolamine kinase

$$\text{Ethanolamine} + \text{ATP} \overset{Mg^{2+}}{\rightleftharpoons} \text{phosphoethanolamine} + \text{ADP}$$

and phosphoethanolamine cytidylyltransferase

$$\text{Phosphoethanolamine} + \text{CTP} \overset{Mg^{2+}}{\rightleftharpoons} \text{CDP-ethanolamine} + PP_i$$

Liver mitochondria also generate phosphatidylethanolamine by decarboxylation of phosphatidylserine, but this is considered a minor pathway (Figure 18.18).

The major source of phosphatidylserine in mammalian tissues is *base exchange* (Figure 18.19) in which the polar head group of phosphatidylethanolamine is exchanged for serine. Since there is no net change in the number or kind of bonds, this reaction is reversible and has no requirement for ATP or any other high-energy compound. Phosphatidylinositol is made via CDP-diacylglycerol and free myoinositol (Figure 18.20) by **phosphatidylinositol synthase** of the endoplasmic reticulum.

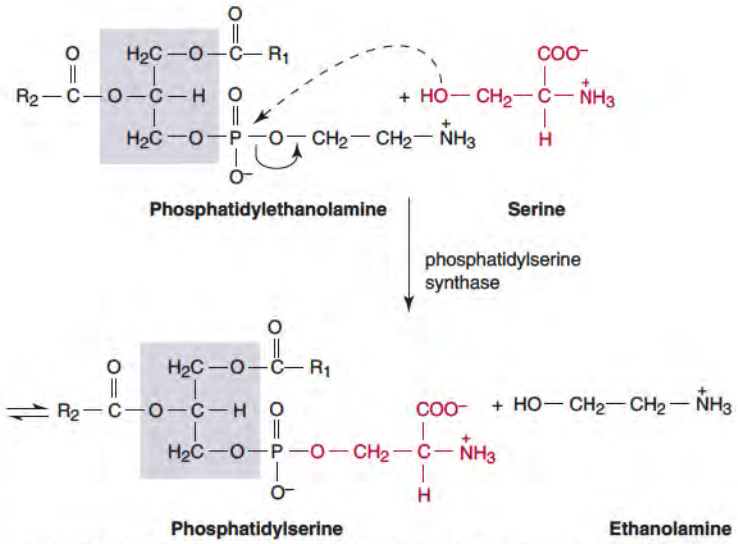

Figure 18.19 **Biosynthesis of phosphatidylserine from serine and phosphatidylethanolamine by base exchange.**

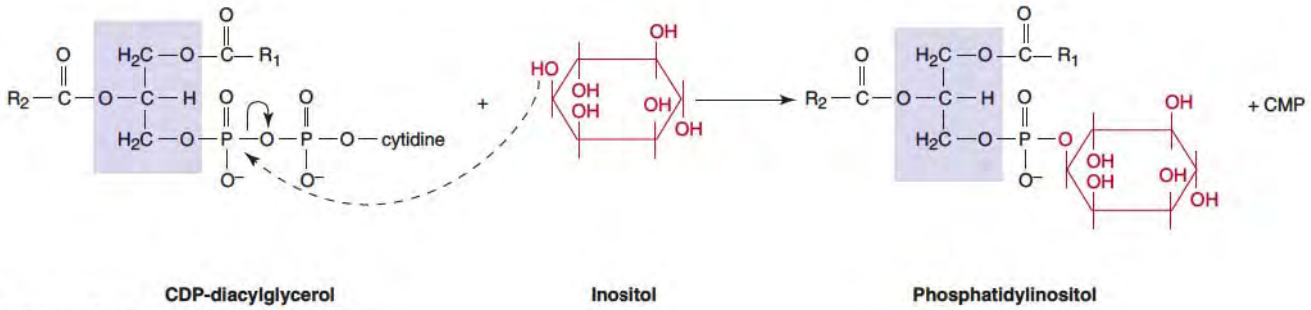

Figure 18.20 **Biosynthesis of phosphatidylinositol.**

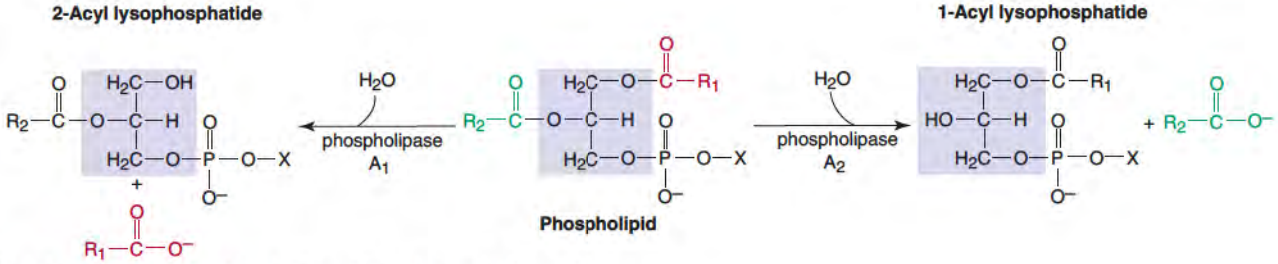

Figure 18.21 **Reactions catalyzed by phospholipase A_1 and phospholipase A_2.**

Asymmetric Distribution of Fatty Acids in Phospholipids Is due to Remodeling Reactions

Phospholipase A_1 and phospholipase A_2 occur in many tissues and function in the remodeling of specific phospholipid structures at the sn-1 and sn-2 positions. Most fatty acyl-CoA transferases and enzymes of phospholipid synthesis lack the specificity required to account for the distribution of fatty acids found in many tissue phospholipids. The fatty acids found in the sn-1 and sn-2 positions of the various phospholipids are often not the same ones transferred to the glycerol backbone in the initial acyl transferase reactions of phospholipid biosynthesis. Phospholipases A_1 and A_2 catalyze reactions indicated in Figure 18.21 where X represents the polar head group of a phospholipid. The phospholipid products are referred to as lysophosphatides or lysophospholipids.

If it becomes necessary for a cell to remove some undesired fatty acid, such as stearic acid from the sn-2 position of phosphatidylcholine, and replace it by a more unsaturated one like arachidonic acid, then this can be accomplished by the action of phospholipase A_2 followed by a reacylation reaction. Insertion of arachidonic acid into the 2 position of sn-2-lysophosphatidylcholine can be accomplished either by direct acylation from arachidonyl CoA by arachidonyl-CoA transacylase (Figure 18.22) or from some other arachidonyl-containing phospholipid by an exchange catalyzed by lysolecithin:lecithin acyltransferase (LLAT) (Figure 18.23). Since there is no change in either the number or nature of the bonds involved in products and reactants, ATP is not required. Reacylation of lysophosphatidylcholine from acyl CoA is the major route for remodeling of phosphatidylcholine.

Lysophospholipids, particularly sn-1-lysophosphatidylcholine, also serve as a source of fatty acid in remodeling reactions. Those involved in synthesis of dipalmitoyllecithin (surfactant) from 1-palmitoyl-2-oleoylphosphatidylcholine are presented in Figure 18.24. Note sn-1 = palmitoyl lysolecithin is the source of palmitic acid in the acyltransferase exchange reaction.

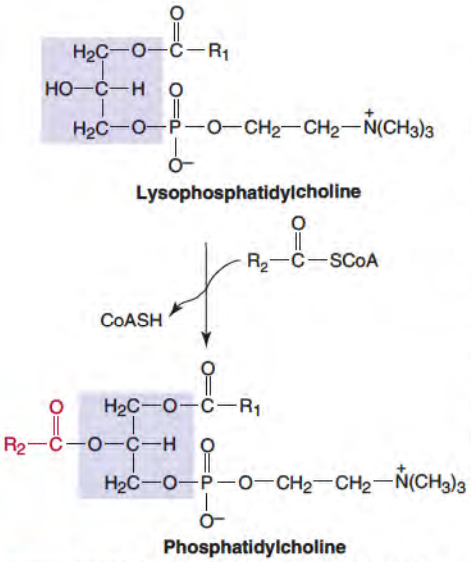

Figure 18.22 **Synthesis of phosphatidylcholine by reacylation of lysophosphatidylcholine where** R_2-C- **represents a rachidonic acid.** This reaction is catalyzed by acyl-CoA:1-acylglycerol-3-phosphocholine *O*-acyltransferase.

Plasmalogens Are Synthesized from Fatty Alcohols

Ether glycerolipids are synthesized from DHAP, long-chain fatty acids and long-chain fatty alcohols as summarized in Figure 18.25. Acyldihydroxyacetone phosphate is formed by acyl-CoA: dihydroxyacetone phosphate acyltransferase (enzyme 1). The ether bond is

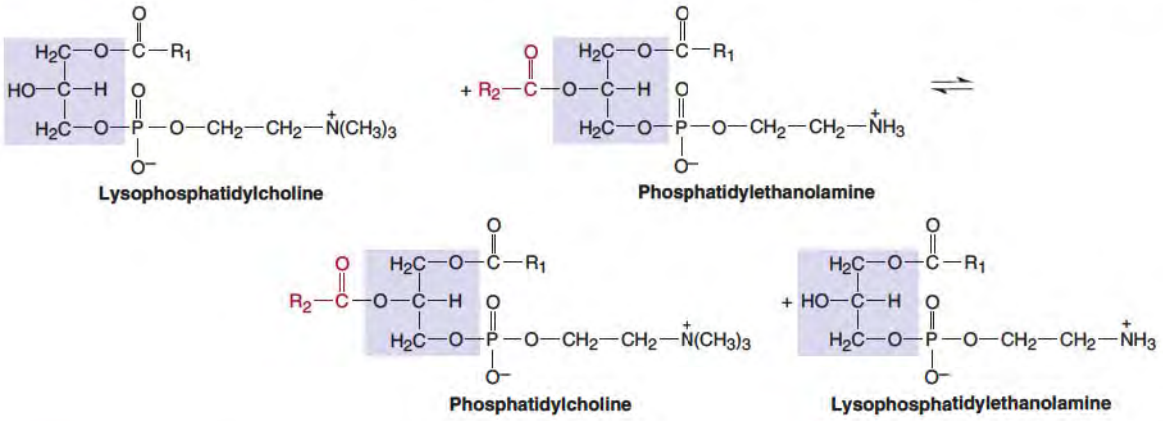

Figure 18.23 Formation of phosphatidylcholine by lysolecithin exchange, where R_2—C(=O)— represents arachidonic acid.

introduced by alkyldihydroxyacetone phosphate synthase (Figure 18.25, enzyme 2) by exchange of the 1-*O*-acyl group of acyldihydroxyacetone phosphate with a long-chain fatty alcohol. The synthase occurs in peroxisomes. Plasmalogen synthesis is completed by transfer of a long-chain fatty acid from its CoA donor to the sn-2 position of 1-alkyl-2-lyso-sn-glycero-3-phosphate (Figure 18.25, Reaction 4). Patients with Zellweger disease lack peroxisomes and cannot synthesize adequate amounts of plasmalogen (see Clin. Corr. 1.7, p. 21).

18.3 • CHOLESTEROL

Cholesterol Is Widely Distributed in Free and Esterified Forms

Cholesterol is an alicyclic compound whose structure includes (1) the perhydrocyclopentenophenanthrene nucleus with its four fused rings, (2) a single hydroxyl group at C3, (3) an unsaturated center between C5 and C6, (4) an eight-membered branched hydrocarbon chain attached to the D ring at C17, and (5) a methyl group (designated C19) attached at position C-10, and another methyl group (designated C-18) attached at position C-13 (Figures 18.26 and 18.27).

Cholesterol has very low solubility in water; at 25°C, the limit of solubility is approximately 0.2 mg/100 dL, or 4.7 μM. The actual cholesterol concentration in plasma of healthy people is usually 150 to 200 mg/dL. This value is almost twice the normal concentration of blood glucose. Such a high concentration of cholesterol in blood is possible due to plasma lipoproteins (mainly LDL and VLDL) that contain large amounts of cholesterol (p. 111). Only about 30% of the total plasma cholesterol is free (unesterified); the rest is cholesteryl esters in which a long-chain fatty acid, usually linoleic acid, is esterified to the C3 hydroxyl of the A ring. This fatty acid residue increases the hydrophobicity of cholesterol (Figure 18.28).

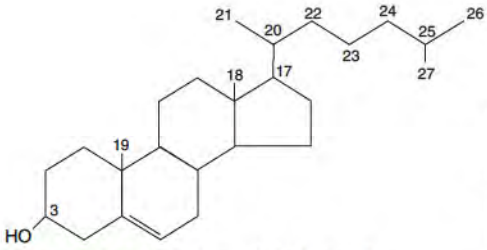

Figure 18.27 **Structure of cholesterol (5-cholesten-3 β-ol).**

Cholesterol, a ubiquitous and essential component of mammalian cell membranes, is abundant in bile (normal concentration is 390 mg/dL, only 4% of which is esterified). Free cholesterol is solubilized partially by the detergent property of the phospholipids in bile that are produced in liver (p. 1058). A chronic disturbance in phospholipid metabolism in liver can lead to deposition of cholesterol-rich gallstones in the biliary tract. Bile salts, which are metabolites of cholesterol, also aid in solubilizing cholesterol. Cholesterol in bile protects gallbladder membranes from potentially irritating or harmful effects of bile salts. Cholesterol is also a precursor of vitamin D (p. 1067).

Total cholesterol is estimated in the clinical laboratory by the Lieberman–Burchard reaction. The ratio of free and esterified cholesterol is determined by gas–liquid chromatography or reverse phase high-pressure liquid chromatography (HPLC).

Cholesterol Is a Membrane Component and Precursor of Bile Salts and Steroid Hormones

Cholesterol is derived from the diet or synthesized *de novo* in all cells of the body. It is the major sterol in humans and a component of all membranes. It is especially abundant in myelinated structures of brain and central nervous system but is present in small amounts in the outer membrane of mitochondria (p. 464). In contrast to plasma where most of the cholesterol is esterified, the cholesterol in cellular membranes is in the free form. The ring

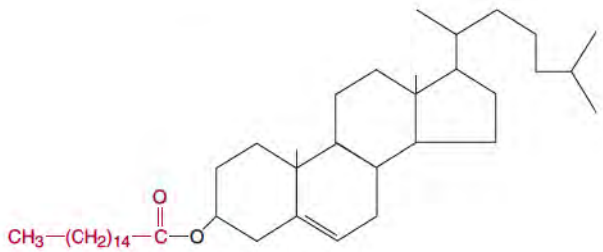

Figure 18.28 **Structure of cholesteryl (palmitoyl-) ester.**

structure of cholesterol cannot be metabolized to CO_2 and water in humans. Excretion of cholesterol is by way of the liver and gallbladder into the intestine in the form of bile acids. Cholesterol is the immediate precursor of bile acids synthesized in liver; they facilitate absorption of dietary triacylglycerols and fat-soluble vitamins (p. 1058).

Cholesterol is the precursor of various steroid hormones (p. 916) including progesterone, corticosteroids (corticosterone, cortisol, and cortisone), aldosterone, and the sex hormones, estrogen and testosterone. Although all steroid hormones are structurally related to and biochemically derived from cholesterol, they have widely different physiological properties. The hydrocarbon skeleton of cholesterol also occurs in plant sterols, for example in ergosterol (Figure 18.29), a precursor of vitamin D, which is converted in skin by ultraviolet irradiation to vitamin D_2 (p. 1067).

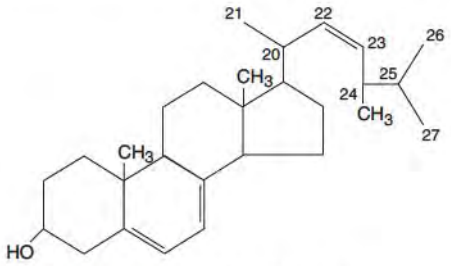

Figure 18.29 **Structure of ergosterol.**

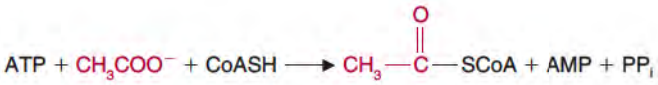
Cholesterol Is Synthesized from Acetyl CoA

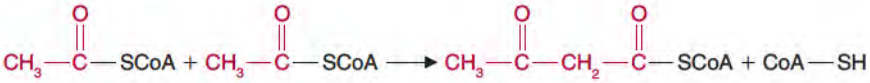
Although synthesis of cholesterol occurs in virtually all cells, the capacity is greatest in liver, intestine, adrenal cortex, and reproductive tissues, including ovaries, testes, and placenta. All carbon atoms of cholesterol are derived from acetate. Reducing power in the form of NADPH is provided mainly by glucose 6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase of the hexose monophosphate shunt pathway (p. 648). Cholesterol synthesis occurs in the cytosol and endoplasmic reticulum and is driven largely by hydrolysis of high-energy thioester bonds of acetyl CoA and phosphoanhydride bonds of ATP.

Mevalonic Acid Is a Key Intermediate

The first compound unique to cholesterol synthesis is mevalonic acid derived from acetyl CoA. There are several sources of acetyl CoA: (1) β-oxidation of fatty acids (p. 692), (2) oxidation of ketogenic amino acids such as leucine and isoleucine (p. 779), and (3) the pyruvate dehydrogenase reaction. Acetate is converted to acetyl CoA at the expense of ATP by acetokinase or acetate thiokinase.



As in the pathway that produces ketone bodies (p. 698), two molecules of acetyl CoA are condensed to acetoacetyl CoA by **acetoacetyl-CoA thiolase** (acetyl-CoA:acetyl-CoA acetyltransferase):



Formation of the carbon–carbon bond in acetoacetyl CoA is favored energetically by cleavage of a thioester bond and generation of coenzyme A.

A third molecule of acetyl CoA is used to form the branched-chain **3-hydroxy-3-methylglutaryl-CoA (HMG CoA)** (Figure 18.30) by **HMG-CoA synthase (3-hydroxy-3-methylutarylyl CoA: acetoacetyl-CoA lyase)**. Liver parenchymal cells contain a cytosolic form of HMG-CoA synthase, which is involved in cholesterol synthesis, and a mitochondrial form that functions in the synthesis of ketone bodies (p. 698). The enzyme catalyzes an aldol condensation between the methyl carbon of acetyl CoA and the β-carbonyl group of acetoacetyl CoA with hydrolysis of the thioester bond of acetyl CoA. The original

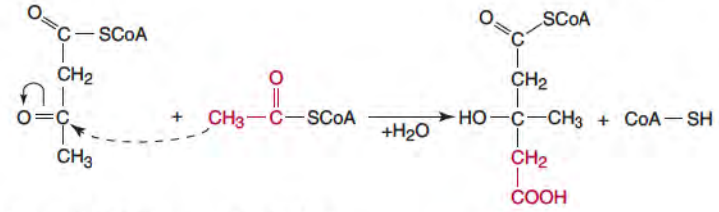


Figure 18.30 **HMG-CoA synthase reaction.**

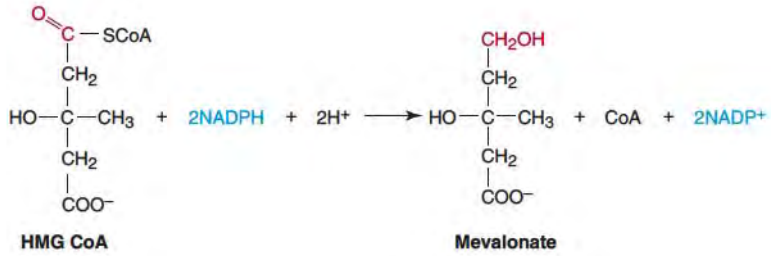

Figure 18.31 HMG-CoA reductase reaction.

thioester bond of acetoacetyl CoA remains intact. HMG CoA is also formed from oxidative degradation of the branched-chain amino acid leucine, through the intermediates 3-methylcrotonyl CoA and 3-methylglutaconyl CoA (p. 777).

Mevalonic acid is formed from HMG CoA by the endoplasmic reticulum enzyme **HMG-CoA reductase** (**mevalonate:NADP$^+$ oxidoreductase**) which has an absolute requirement for NADPH (Figure 18.31). The reduction consumes two molecules of NADPH, results in hydrolysis of the thioester bond of HMG CoA, and generates the primary alcohol group of mevalonate. This reduction is irreversible and produces (R)-(+) mevalonate. HMG-CoA reductase catalyzes the rate-limiting reaction in cholesterol biosynthesis. It is an intrinsic protein of the endoplasmic reticulum with its catalytic C-terminal domain extending into the cytosol. Phosphorylation of HMG-CoA reductase diminishes its catalytic activity (V_{max}) and enhances its degradation by increasing its susceptibility to proteolysis. Increased intracellular cholesterol stimulates phosphorylation of HMG-CoA reductase.

The central role of HMG-CoA reductase in cholesterol homeostasis is evidenced by the effectiveness of a family of drugs called statins used to lower plasma cholesterol levels. Statins (e.g., lovastatin, pravastatin, fluvastatin, cerivastatin, atorvastatin, simvastatin) inhibit HMG-CoA reductase activity, particularly in liver, and commonly decrease total plasma cholesterol and LDL-cholesterol by as much as 50%.

Mevalonic Acid Is Precursor of Farnesyl Pyrophosphate

Reactions that convert mevalonate to **farnesyl pyrophosphate** are summarized in Figure 18.32. The stepwise transfer of the terminal phosphate group from two molecules of ATP to mevalonate (A) to form 5-pyrophosphomevalonate (B) is catalyzed by mevalonate kinase (enzyme I) and phosphomevalonate kinase (enzyme II). Decarboxylation of 5-pyrophosphomevalonate by pyrophosphomevalonate decarboxylase generates Δ^3-isopentenyl pyrophosphate (D). In this ATP-dependent reaction, ADP,

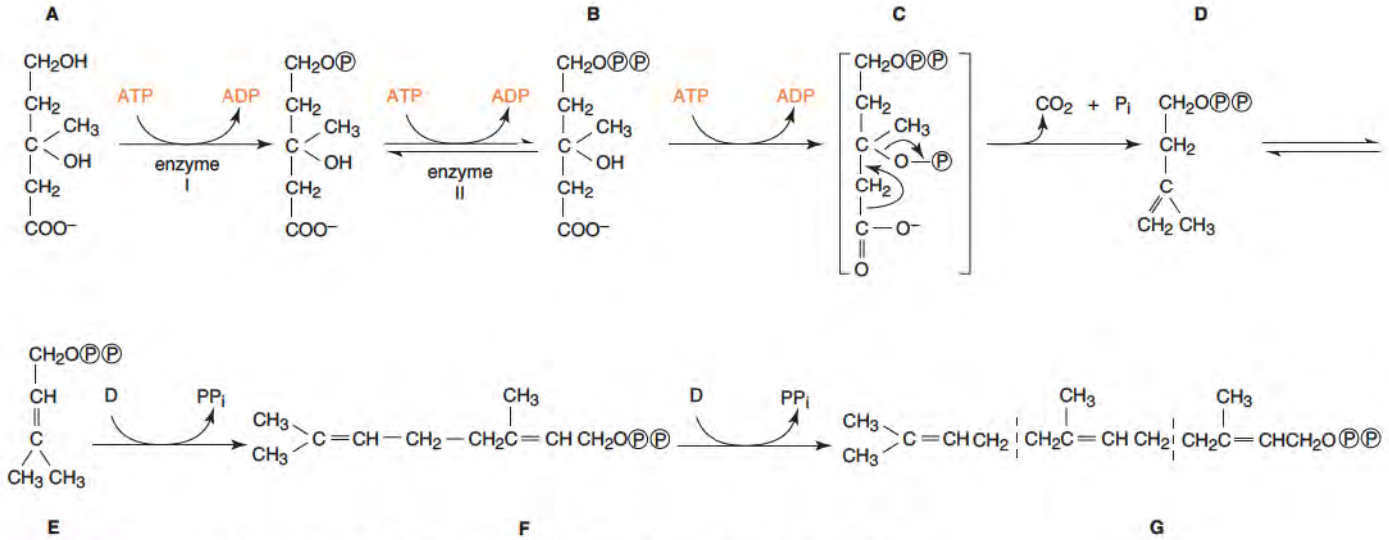

Figure 18.32 Formation of farnesyl-PP (F) from mevalonate (A). Dotted lines divide molecules into isoprenoid-derived units. D is 3-isopentenyl pyrophosphate.

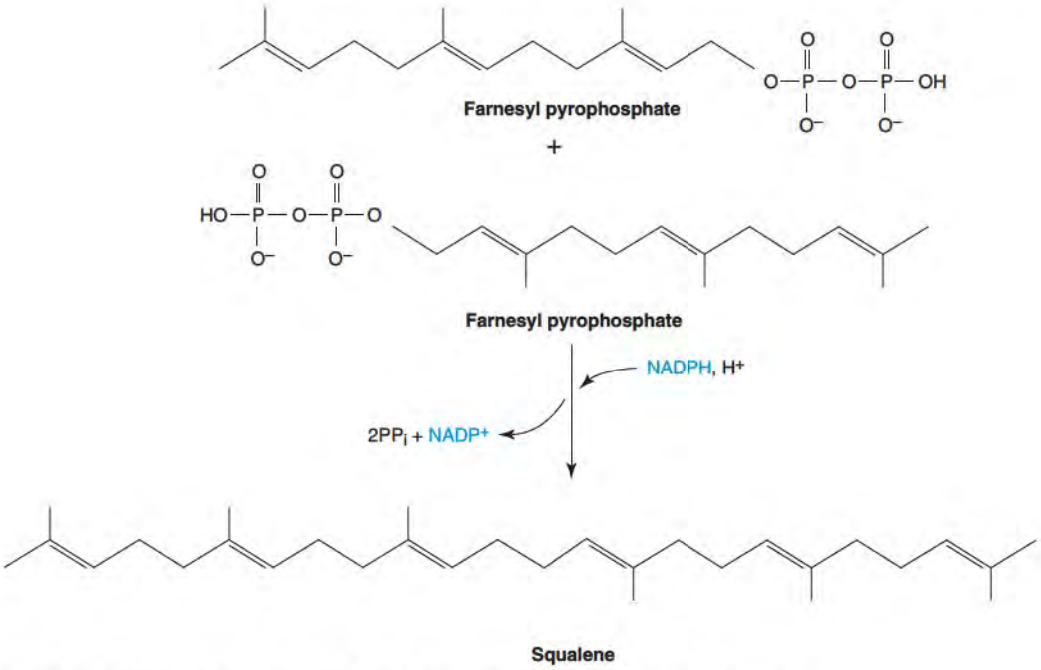

Figure 18.33 Formation of squalene from two molecules of farnesyl pyrophosphate.

P_i, and CO_2 are produced. It is thought that decarboxylation–dehydration proceeds by way of the intermediate 3-phosphomevalonate 5-pyrophosphate (C). Isopentenyl pyrophosphate is converted to its allylic isomer 3,3-dimethylallyl pyrophosphate (E) by isopentenyl pyrophosphate isomerase in a reversible reaction. The condensation of 3,3-dimethylallyl pyrophosphate (E) and 3-isopentenyl pyrophosphate (D) generates geranyl pyrophosphate (F).

The stepwise condensation of three C_5 isopentenyl units to form the C_{15} farnesyl pyrophosphate (G) is catalyzed by a cytosolic prenyl transferase called **geranyltransferase**.

Cholesterol Is Formed from Farnesyl Pyrophosphate via Squalene

The last steps in cholesterol synthesis involve "head-to-head" fusion of two molecules of farnesyl pyrophosphate to form squalene and finally cyclization of squalene to yield cholesterol. Formation of the C_{30} carbon molecule of squalene (Figure 18.33) by squalene synthase of endoplasmic reticulum releases two pyrophosphate groups and requires NADPH. Several intermediates probably occur. By rotation about carbon–carbon bonds, the conformation of squalene indicated in Figure 18.34 can be obtained. Note that the overall shape of squalene resembles that of cholesterol and that squalene is devoid of oxygen atoms.

Cholesterol synthesis from squalene by squalene cyclase proceeds through the intermediate lanosterol, which contains the fused tetracyclic ring system and an eight-carbon side chain:

$$\text{Squalene} \longrightarrow \text{squalene 2,3-epoxide} \longrightarrow \text{lanosterol}$$

The ER enzyme that catalyzes this reaction is bifunctional and contains squalene epoxidase or monooxygenase and a cyclase (**lanosterol cyclase**) activity. The many carbon–carbon bonds formed during cyclization of squalene are generated in a concerted fashion as indicated in Figure 18.35. The OH group of lanosterol projects above the plane of the A ring; that is, it is in the β-orientation. In this reaction sequence, an OH group is added to C3, two methyl groups undergo shifts and a proton is eliminated.

Cyclization is initiated by epoxide formation between the future C2 and C3 of cholesterol, the epoxide being formed at the expense of NADPH.

$$\text{Squalene} + O_2 + \text{NADPH} + H^+ \longrightarrow \text{squalene 2,3-epoxide} + H_2O + \text{NADP}^+$$

The hydroxylation at C3 triggers the cyclization of squalene to lanosterol (Figure 18.35).

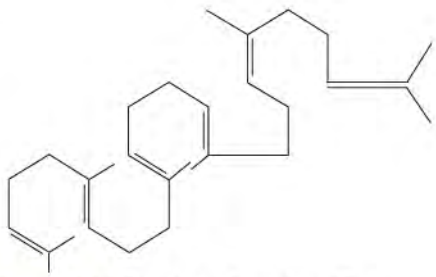

Figure 18.34 Structure of squalene (C_{30}).

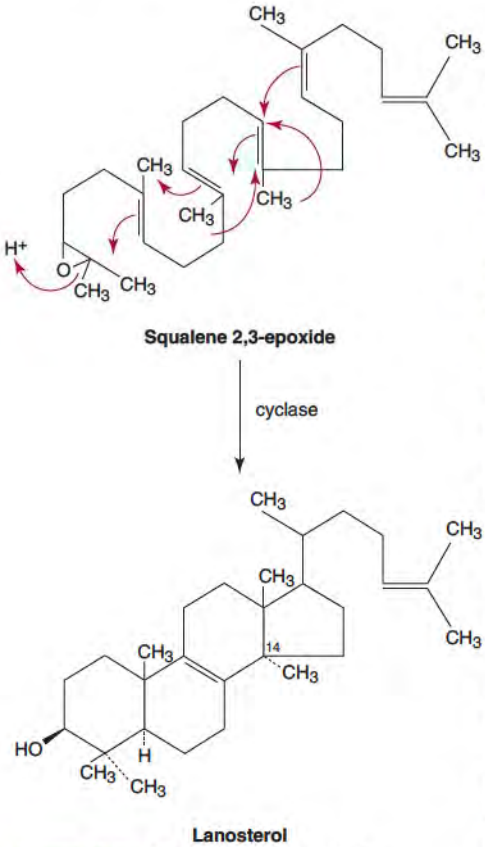

Figure 18.35 Conversion of squalene 2,3-epoxide to lanosterol.

Transformation of lanosterol to cholesterol involves many poorly understood steps and several enzymes. These reactions include (1) removal of the methyl group at C14, (2) removal of two methyl groups at C4. (3) migration of the double bond from C8 to C5, and (4) reduction of the double bond between C24 and C25 in the side chain (Figure 18.36).

Plasma Lipoproteins

Blood contains triacylglycerols, cholesterol, and cholesteryl esters at concentrations that far exceed their solubilities in water. Blood lipids are kept in solution, or at least thoroughly dispersed, by incorporation into macromolecular structures called lipoproteins. The plasma lipoproteins facilitate lipid metabolism and transfer of lipids between tissues. There are five major lipoprotein classes: **high-density lipoprotein (HDL)**, **low-density lipoprotein (LDL)**, **intermediate-density lipoproteins (IDLs)**, **very low-density lipoproteins (VLDL)**, and **chylomicrons**. Their physical characteristics are presented in Table 3.13, p. 108, and the lipid composition in Table 3.15, p. 111. All contain phospholipids and one or more proteins called apoproteins; there are 10 common apoproteins (Table 18.1).

Lipoproteins are spherical particles with the most hydrophobic lipids such as cholesteryl esters and triacylglycerols located in the core, sequestered away from water, whereas free (nonesterified) cholesterol, phospholipids, and the protein(s) are arrayed on the surface (see Figure 3.47, p. 110). The amphipatic phospholipids and proteins keep the otherwise highly insoluble lipids in solution. The apoproteins on the surface of the particles also serve as ligands for cell receptors, and cofactors for enzymes involved in lipoprotein metabolism.

Lipoproteins are vehicles by which cholesterol and its esters and triacylglycerols are transported in the body. For example, one function of LDL is to deliver cholesterol to peripheral tissues that require cholesterol for membrane formation or steroid hormone synthesis. The cholesterol carried to the liver from peripheral tissues and the cholesterol in chylomicrons regulates hepatic cholesterol synthesis (Figure 18.37, p. 724). In contrast, HDL, which is rich in cholesterol but poor in triacylglycerol, carries cholesterol from the periphery to the liver where it is excreted in bile as cholesterol or after conversion to bile salts. VLDL and chylomicrons transport triacylglycerols to be used for energy (e.g., muscle) or stored (e.g., fat cells).

Plasma lipoproteins are substrates for several enzymes in blood. Lipoprotein lipase is attached to the luminal surface of the vascular endothelium by binding to heparan sulfate proteoglycans and hydrolyses triacylglycerols of VLDL and chylomicrons. It is activated by apolipoprotein C-II (apoC-II) and by heparin released from mast cells and cells of the macrophage/reticuloendothelial system. The fatty acids released by lipoprotein lipase can then be taken up by cells and oxidized by β-oxidation, incorporated into phospholipids for membrane assembly or, in adipocytes, stored as triacylglycerols. These fatty acids are incorporated into milk fat in

TABLE 18.1 • Apoproteins of Human Plasma Lipoproteins

Apolipoprotein	*Molecular Weight*	*Plasma Concentration (g L^{-1})*	*Lipoprotein Distribution*

the mammary gland. Hydrolysis of triacylglycerols also results in the release of phospholipids, free cholesterol, and exchangeable apolipoproteins on the surface shell and their transfer to other circulating lipoproteins, especially HDL. As chylomicrons lose their triacylglycerol core they become the smaller chylomicron remnants that are rich in cholesteryl esters, bind specific receptors on hepatic membranes, and, are catabolized in the liver following endocytosis (Figure 18.37). Clearly, lipoproteins are dynamic in structure and composition.

Main sites of synthesis of the apoprotein components are liver and small intestine. For example, apoB-48 is produced in the intestine whereas apoB-100 is synthesized mainly in hepatocytes. ApoB-48 is 48% as long as apoB-100 and is formed from the same message as that for apoB-100. A stop codon introduced into the apoB mRNA in the intestine terminates translation 48% of the way along the mRNA molecule. ApoB-48 is synthesized during the course of fat digestion and is used in production of chylomicrons. ApoB-100 is used in the production of VLDL. The fatty acids of triacylglycerols of newly produced VLDL particles are synthesized from sugars, glucose in particular, after they have been oxidized to acetyl CoA, or from the acetate derived from oxidation of ethanol. VLDL acquires freshly synthesized

cholesteryl esters in the liver, as well as from other lipoproteins, during its transport in the circulation. In the circulation, the net transfer of cholesteryl ester and triacylglycerols between HDL and VLDL and LDL is facilitated by **cholesteryl ester transfer protein (CETP)**. CETP is associated with HDL in the plasma. CETP is synthesized and secreted by hepatocytes and adipocytes, and its expression is stimulated by diet-induced hypercholesterolemia. Lipoprotein lipase (LpL) converts VLDL into intermediate density lipoprotein (IDL), and then, as additional triacylglycerol is subjected to lipolysis, into LDL (Figure 18.37).

HDL is synthesized mainly in liver and to a lesser extent in the intestine and has the unique function of being a reservoir for apoE and apoC-II, which are activators of lipoprotein

lipase. It is secreted as apoprotein A-1 without phospholipids or triacylglycerol. HDL regulates exchange of apoproteins and lipids between various lipoproteins in the blood. HDL particles donate apoE and apoC-II to chylomicrons and VLDL. Once the triacylglycerols in chylomicrons and VLDL are extensively hydrolysed and these lipoproteins are transformed into LDL and chylomicron remnants, respectively, the apoE and apoC-II are returned to HDL (Figure 18.37).

HDL also participates in removal of excess cholesterol from cells and its transport to the liver for elimination as cholesterol and bile salts. This phenomenon is termed *reverse cholesterol transport* (Figure 18.38). It is free (nonesterified) cholesterol that exchanges readily between lipoproteins and the plasma membrane of cells. The transfer of free cholesterol from the plasma membrane to apoA-I or a lipid-poor species of HDL to produce what is called pre-β HDL or nascent HDL is mediated by a membrane transporter designated *ATP-binding cassette transporter* (ABCA1). ABCA1 also transfers phospholipids, along with free cholesterol, from the membrane to nascent HDL to produce HDL3. Absence of the ABCA1 transporter results in the HDL-deficiency disease called Tangier disease. Further addition of esterified cholesterol to HDL3 produces HDL2.

Cholesterol is esterified by **lecithin:cholesterol acyl transferase** (**LCAT**) associated with HDL. This freely reversible reaction (Figure 18.39) transfers the fatty acid in the

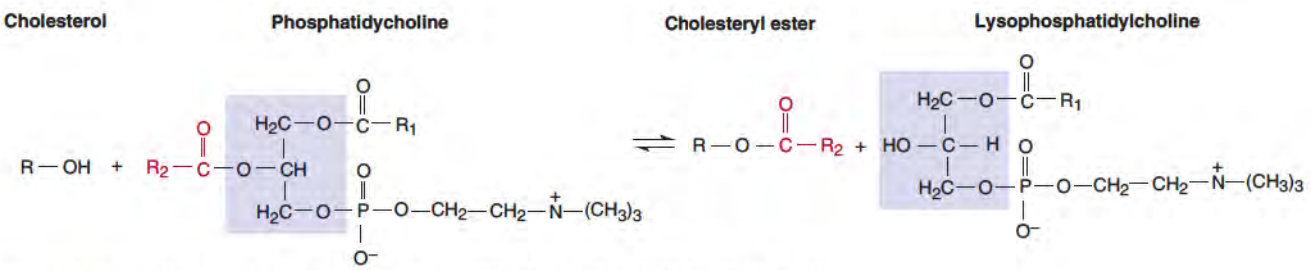

Figure 18.39 Lecithin:cholesterol acyltransferase (LCAT) reaction. R-OH = cholesterol.

sn-2 position of phosphatidylcholine to the 3-hydroxyl of cholesterol. LCAT is produced mainly by the liver, bound to HDL in plasma, and activated by the apoA-1 component of HDL. Cholesteryl ester generated in the LCAT reaction is transferred to VLDL and LDL by CETP associated with the HDL particle, and eventually taken up by the liver.

A phospholipid transfer protein (PLTP) catalyzes transfer of lipids, particularly phospholipids, between lipoproteins. As LpL-catalyzed triacylglycerol hydrolysis occurs and VLDL and chylomicrons both get smaller; PLTP removes excess phospholipid from the surface of these particles and transfers it to HDL. This provides substrate for the LCAT reaction in reverse cholesterol transport.

The degradation of HDL takes place in the liver following the selective uptake of cholesteryl esters mediated by a plasma membrane protein called *scavenger receptor-BI* (SR-BI). SR-BI is a multiligand receptor that binds not only HDL but VLDL and LDL as well. The uptake and degradation of HDL by the liver involve cell surface hepatic lipase that hydrolyzes the triacylglycerols of HDL particles. The apoA1 from the degradation of HDL is recycled for new HDL formation. An inverse relationship exists between plasma HDL concentration and the incidence of coronary artery disease, and a positive relationship exists between plasma cholesterol levels and coronary heart disease.

Liver cells metabolize chylomicron remnants by a similar mechanism; however, macrophages and many other cells have specific receptors that recognize chylomicron remnants and internalize them. These receptors recognize the apoE of chylomicron remnants. Some LDL is taken up via nonspecific scavenger receptors on certain cells, macrophages in particular.

Cholesterol Synthesis Is Regulated

Elevated plasma cholesterol predisposes to atherosclerotic vascular disease. In healthy individuals, plasma cholesterol levels are maintained within a relatively narrow concentration range largely by the liver which (1) expresses the majority of the body's LDL receptors, (2) is the major site for conversion of cholesterol to bile acids, and (3) has the highest level of HMG-CoA reductase activity. The cholesterol pool of the body is derived from dietary cholesterol and cholesterol synthesis primarily in liver and intestine. Cholesterol synthesis increases in liver and intestine when dietary cholesterol intake is reduced. This cholesterol is then transported from liver and intestine to peripheral tissues by VLDLs and chylomicrons, respectively.

The committed step and the rate-limiting reaction in cholesterol synthesis (Figure 18.40) is that of the HMG-CoA reductase which catalyses the step that produces mevalonic acid. Cholesterol exerts feedback inhibition on HMG-CoA reductase and promotes degradation of the enzyme by mechanisms that remain to be elucidated.

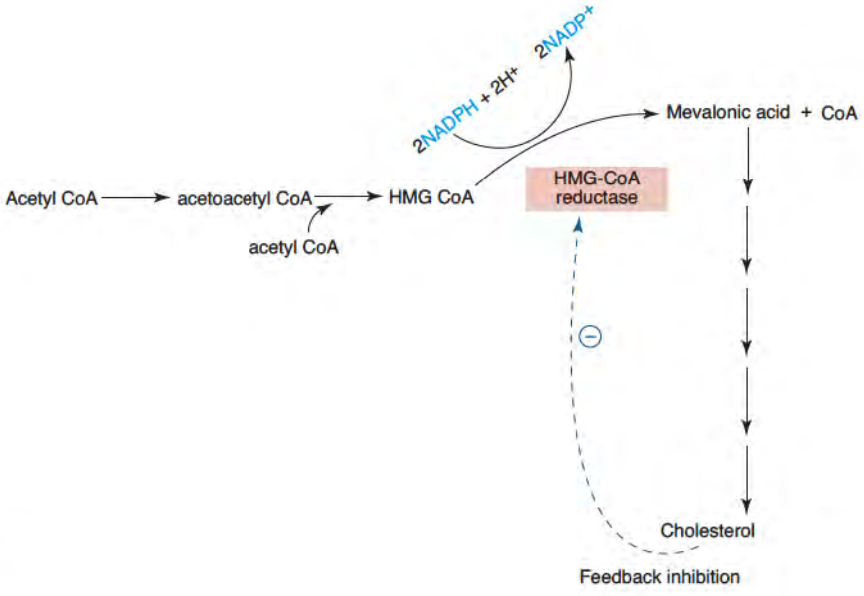

Figure 18.40 Summary of cholesterol synthesis indicating feedback inhibition of HMG-CoA reductase by cholesterol.

In a normal healthy adult on a low cholesterol diet, about 1300 mg of cholesterol is presented to the liver each day for disposal. This cholesterol comes from the diet and peripheral tissues and is disposed of by (1) excretion in bile of about 250 mg bile salts and about 550 mg of cholesterol, (2) storage as cholesteryl esters, and (3) incorporation into VLDL and secretion into the circulation. In the same adult, liver synthesizes about 800 mg of cholesterol per day to replace bile salts and cholesterol.

LDL is responsible for cholesterol delivery to and transport into peripheral tissues that require cholesterol for synthesis and maintenance of their membranes or by specialized cells for steroid hormone synthesis. The removal of LDL from circulation involves **LDL receptors** on the surface of hepatocytes and cells in the periphery.

About 75% of LDL catabolism occurs in liver via an LDL receptor-mediated process. The binding of LDL to hepatocytes and cells in the periphery is characterized by saturability, high affinity, and high degree of specificity. The receptor recognizes apolipoprotein E (apoE) and apolipoprotein B-100 (apoB-100) on LDL and VLDL. Binding occurs on the plasma membrane at pits coated with clathrin and leads to ligand-receptor complexes internalized as clathrin-coated vesicles. This is called receptor-mediated endocytosis. Intracellularly, the vesicles lose their clathrin and become endosomes that fuse with lysosomes that contain proteases and cholesteryl esterase. In this relatively acid (approximately pH 5.0) environment the receptor separates from LDL and returns to the cell surface while the cholesteryl esters are hydrolyzed by cholesteryl esterase to cholesterol and a long-chain fatty acid and the protein is degraded to amino acids that enter the cell's amino acid pool. The free cholesterol diffuses into the cytosol where it inhibits HMG-CoA reductase and suppresses synthesis of the enzyme. At the same time, **fatty acyl CoA:cholesterol acyltransferase** (**ACAT**) of the endoplasmic reticulum is activated by cholesterol, promoting formation of cholesteryl esters, principally cholesteryl oleate.

$$\text{Cholesterol} + \text{oleoyl CoA} \rightarrow \text{cholesteryl oleate} + \text{CoA}$$

Accumulation of intracellular cholesterol inhibits the synthesis and replenishment of LDL receptors by down-regulation of their expression, thereby blocking further uptake and accumulation of cholesterol and increasing the plasma cholesterol concentration. The mechanism of cholesterol regulation of HMG-CoA reductase involves a transcription factor, called the sterol regulatory element binding protein (SREBP), and two other proteins, designated COPII and InSig. Much of the LDL-cholesterol internalized by hepatocytes is metabolized to bile acids and secreted into bile or released directly as cholesterol into bile.

The LDL receptor is a single-chain glycoprotein; numerous mutations in its gene are associated with familial hypercholesterolemia. The receptor spans the plasma membrane once with the carboxyl terminus on the cytoplasmic face and the amino terminus, which binds apoB-100 and apoE-100, extending into the extracellular space.

The correlation between high plasma cholesterol level, particularly LDL cholesterol, and heart attacks and strokes has lead to dietary and therapeutic approaches to lower blood cholesterol (Clin. Corr. 18.3). Patients with familial (genetic) hypercholesterolemia suffer from accelerated atherosclerosis (Clin. Corr. 18.4). In most cases, called receptor negative, there is a lack of functional LDL receptors because the mutant alleles produce little or no LDL receptor protein. In other cases, the receptor is synthesized and transported normally to the cell surface, but an amino acid substitution or other alteration in the primary structure adversely affects LDL binding. As a result, there is little or no binding of LDL to the cell, cholesterol synthesis is not inhibited, and the blood cholesterol level increases. Some LDL-deficient patients synthesize the LDL receptor but have a defect in the transport mechanism that delivers the glycoprotein to the plasma membrane. Another group has LDL receptors that have a defect in the cytoplasmic carboxyl terminus and are unable to internalize the LDL–LDL receptor complex.

In specialized tissues such as the adrenal cortex and ovaries, cholesterol derived from LDL is the precursor for steroid hormones, such as cortisol and estradiol, respectively. In liver, cholesterol extracted from LDL and HDL is converted into bile salts that function in intestinal fat digestion.

CLINICAL CORRELATION 18.3

Treatment of Hypercholesterolemia

Many authorities recommend screening asymptomatic individuals by measuring plasma cholesterol. A level less than 200 mg% is considered desirable; over 240 mg% requires lipoprotein analysis, especially determination of LDL cholesterol. Reduction of LDL cholesterol depends on dietary restriction of cholesterol to less than 300 mg/day, of calories to attain ideal body weight, and of total fat intake to less than 30% of total calories. Approximately two-thirds of the fat should be mono- or poly-unsaturated. The second line of therapy is with drugs. Cholestyramine and colestipol are bile salt-binding drugs that promote excretion of bile salts, increasing hepatic bile salt synthesis, and LDL uptake by the liver. Lovastatin inhibits HMG-CoA reductase, decreases endogenous synthesis of cholesterol and stimulates uptake of LDL via the LDL receptor. The combination of lovastatin and cholestyramine is sometimes used for severe hyperlipidemia.

Expert Panel: Evaluation and treatment of high blood cholesterol in adults. *Arch. Intern. Med.* 148: 36, 1988.

CLINICAL CORRELATION 18.4

Atherosclerosis

Atherosclerosis is the leading cause of death in Western industrialized countries. The risk of developing it is directly related to the plasma LDL cholesterol and inversely related to the HDL cholesterol level. This explains why the former is frequently called "bad" cholesterol and the latter "good" cholesterol, though chemically there is no difference. In atherosclerosis the arterial wall contains accumulated cholesteryl esters in cells derived from the monocyte-macrophage line, there is also smooth muscle cell proliferation and fibrosis. The earliest abnormality is migration of blood monocytes to the subendothelium of the artery. These cells then differentiate into macrophages and accumulate cholesteryl esters derived from plasma LDL. Some of the LDL may be taken up via pathways that do not require the LDL receptor. For instance, there are receptors that take up acetylated LDL or LDL complexed with dextran sulfate; however, this pathway is not regulated by cellular cholesterol content. Distortion of the subendothelium leads to platelet aggregation on the endothelial surface and release of platelet-derived mitogens such as platelet-derived growth factor (PDGF) which stimulates smooth muscle cell growth. Death of the foam cells leads to deposition of the cellular lipid and fibrosis. The resulting atherosclerotic plaque narrows the blood vessel and leads to thrombus formation, which precipitates myocardial infarction (heart attack).

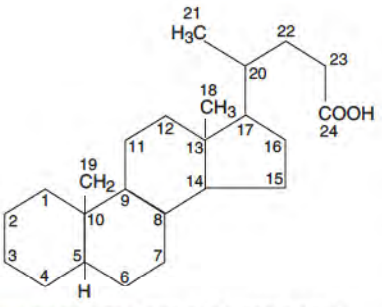

Figure 18.41 **Structure of cholanic acid.**

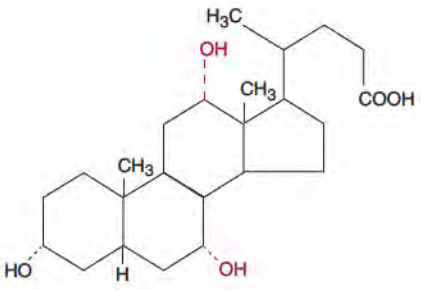
Cholesterol Is Excreted Primarily as Bile Acids

Bile acids are the products of cholesterol metabolism. Primary bile acids are synthesized in hepatocytes from cholesterol. The bile acids are derivatives of cholanic acid (Figure 18.41). Cholic acid and chenodeoxycholic acid (Figure 18.42) are C_{24} compounds containing three and two OH groups, respectively, and a C-5 side chain that ends in a carboxyl group that is ionized at pH 7.0 (hence the name bile salt). The carboxyl group is often conjugated via an amide bond to glycine ($NH_2—CH_2—COOH$) (Figure 18.43) or taurine ($NH_2—CH_2—CH_2—SO_3H$) to form glycocholic or taurocholic acid, respectively.

Microorganisms in the gut modify primary bile acids to secondary bile acids. Deoxycholic acid and lithocholic acid are derived from cholic acid and chenodeoxycholic acid,



Cholic acid

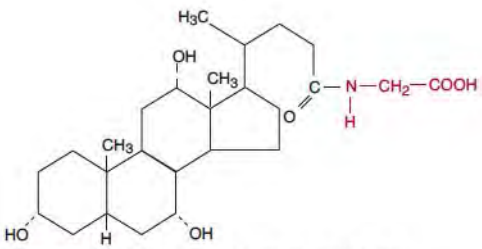

Figure 18.43 **Structure of glycocholic acid, a conjugated bile acid.**

respectively, by the removal of one OH group (see Figure 18.42). Transformation of cholesterol to bile acids requires (1) epimerization of the 3β-OH group, (2) reduction of the C5 double bond, (3) introduction of OH groups at C7 (chenodeoxycholic acid) or at C7 and C12 (cholic acid), and (4) conversion of the C27 side chain into a C24 carboxylic acid by elimination of a propyl equivalent.

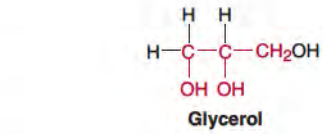
Bile acids are secreted into bile, stored in the gallbladder, and then secreted into the small intestine. Liver production of bile acids is insufficient to meet the physiological needs, so the body relies on an enterohepatic circulation that carries the bile acids from the intestine back to the liver several times each day.

Bile acids and phospholipids solubilize cholesterol in bile, thereby preventing cholesterol from precipitating in the gall bladder. Bile acids in the gut act as emulsifying agents for dietary triacylglycerols, facilitating their hydrolysis by pancreatic lipase. Bile acids play a direct role in activating pancreatic lipase (p. 1051) and facilitate the absorption of fat-soluble vitamins, particularly vitamin D (p. 1067), from the intestine.

18.4 • SPHINGOLIPIDS

Synthesis of Sphingosine

Sphingolipids are complex lipids whose core structure is provided by the long-chain amino alcohol sphingosine (Figure 18.44) (4-sphingenine or trans-1,3-dihydroxy-2-amino-4-octadecene). Sphingosine has two asymmetric carbon atoms (C2 and C3); of the four possible optical isomers, naturally occurring sphingosine is the D-erythro form. The double bond has the *trans* configuration. The primary alcohol group at C1 is a nucleophilic center that is linked with sugars in glycosphingolipids. The amino group at C2 always bears a long-chain fatty acid (usually $C_{20}-C_{26}$) in amide linkage in ceramides. The secondary alcohol at C3 is always free. Note the structural similarity of this part of the sphingosine molecule to the glycerol moiety of the acylglycerols (Figure 18.44).



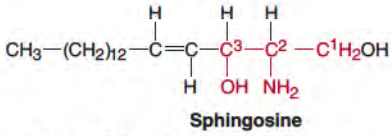


Figure 18.44 **Comparison of structures of glycerol and sphingosine (trans-1,3,dihydroxy-2-amino-4-octadecene).**

Sphingolipids occur in blood and the plasma membranes of nearly all cells. The highest concentrations are found in the white matter of the central nervous system.

Sphingosine is synthesized by way of sphinganine (dihydrosphingosine) from serine and palmitoyl CoA. Serine provides C1, C2, and the amino group of sphingosine and palmitic acid provides the remaining carbon atoms. The condensation of serine and palmitoyl CoA is catalyzed by **serine palmitoyltransferase**, a pyridoxal phosphate-dependent enzyme. The driving force for the reaction is provided by both cleavage of the reactive, high-energy, thioester bond of palmitoyl CoA and the release of CO_2 from serine (Figure 18.45). Reduction of the carbonyl group in 3-ketodihydrosphingosine by 3-ketosphinganine reductase to produce sphinganine (Figure 18.46) occurs at the expense of NADPH. Insertion of the double bond into sphinganine produces sphingosine.

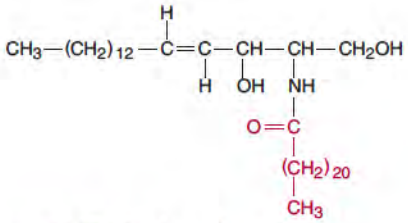

Figure 18.47 **Structure of a ceramide (*N*-acylsphingosine).**

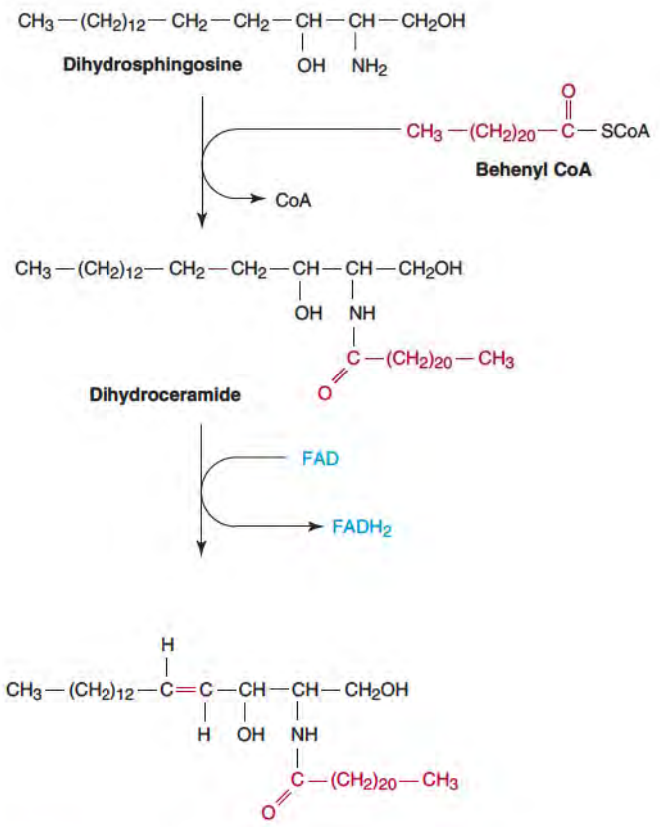

Figure 18.48 **Formation of ceramide from dihydrosphingosine.**

Ceramides Are Fatty Acid Amide Derivatives of Sphingosine

Sphingosine is the precursor of ceramide, a long-chain fatty acid amide derivative of sphingosine, which provides the core structure of sphingolipids. The fatty acid is attached to the 2-amino group of sphingosine through an amide bond (Figure 18.47). Most often the acyl group is behenic acid, a saturated 22-carbon fatty acid, but other long-chain acyl groups can be used. The two long-chain hydrocarbon domains in the ceramide molecule regions are responsible for the lipid character of sphingolipids.

Ceramide is synthesized from dihydrosphingosine (sphinganine) and a long-chain fatty acyl CoA by an endoplasmic reticulum enzyme. Dihydroceramide is an intermediate that is then desaturated at C4 and C5 (Figure 18.48). Ceramide is not a component of membrane lipids but rather is an intermediate in synthesis and catabolism of glycosphingolipids and sphingomyelin. Structures of prominent sphingolipids of humans are presented in Figure 18.49 in diagrammatic form.

Sphingomyelin Is a Phosphorus-Containing Sphingolipid

Sphingomyelin, a major component of membranes of nervous tissue, is a phospholipid. Since this ceramide phosphocholine contains one negative and one positive charge, it is neutral at physiological pH (Figure 18.50). The most common fatty acids in sphingomyelin are palmitic (16:0), stearic (18:0), lignoceric (24:0), and nervonic acid (24:1). The sphingomyelin of myelin contains predominantly lignoceric acid and nervonic acid, whereas that of gray matter contains largely stearic acid. Excessive accumulation of sphingomyelin occurs in Niemann–Pick disease. Conversion of ceramide to sphingomyelin by sphingomyelin synthase involves transfer of a phosphocholine moiety from phosphatidylcholine (lecithin) (Figure 18.51).

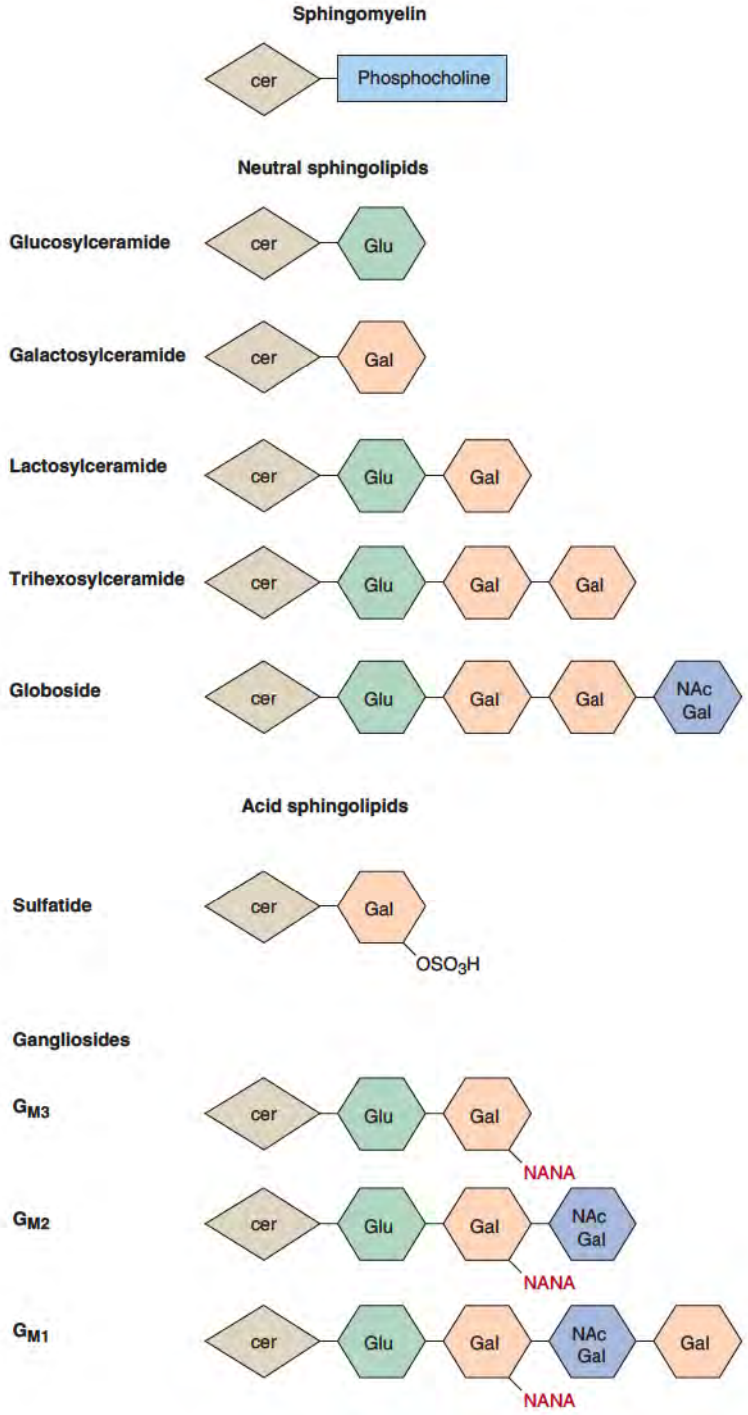

Figure 18.49 Structures of some common sphingolipids in diagrammatic form. Cer = ceramide, Glu = glucose, Gal = galactose, NAcGal = *N*-acetylgalactosamine, and NANA = *N*-acetylneuraminic acid (sialic acid).

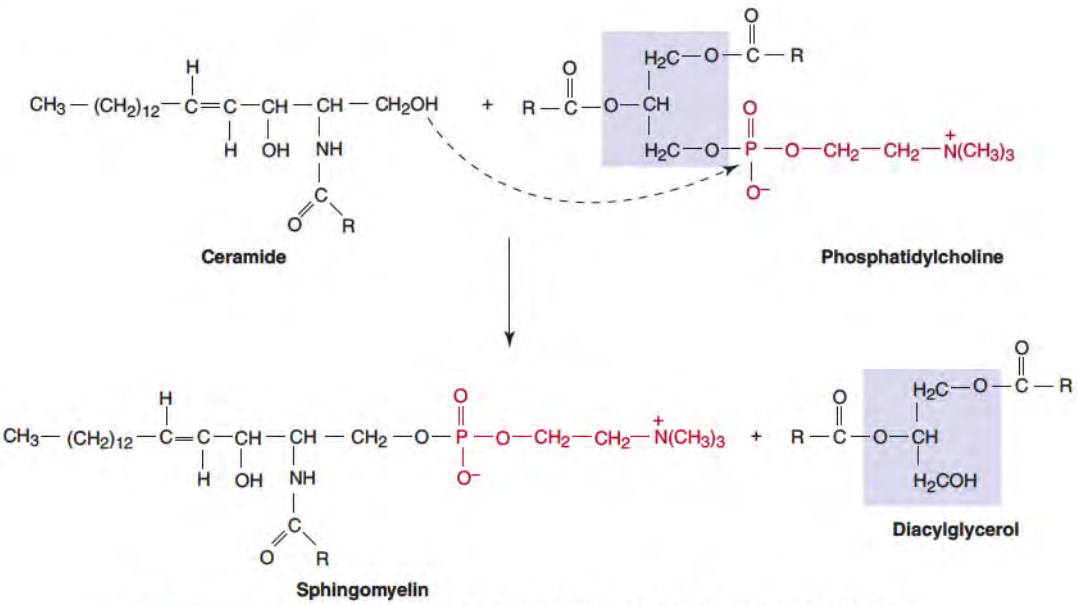

Figure 18.51 **Sphingomyelin synthesis from ceramide and phosphatidylcholine.**

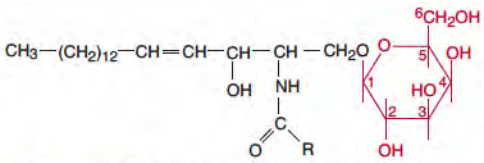

Figure 18.52 **Structure of galactocerebroside (galactolipid).**

Glycosphingolipids Usually Contain Galactose or Glucose

The principal glycosphingolipid classes are cerebrosides, sulfatides, globosides, and gangliosides. In glycolipids the polar head group attached to sphingosine is a sugar molecule.

Cerebrosides Are Glycosylceramides

Cerebrosides are ceramide monohexosides; the most common are **galactocerebroside** and **glucocerebroside**. Unless specified otherwise, the term *cerebroside* usually refers to galactocerebroside, also called *galactolipid*. In Figure 18.52 note that C1 of the monosaccharide unit is attached to C1 of the ceramide and the anomeric configuration of the sugar moiety in both galactocerebroside and glucocerebroside is β. Most galactocerebroside in healthy individuals is found in the brain. Moderate amounts of galactocerebroside accumulate in the white matter in Krabbe disease, or globoid leukodystrophy, a deficiency in lysosomal galactocerebrosidase.

Glucocerebroside (glucosylceramide) (Figure 18.53) is not normally a component of membranes. It is an intermediate in the synthesis and degradation of more complex glycosphingolipids. However, 100-fold increases in glucocerebroside occur in spleen and liver in the genetic lipid storage disorder called Gaucher disease, a deficiency of lysosomal glucocerebrosidase.

Galactocerebroside and glucocerebroside are synthesized from ceramide, and UDP-galactose and UDP-glucose, respectively. The glucosyl and galactosyl transferases that catalyze these reactions are associated with the endoplasmic reticulum (Figure 18.54). In some tissues, synthesis of glucocerebroside proceeds by glucosylation of sphingosine by glucosyltransferase.

$$\text{Sphingosine} + \text{UDP-glucose} \rightarrow \text{glucosylsphingosine} + \text{UDP}$$

followed by fatty acylation

$$\text{Glucosylsphingosine} + \text{stearoyl CoA} \rightarrow \text{glucocerebroside} + \text{CoASH}$$

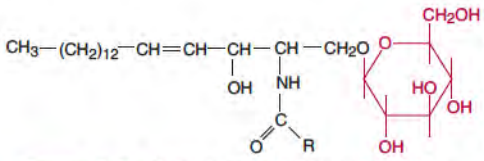

Figure 18.53 **Structure of glucocerebroside.**

Sulfatide Is a Sulfuric Acid Ester of Galactocerebroside

Sulfatide, or sulfogalactocerebroside, is a sulfuric acid ester of galactocerebroside. Galactocerebroside 3-sulfate is the major sulfolipid of brain, accounting for ~15% of lipids of white matter (Figure 18.55). It is synthesized from galactocerebroside and 3′-phosphoadenosine 5′-phosphosulfate (PAPS) by sulfotransferase.

$$\text{Galactocerebroside} + \text{PAPS} \rightarrow \text{PAP} + \text{galactocerebroside 3-sulfate}$$

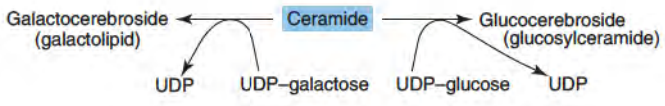

Figure 18.54 **Synthesis of galacto- and glucocerebrosides.**

The structure of PAPS, sometimes referred to as *activated sulfate,* is indicated in Figure 18.56. Large quantities of sulfatide accumulate in the central nervous system in metachromatic leukodystrophy due to a deficiency of lysosomal sulfatase.

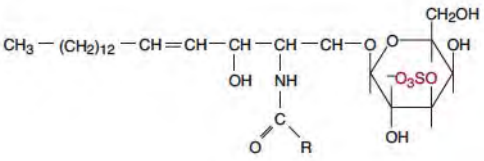

Figure 18.55 **Structure of galactocerebroside sulfate (sulfolipid).**

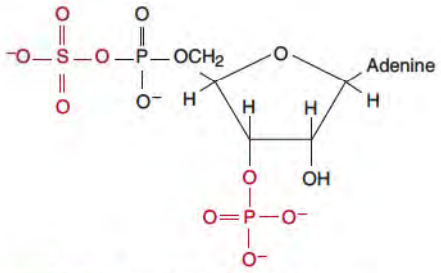

Figure 18.56 **Structure of PAPS (3′-phosphoadenosine-5′-phosphosulfate).**

Globosides Are Ceramide Oligosaccharides

Globosides are cerebrosides that contain two or more sugar residues, usually galactose, glucose, or *N*-acetylgalactosamine. The oligosaccharides are uncharged and contain no free amino groups. Lactosylceramide is present in the erythrocyte membrane (Figure 18.57). Another prominent globoside of the nervous system is ceramide trihexoside or ceramide galactosyllactoside: ceramide-β-glc(4 → 1)-β-gal-(4 → 1)-α-gal. Note that the terminal galactose residue of this globoside has the α-anomeric configuration. Ceramide trihexoside accumulates in kidneys of patients with Fabry disease, a deficiency of lysosomal α-galactosidase A.

Gangliosides Contain Sialic Acid

Gangliosides are sialic acid-containing glycosphingolipids highly concentrated in ganglion cells of the central nervous system, particularly in the nerve endings. The central nervous system is unique among human tissues because more than one-half of its sialic acid is in gangliosides, the remainder occurring in glycoproteins. Lesser amounts of gangliosides are present in the plasma membranes of cells of most extraneural tissues where they account for less than 10% of the total sialic acid.

Neuraminic acid (abbreviated Neu) is present in gangliosides, glycoproteins, and mucins. Its amino group occurs most often as the *N*-acetyl derivative, producing *N*-acetylneuraminic acid (NANA) or sialic acid (Figure 18.58). The OH group on C2 occurs most often in the α-anomeric configuration and is linked to the ceramide oligosaccharide through the OH group on position 2 of *N*-acetylneuraminic acid. Structures of some common gangliosides are indicated in Table 18.2. The principal gangliosides in brain are G_{M1}, G_{D1a}, G_{D1b}, and G_{T1b}. Nearly all of the gangliosides in the body are derived from glucosylceramide. In the naming of sialoglycosphingolipids, the letter G refers to ganglioside. The subscripts M, D, T, and Q indicate mono-, di-, tri-, and quatra (tetra)-sialic acid-containing gangliosides, and the subscripts 1, 2, and 3 designate the carbohydrate sequence that is attached to ceramide as follows: 1, Gal-GalNAc-Gal-Glc-ceramide; 2, GalNAc-Gal-Glc-ceramide; and 3, Gal-Glc-ceramide. In the Tay–Sachs ganglioside, the designation G_{M2} denotes the structure shown in Table 18.2.

A ganglioside on intestinal mucosal cells binds cholera toxin, an 84-kDa protein secreted by the pathogen *Vibrio cholerae.* The toxin stimulates secretion of chloride ions into the gut lumen, resulting in the copious diarrhea of cholera. The cholera toxin contains an A subunit (28 kDa) and five B subunits (~11,000 kDa each). After binding to the cell surface membrane through the B subunits, the A subunit enters the cell and acts as an ADP-ribosyltransferase that transfers ADP-ribose of NAD^+ onto the $G_{\alpha s}$ subunit of a G protein on the cytoplasmic side of the cell membrane (p. 522). This leads to activation of adenylate cyclase that stimulates secretion of chloride ion and produces diarrhea. The choleragenoid domain, as the B subunits are called, binds to the ganglioside G_{M1} (Table 18.2).

Gangliosides may also bind other toxins, such as tetanus toxin, and certain viruses, such as the influenza viruses. They may play an informational role in cell–cell interactions by providing specific recognition determinants on the cell surface.

Several lipid storage disorders involve accumulation of sialic acid-containing glycosphingolipids. The two most common gangliosidoses involve the gangliosides G_{M1} (G_{M1}

gangliosidosis) and G_{M2} (Tay–Sachs disease). G_{M1} gangliosidosis is an autosomal recessive metabolic disease characterized by impaired psychomotor function, mental retardation, hepatosplenomegaly, and death within the first few years of life. The massive cerebral and visceral accumulation of G_{M1} is due to a marked deficiency of β-galactosidase.

Sphingolipidoses Are Lysosomal Storage Diseases

Sphingolipids are degraded within lysosomes of phagocytic cells, particularly the histiocytes or macrophages of the reticuloendothelial system located primarily in liver, spleen, and bone marrow. Degradation begins with engulfment of membranes of white cells and erythrocytes that are rich in lactosylceramide (Cer-Glc-Gal) and hematoside (Cer-Glc-Gal-NANA). In the brain, the majority of cerebrosides are gangliosides and, particularly during the neonatal period, ganglioside turnover is extensive. Sphingolipid catabolism is summarized in Figure 18.59. This pathway requires enzymes that cleave specific bonds, including α- and β-galactosidases, a β-glucosidase, a neuraminidase, hexosaminidase, sphingomyelin-specific

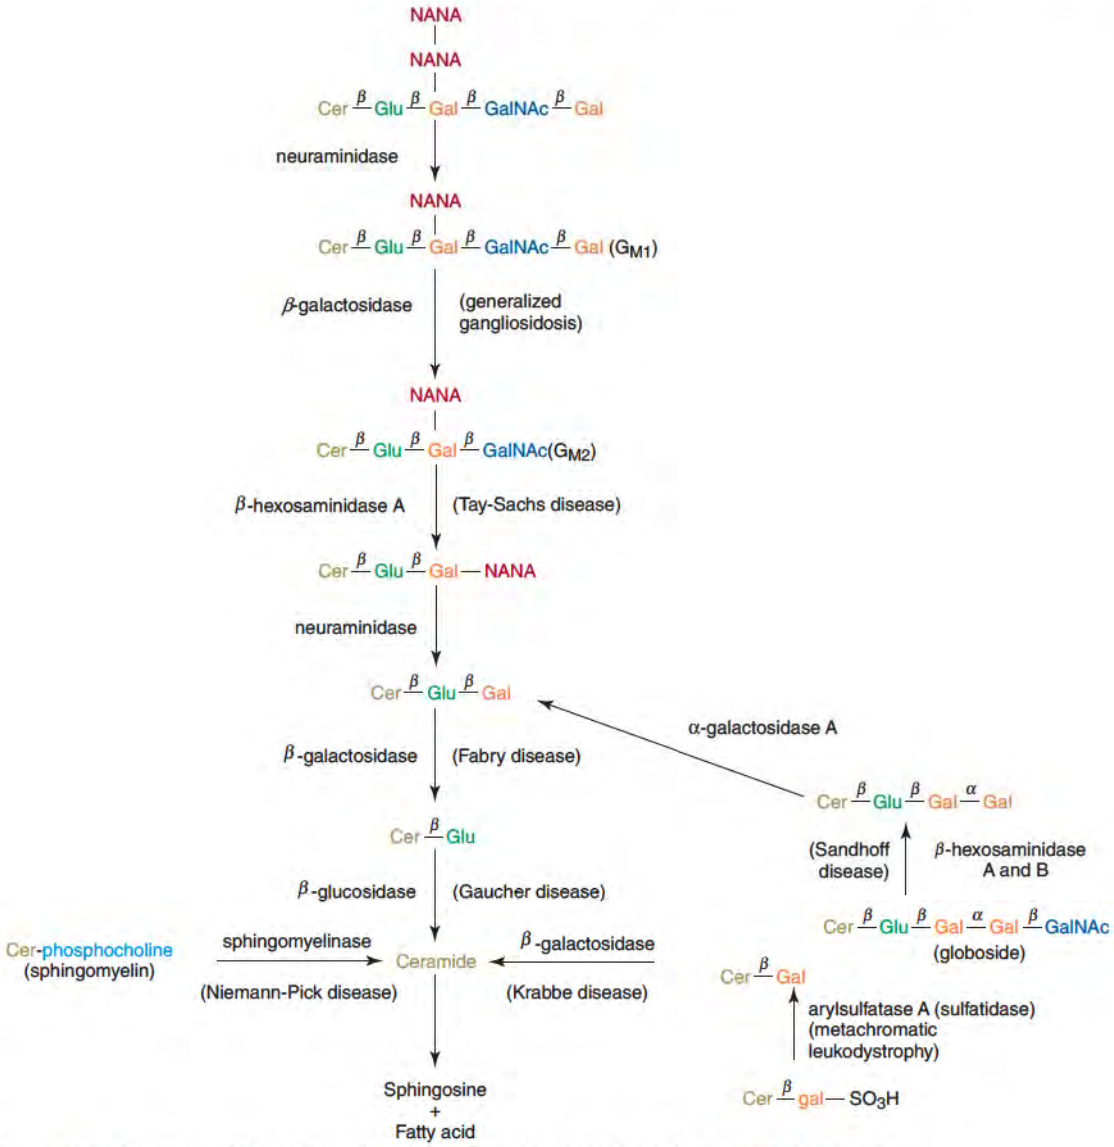

Figure 18.59 Summary of the pathways for catabolism of sphingolipids by lysosomal enzymes. The genetically determined enzyme deficiency diseases are indicated in the parentheses.

phosphodiesterase (sphingomyelinase), a sulfate esterase (sulfatase), and a ceramide-specific amidase (ceramidase). Important features of the catabolic pathway are (1) all the reactions occur within lysosomes; (2) the enzymes are hydrolases; (3) the pH optima of the enzymes is in the acid range, pH 3.5–5.5; (4) most of the enzymes are relatively stable and occur as isoenzymes, for example, hexosaminidase A (HexA) and hexosaminidase B (HexB); (5) the enzymes are glycoproteins and often occur firmly bound to the lysosomal membrane; and (6) the adjacent intermediates in the pathway differ by one sugar molecule, a sulfate group, or a fatty acid residue and are formed by the removal of one constituent at a time, such as sugars and sulfate, by irreversible reactions.

Sphingolipid catabolism normally functions smoothly, all of the glycosphingolipids and sphingomyelin being degraded to their constituents. However, when the activity of one enzyme in the pathway is markedly reduced due to a genetic error, then the substrate for that enzyme accumulates and is deposited within the lysosomes of the tissue in which catabolism of that sphingolipid normally occurs. An enzyme deficiency has been described for most reactions in Figure 18.59. These disorders, called sphingolipidoses, are summarized in Table 18.3.

Common features of lipid storage diseases are (1) usually only a single sphingolipid accumulates in the involved organs. (2) the ceramide portion is shared by the various

TABLE 18.3 • Sphingolipid Storage Diseases of Humans

Disorder	*Principal Signs and Symptoms*	*Principal Storage Substance*	*Enzyme Deficiency*
1. Tay–Sachs disease	Mental retardation, blindness, cherry red spot on macula, death between second and third year	Ganglioside G_{M2}	Hexosaminidase A
2. Gaucher disease	Liver and spleen enlargement, erosion of long bones and pelvis, mental retardation in infantile form only	Glucocerebroside	Glucocerebrosidase
3. Fabry disease	Skin rash, kidney failure, pain in lower extremities	Ceramide trihexoside	α-Galactosidase A
4. Niemann–Pick disease	Liver and spleen enlargement, mental retardation	Sphingomyelin	Sphingomyelinase
5. Globoid leukodystrophy (Krabbe disease)	Mental retardation, absence of myelin	Galactocerebroside	Galactocerebrosidase
6. Metachromatic leukodystrophy	Mental retardation, nerves stain yellowish brown with cresyl violet dye (metachromasia)	Sulfatide	Arylsulfatase A
7. Generalized gangliosidosis	Mental retardation, liver enlargement, skeletal involvement	Ganglioside G_{M1}	G_{M1} ganglioside: β-galactosidase
8. Sandhoff-Jatzkewitz disease	Same as 1; disease has more rapidly progressing course	G_{M2} ganglioside, globoside	Hexosaminidase A and B
9. Fucosidosis	Cerebral degeneration, muscle spasticity, thick skin	Pentahexosylfucoglycolipid	α-L-Fucosidase

storage lipids, (3) the rate of synthesis of the accumulating lipid is normal, (4) a catabolic enzyme is missing, and (5) the enzyme deficiency occurs in all tissues.

Diagnostic Assays for Sphingolipidoses

Diagnosis of a sphingolipidosis is made from biopsy of the involved organ, usually bone marrow, liver, or brain, on morphologic grounds based on the highly characteristic appearance of the storage lipid within lysosomes. Assay of enzyme activity confirms the diagnosis. Peripheral leukocytes, cultured skin fibroblasts, and chorionic villus that normally express the relevant enzyme are used for diagnostic purposes. In some cases (e.g., Tay–Sachs disease) serum or tears can be used for the diagnosis. Sphingolipidoses, for the most part, are autosomal recessive, the disease occurring only in homozygotes with a defect in both alleles. Enzyme assays can identify carriers or heterozygotes.

In Niemann–Pick disease, the deficient enzyme is sphingomyelinase (Figure 18.60). Sphingomyelin, C^{14}-labeled in the methyl groups of choline, is a useful substrate for

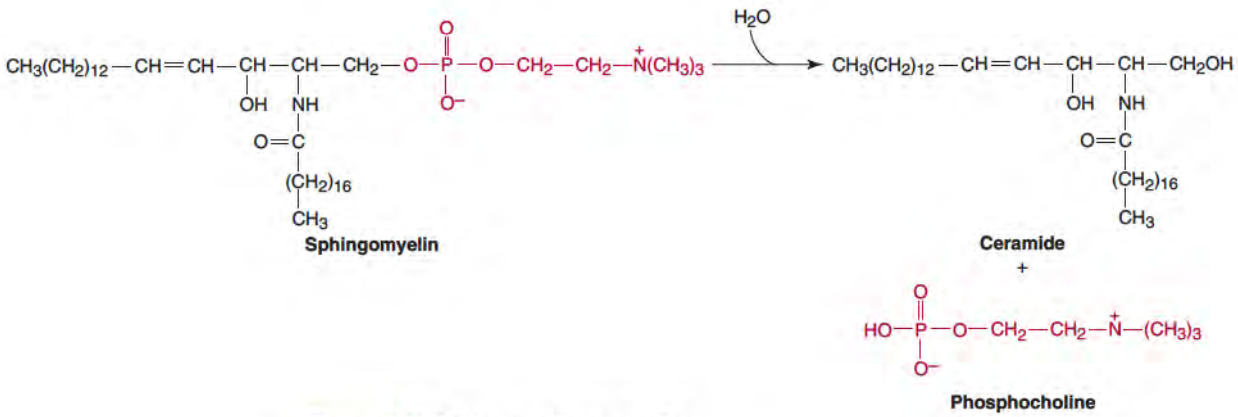

Figure 18.60 **Sphingomyelinase reaction.**

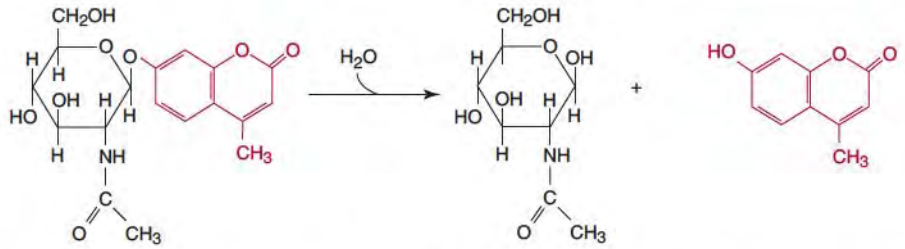

Figure 18.61 **β-Hexosaminidase reaction.**

determining sphingomyelinase activity. Extracts of white blood cells from healthy controls produce phosphocholine, which is water soluble. Extraction of the final incubation medium with an organic solvent such as chloroform will show radioactivity in the upper, aqueous phase. White blood cells from a patient with Niemann–Pick disease show little or no radioactivity (i.e., phosphocholine) in the aqueous phase.

Tay–Sachs disease, the most common form of G_{M2} gangliosidosis, is diagnosed by use of an artificial substrate. Ganglion cells of the cerebral cortex in this fatal disorder become swollen and many lysosomes are engorged with the acidic lipid, G_{M2} ganglioside. There is loss of ganglion cells, proliferations of glial cells, and demyelination of peripheral nerves. The pathognomonic finding is a cherry red spot on the macula caused by swelling and necrosis of ganglion cells in the eye. The substrate 4-methylumbelliferyl-β-*N*-acetylglucosamine is used to confirm the diagnosis. Hydrolysis of the substrate by hexosaminidase A, which is lacking in this disease, produces the intensely fluorescent 4-methylumbelliferone (Figure 18.61). Unfortunately, the diagnosis can be confused by the presence of hexosaminidase B, which is not deficient in this disease. The problem is usually resolved by taking advantage of the relative heat lability of hexosaminidase A and heat stability of hexosaminidase B. First, the total activity is assayed and then an aliquot of the tissue extract or serum specimen is heated at 55°C for 1 h and assayed. The difference between the two assays is a measure of hexosaminidase A activity and is used in making the diagnosis.

Once carriers of a lipid storage disease have been identified or if there has been a previously affected child in a family, the pregnancies at risk for these diseases can be monitored. All of the lipid storage disorders are transmitted as autosomal recessive genetic abnormalities. Fabry disease is X-chromosome linked. In the autosomal conditions, statistically one of four fetuses will be homozygous (or hemizygous in Fabry disease), two fetuses will be carriers, and one will be completely normal. Enzyme assays are used to detect affected fetuses and carriers *in utero*, using cultured fibroblasts obtained by amniocentesis as a source of enzyme.

Enzyme replacement therapy is available for Gaucher disease and Fabry disease and is being developed for several other sphingolipidoses. Prevention of the sphingolipidoses through genetic counseling based on enzyme assays and DNA analysis is available. A discussion of the diagnosis and therapy of Gaucher disease is presented in Clin. Corr. 18.5.

CLINICAL CORRELATION 18.5

Diagnosis of Gaucher Disease in an Adult

Gaucher disease (OMIM 230800) is an inherited disease of lipid catabolism in which glucocerebroside accumulates in macrophages of the reticuloendothelial system. Because of the large numbers of macrophages in the spleen, bone marrow, and, liver, hepatomegaly, splenomegaly and its sequelae (thrombocytopenia or anemia), and bone pain are the most common signs and symptoms of the disease.

Gaucher disease results from a deficiency of glucocerebrosidase. Some patients suffer severe neurologic deficits as infants, while others do not exhibit symptoms until adulthood. The diagnosis can be made by assaying leukocytes or fibroblasts for their ability to hydrolyze the β-glycosidic bond of artificial substrates (β-glucosidase activity) or of glucocerebroside (glucocerebrosidase activity). Gaucher disease has been treated with regular infusions of purified glucocerebrosidase and the long-term efficacy of the therapy appears good.

Brady, R. O., Kanfer, J. N., Bradley, R. M., and Shapiro, D. Demonstration of a deficiency of glucocerebroside-cleaving enzyme in Gaucher's disease. *J. Clin. Invest.* 45:1112, 1966.

18.5 • PROSTAGLANDINS AND THROMBOXANES

Prostaglandins and Thromboxanes Are Derivatives of Monocarboxylic Acids

In mammalian cells, two major pathways of arachidonic acid metabolism produce important mediators of cellular and bodily functions: the cyclooxygenase and the lipoxygenase pathways. The substrate for both pathways is free arachidonic acid. The cyclooxygenase pathway leads to a series of compounds including prostaglandins and thromboxanes. Prostaglandins were discovered through their ability to promote contraction of intestinal and uterine muscle and lower blood pressure. Although the complexity of their structures and

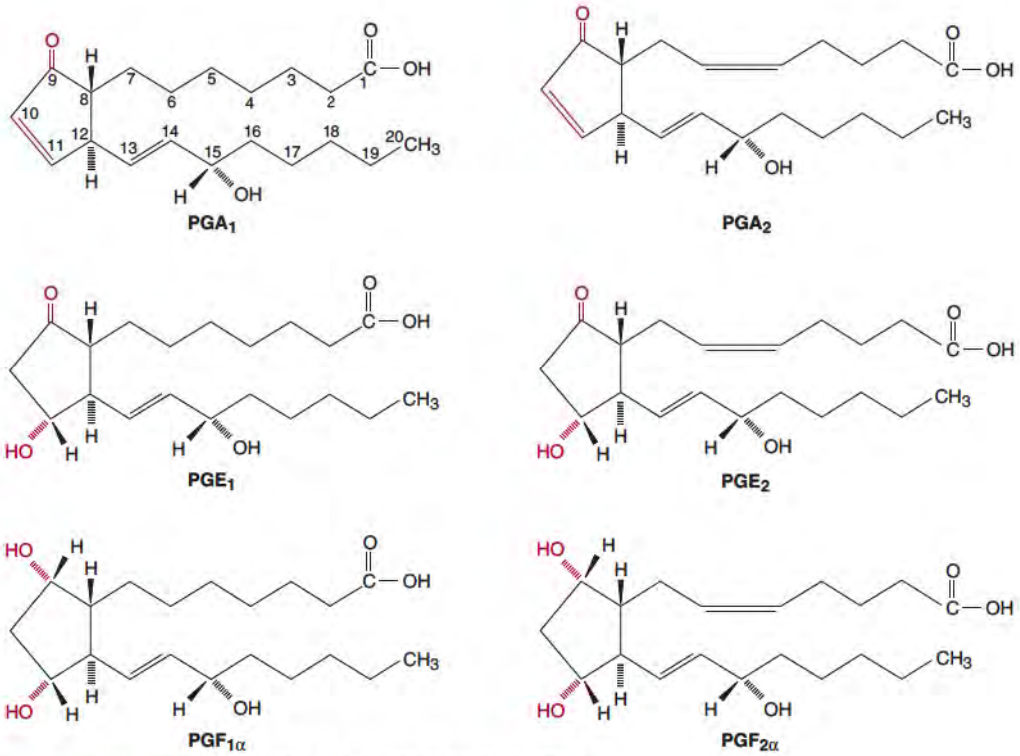

Figure 18.62 **Structures of the major prostaglandins.**

the diversity of their sometimes conflicting functions often create a sense of frustration, the potent pharmacological effects of the prostaglandins have made them important in human biology and medicine. With the exception of red blood cells, prostaglandins are produced and released by nearly all mammalian cells. Prostaglandins are not stored in cells but are released immediately after they are synthesized.

Structures of the more common prostaglandins A, E, and F are shown in Figure 18.62. All are structurally related to prostanoic acid (Figure 18.63). Note that the prostaglandins contain a multiplicity of functional groups; for example, PGE_2 contains a carboxyl group, a β-hydroxy-ketone ring, a secondary alkylic alcohol and two carbon–carbon double bonds. The three classes are distinguished by the functional groups of the cyclopentane ring: the E series contains a β-hydroxy-ketone ring, the F series are 1,3-diols, and the A series are α, β-unsaturated ketones. The subscript numerals 1, 2, and 3 refer to the number of double bonds in the side chains. The subscript α refers to the configuration of a C-9 OH group. An α-hydroxyl group projects *down* from the plane of the ring.

The most important dietary precursor of prostaglandins is linoleic acid [18:2(9,12)], an essential fatty acid. About 10 g of linoleic acid is ingested daily in adults. A small part of this intake is converted by elongation and desaturation in liver to arachidonic acid (eicosatetraenoic acid) and to some extent to dihomo-γ-linoleic acid. Since the total daily excretion of prostaglandins and their metabolites is only about 1 mg, formation of prostaglandins is a quantitatively unimportant pathway in the overall metabolism of fatty acids. However, the metabolism of prostaglandins is completely dependent on a regular and constant supply of linoleic acid.

Synthesis of Prostaglandins Involves a Cyclooxygenase

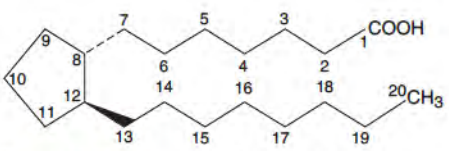

Figure 18.63 **Structure of prostanoic acid.**

The immediate precursors of prostaglandins are C_{20} polyunsaturated fatty acids that contain three, four, or five carbon–carbon double bonds. Since arachidonic acid and most of its metabolites contain 20 carbons, they are referred to as eicosanoids. These fatty acids are cyclized and take up oxygen during their transformation into prostaglandins. The number of carbon–carbon double bonds in the side chain of a particular prostaglandin depends on the fatty acid precursor. Dihomo-γ-linolenic acid [20:3(8,11,14)] is the precursor of PGE_1

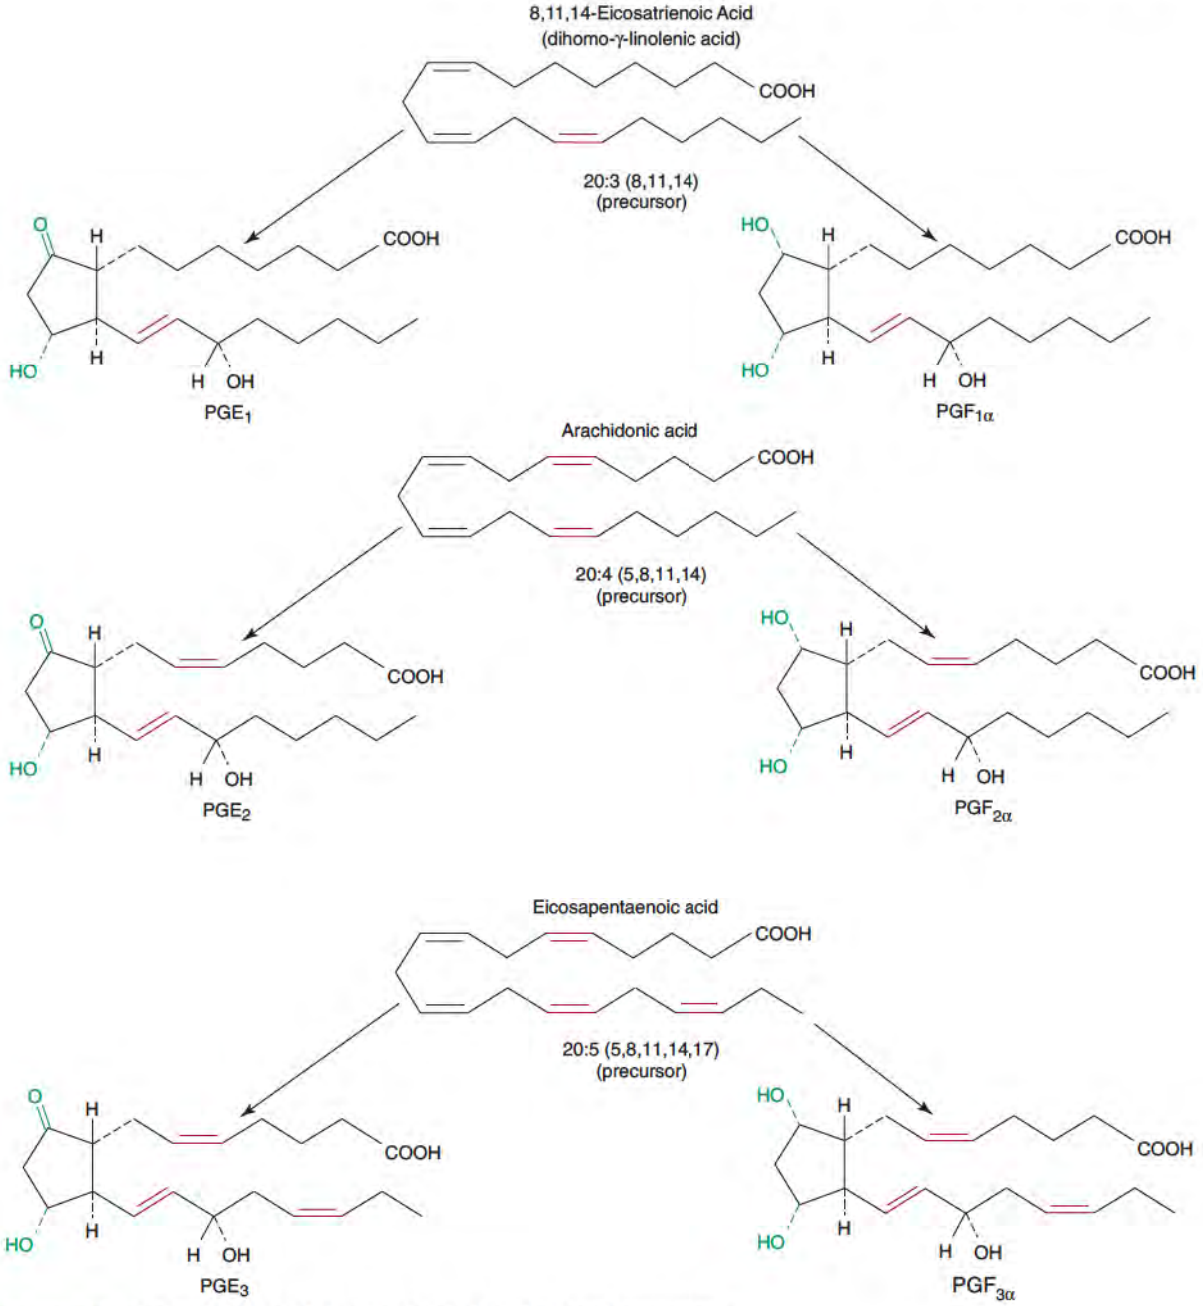

Figure 18.64 Synthesis of E and F prostaglandins from fatty acid precursors.

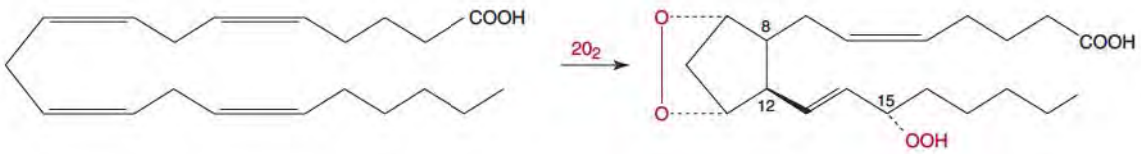
and $PGF_{1\alpha}$, arachidonic acid [20:4(5,8,11,14)] of PGE_2 and $PGF_{2\alpha}$, and eicosapentaenoic acid [20:4(5,8,11,14,17)] of PGE_3 and $PGF_{3\alpha}$ (Figure 18.64).

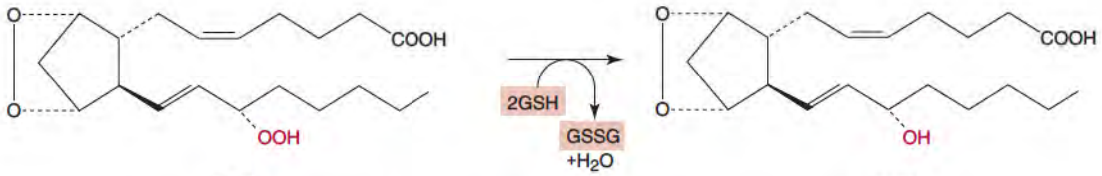
The 2-series prostaglandins derived from arachidonic acid are the principal prostaglandins in humans and are of the greatest significance biologically. Arachidonic acid is released from membrane phospholipids by the action of phospholipase A_2. This is the rate-limiting step in prostaglandin synthesis, and some agents that stimulate prostaglandin production do so by stimulating phospholipase A_2. Cholesteryl esters containing arachidonic acid also serve as a source of arachidonic acid. The key enzyme of prostaglandin biosynthesis is the bifunctional prostaglandin G/H synthase (PGS), which catalyzes oxidative cyclization of polyunsaturated fatty acids.

The cyclooxygenase (COX) component of PGS catalyzes cyclization of C8—C12 of arachidonic acid to form the 9,11-endoperoxide 15-hydroperoxide, PGG_2. This reaction requires two molecules of molecular oxygen (Figure 18.65) and involves stereospecific removal of the 13-pro-S-hydrogen of arachidonic acid. PGG_2 is then converted to



Arachidonic acid **PGG_2**

Figure 18.65 **Cyclooxygenase reaction.**



PGG_2 **PGH_2**

Figure 18.66 **Conversion of PGG_2 to PGH_2; PG hydroperoxidase (PGH synthase) reaction.**

prostaglandin H_2 (PGH_2) by the reduced glutathione-dependent peroxidase (PG hydroperoxidase) component of PGS (Figure 18.66). Reactions cyclizing polyunsaturated fatty acids occur in the membranes of the endoplasmic reticulum. Major pathways of prostaglandin biosynthesis are summarized in Figure 18.67. Depending on cell type, different enzymes mediate formation of prostaglandins of the D, E, and F series and of thromboxanes and prostacyclin (PGI_2). This produces some tissue specificity as to type and quantity of prostaglandin produced. In kidney and spleen, PGE_2 and $PGF_{2\alpha}$ are the major prostaglandins formed. In contrast, blood vessels produce mostly PGI_2 and $PGF_{2\alpha}$. In the heart PGE_2, $PGF_{2\alpha}$, and PGI_2 are formed in about equal amounts. Thromboxane A_2 (TXA_2) is the main prostaglandin endoperoxide formed in platelets.

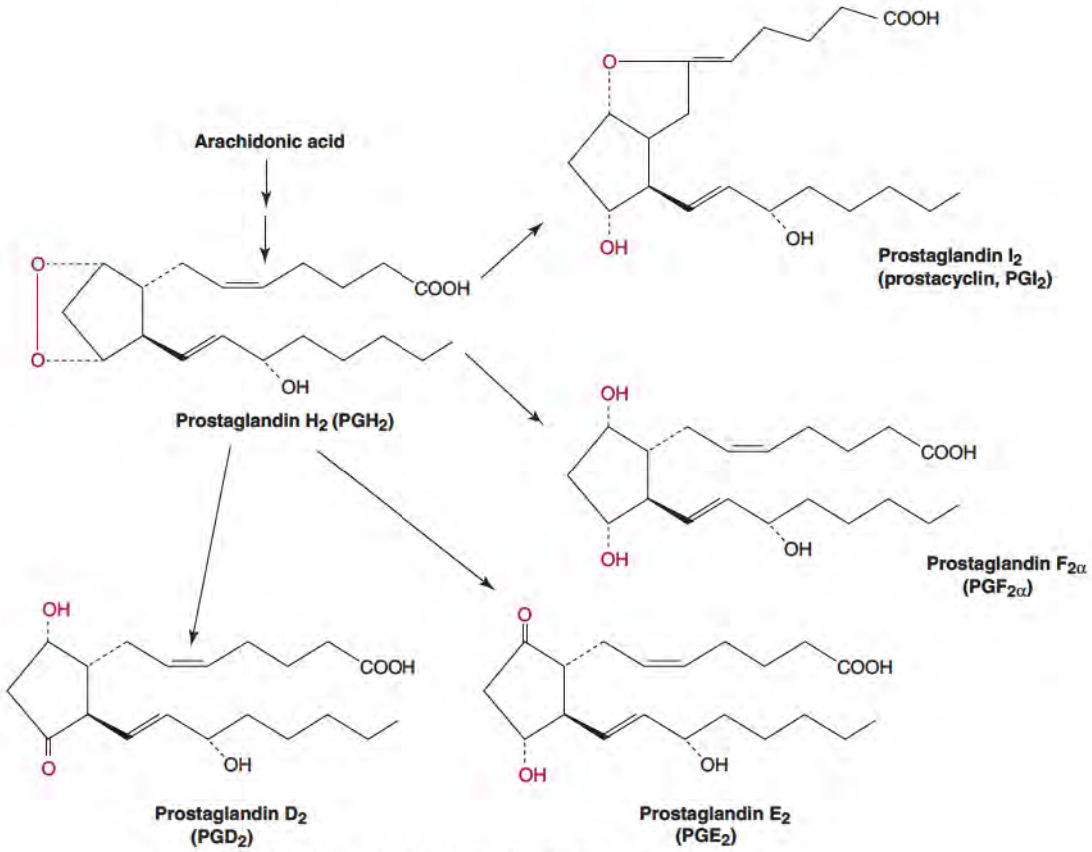


Figure 18.67 **Major routes of prostaglandin biosynthesis.**

There are two forms of cyclooxygenase (COX) or prostaglandin G/H synthase (PGS). COX-1, or PGS-1, is a constitutive enzyme of gastric mucosa, platelets, vascular endothelium, and kidney. COX-2, or PGS-2, is inducible and is produced in response to inflammation. The two prostaglandin synthases are homodimers. The two subunits each have PG hydroperoxidase and cyclooxygenase domains and these two catalytic centers are located close together. There is also a third domain, the membrane-binding domain, through which the enzyme is attached to the endoplasmic reticulum. COX-2 is mainly expressed in activated macrophages and monocytes that are stimulated by platelet-activating factor (PAF), interleukin-1, or bacterial lipopolysaccharide (LPS), and in smooth muscle cells, epithelial and endothelial cells, and neurons. PGS-2 induction is inhibited by glucocorticoids.

Prostaglandins have a very short half-life. They are rapidly taken up by cells soon after release through a receptor-mediated process, and inactivated by oxidation of the 15-hydroxy group or by β-oxidation from the carboxy end. The lungs have an important role in inactivating prostaglandins.

Thromboxanes are highly active metabolites of the PGG_2- and PGH_2-type prostaglandin endoperoxide in which the cyclopentane ring is replaced by a six-membered oxygen-containing (oxane) ring. The term **thromboxane** refers to their thrombus-forming potential. Thromboxane A_2 synthase of the endoplasmic reticulum is abundant in lung and platelets and converts endoperoxide PGH_2 to TXA_2. The half-life of TXA_2 is very short in water ($t_{1/2} \approx 1$ min) as it is transformed rapidly into inactive thromboxane B_2 (TXB_2) by the reaction shown in Figure 18.68.

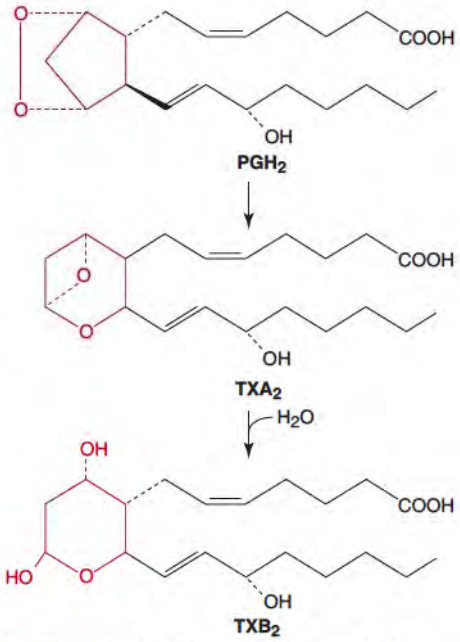

Figure 18.68 **Synthesis of TXB_2 from PGH_2.**

Prostaglandin Production Is Inhibited by Steroidal and Nonsteroidal Anti-inflammatory Agents

The **nonsteroidal anti-inflammatory drugs** (**NSAIDs**), such as aspirin (acetylsalicylic acid), indomethacin, and phenylbutazone, block prostaglandin production by inhibiting cyclooxygenase. Aspirin inhibits by acetylating the enzyme. Other NSAIDs inhibit cyclooxygenase by binding noncovalently rather than by acetylating it; they are called *nonaspirin NSAIDS*. Aspirin is more potent against COX-1 than COX-2. Most NSAIDs inhibit COX-2 more than COX-1. These drugs have undesirable side effects; for example, aplastic anemia can result from phenylbutazone therapy. Steroidal anti-inflammatory drugs like hydrocortisone, prednisone, and betamethasone block prostaglandin release by inhibiting phospholipase A_2 activity and interfering with release of arachidonic acid (Figure 18.69). A family of proteins called anexins mediates corticosteroid inhibition of COX-2.

Control of the synthesis of prostaglandins is poorly understood. In general, prostaglandin release seems to be triggered by hormonal or neural excitation or by muscular activity. For example, histamine increases prostaglandin concentration in gastric perfusates. In addition, prostaglandins are released during labor and after cellular injury (e.g., platelets exposed to thrombin and lungs irritated by dust).

Prostaglandins Exhibit Many Physiological Effects

Prostaglandins are natural mediators of inflammation. Inflammatory reactions most often involve the joints (e.g., rheumatoid arthritis), skin (e.g., psoriasis), and eyes and are treated frequently with corticosteroids that inhibit prostaglandin synthesis. Administration of PGE_2 and PGE_1 induces redness and heat (due to arteriolar vasodilation), and swelling and edema resulting from increased capillary permeability characteristic of inflammation. PGE_2 generated in immune tissues (e.g., macrophages, mast cells, B cells) evokes chemotaxis of T cells. PGE_2 in amounts that do not cause pain, prior to administration of histamine and bradykinin, enhances the intensity and duration of pain caused by these two agents. Pyrogens (fever-inducing agents) activate the prostaglandin synthesis pathway with release of PGE_2 in the hypothalamus where body temperature is regulated. Aspirin is an antipyretic drug that acts by inhibiting cyclooxygenase.

Prostaglandins are synthesized in the uterus where they soften tissues and stimulate contraction to expel the fetus. Increased production of PGE_2 within the ovary follicle is

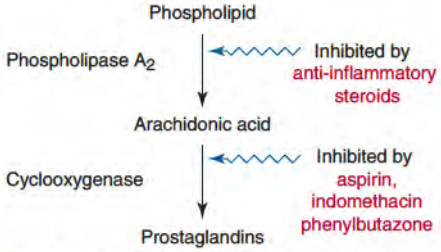

Figure 18.69 **Site of action of inhibitors of prostaglandin synthesis.**

essential for ovulation. The PGE agonist misoprostol has been used to induce parturition and to terminate unwanted pregnancies. There is also evidence that the PGE series of prostaglandins may be effective in treating infertility in males.

Synthetic prostaglandins are very effective in inhibiting gastric acid secretion in patients with peptic ulcer. They appear to inhibit cAMP formation in gastric mucosal cells and accelerate the healing of gastric ulcers. PGE, PGA, and PGI_2 are vasodilators that lower systemic arterial pressure, thereby increasing local blood flow and decreasing peripheral resistance. TXA_2 causes contraction of vascular smooth muscle and glomerular mesangium. In the fetus, PGE_2 maintains the patency of the ductus arteriosus prior to birth. If the ductus remains open after birth, closure can be hastened by the cyclooxygenase inhibitor indomethacin. In infants born with congenital abnormalities where the defect can be corrected surgically, infusion of prostaglandins maintains blood flow through the ductus until surgery is performed.

PGI_2 inhibits platelet aggregation, whereas PGE_2 and TXA_2 promote this clotting process. TXA_2 is produced by platelets and accounts for their aggregation when in contact with some foreign surface, collagen, or thrombin. Endothelial cells lining blood vessels release PGI_2, which may account for the lack of adherence of platelets to the healthy blood vessel wall. PGE_2 and PGD_2 dilate renal blood vessels and increase blood flow through the kidney. They also regulate sodium excretion and glomerular filtration rate.

18.6 • LIPOXYGENASE AND OXY-EICOSATETRAENOIC ACIDS

Cyclooxygenase directs polyunsaturated fatty acids into the prostaglandin pathway that has arachidonic acid as substrate. Lipoxygenase is a dioxygenase that also acts on arachidonic acid. Different lipoxygenases are specific for the double bond of arachidonic acid at which oxygen attack initially occurs (e.g., positions 5, 11, or 15). In humans, the most important leukotrienes are the 5-lipoxygenase products that mediate inflammatory disorders. Lipoxygenases occur widely in plants and fungi as well as in animals, but are absent from yeasts and most prokaryotes. They contain nonheme iron and are active when this iron is in the ferric state.

Monohydroperoxyeicosatetraenoic Acids Are Products of Lipoxygenase Action

Lipoxygenase adds a hydroperoxy group to arachidonic acid to produce monohydroperoxyeicosatetraenoic acids (HPETEs) (Figure 18.70). In contrast to the cyclooxygenase of prostaglandin endoperoxide synthase, which catalyzes the bis-dioxygenation of unsaturated fatty acids to endoperoxide, lipoxygenases catalyze the monodioxygenation of unsaturated fatty acids to allylic hydroperoxides. Hydroperoxy substitution of arachidonic acid by lipoxygenases may occur at position 5, 12, or 15. A 15-lipoxygenase (15-LOX) oxygenates arachidonic acid at carbon-15. 5-HPETE is the major product in basophils, polymorphonuclear (PMN) leukocytes, macrophages, mast cells, and any organ undergoing an inflammatory response; 12-HPETE predominates in platelets, pancreatic islet cells, vascular smooth muscle, and glomerular cells; and 15-HPETE is the principal product in reticulocytes, eosinophils, T-lymphocytes, and tracheal epithelial cells. The 5-, 12-, and 15-lipoxygenases occur mainly in the cytosol. Since the oxygenated carbon atom in HPETEs is asymmetric, there are two possible stereoisomers of the hydroperoxy acid, (*R*) or (*S*). For example, the stereo configuration is specified 12R-LOX or 12S-LOX. The three major HPETEs are of the (S) configuration. 5-LOX has a dioxygenase activity that converts arachidonic acid to 5-HPETE and a dehydrase activity that transforms 5-HPETE to LTA_4. 5-LOX activity is restricted to a few cell types, including B-lymphocytes, but not T lymphocytes. It is activated by an accessory protein called

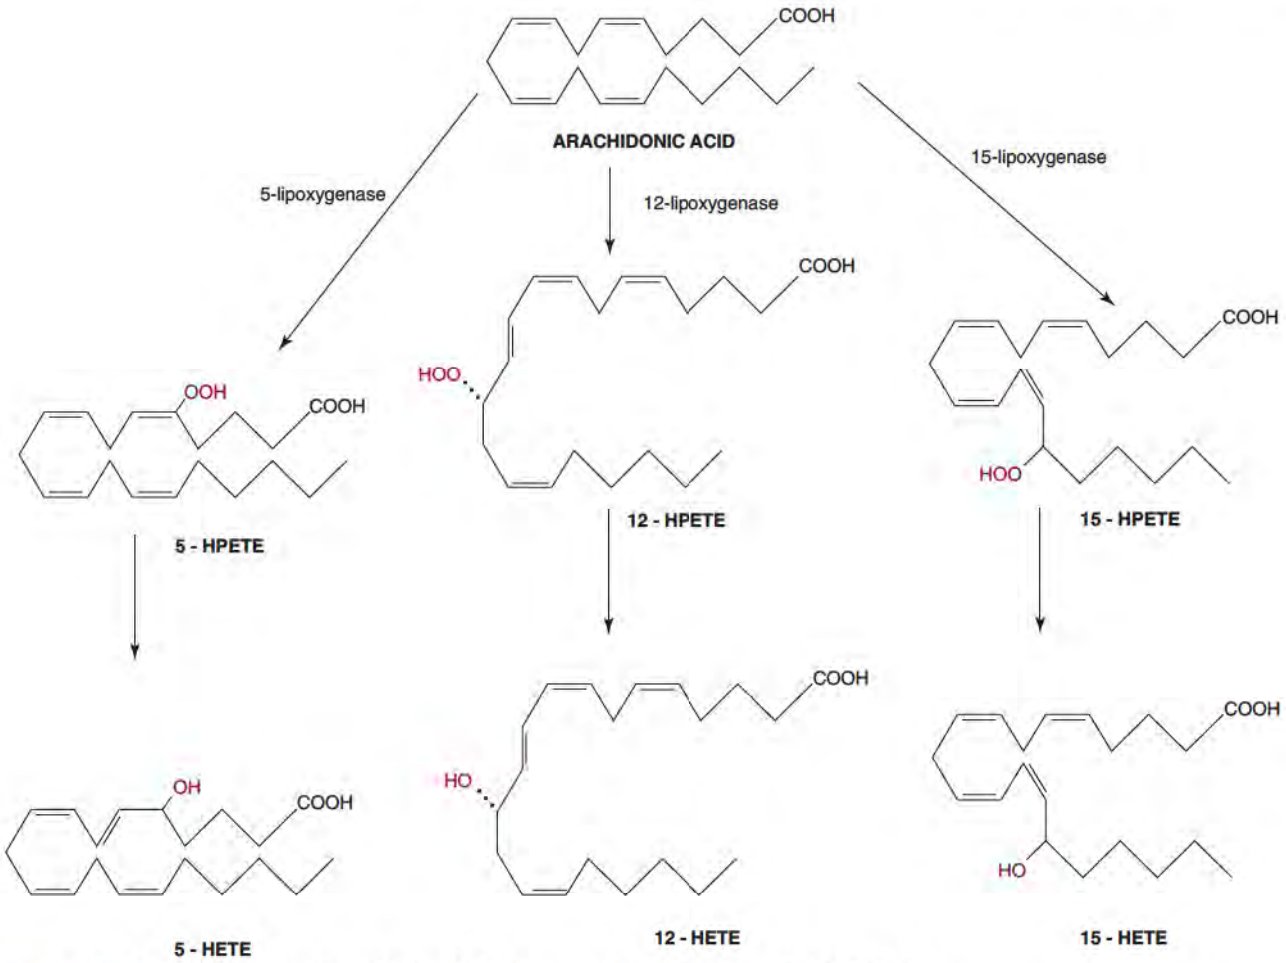

Figure 18.70 Lipoxygenase reaction and role of 5-hydroperoxyeicosatetraenoic acids (HPETEs) as precursors of hydroxyeicosatetraenoic acids (HETEs).

5-lipoxygenase activating protein (FLAP). In human leukocytes, FLAP is an arachidonic acid transfer protein that presents the fatty acid substrate to the 5-LOX located on the nuclear membrane.

Leukotrienes, Hydroxyeicosatetraenoic Acids, and Lipoxins Are Hormones Derived from HPETEs

HPETE-hydroperoxides are highly reactive, unstable intermediates that are converted either to the analogous alcohol (hydroxy fatty acid) by reduction of the peroxide moiety or to leukotrienes. The HPETEs are reduced either spontaneously or by the action of peroxidases to the corresponding hydroxyeicosatetraenoic acids (HETEs) (Figure 18.70). Leukotrienes contain at least three conjugated double bonds. Figure 18.71 shows how 5-HPETE is rearranged by LTA_4 synthase to the epoxide leukotriene A_4 (LTA_4), which is then converted by LTB_4 synthase (hydratase) to LTB_4 or LTC_4, emphasizing that 5-HPETE is an important branch point in the lipoxygenase pathway. Note that the subscript indicates the number of double bonds. Thus, while double-bond rearrangement may occur, the number of double bonds in the leukotriene product is the same as in the original arachidonic acid.

The conversion of LTA_4 to leukotrienes LTC_4, LTD_4, and LTE_4 requires the participation of reduced glutathione that opens the epoxide ring in LTA_4 to produce LTC_4 (Figure 18.71). Sequential removal of glutamic acid and glycine residues by specific dipeptidases yields the leukotrienes LTD_4 and LTE_4 (Figure 18.72).

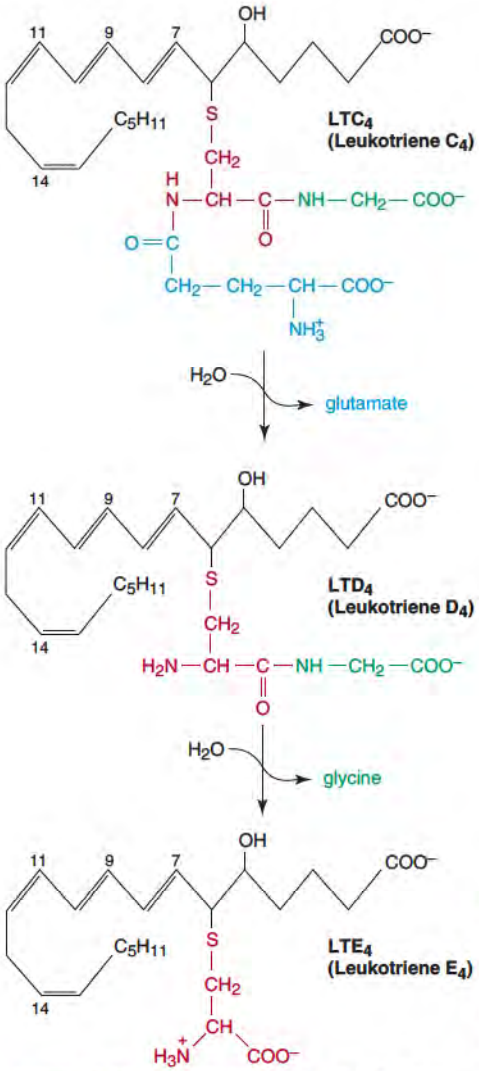

Figure 18.72 **Conversion of LTC_4 to LTD_4 and LTE_4.**

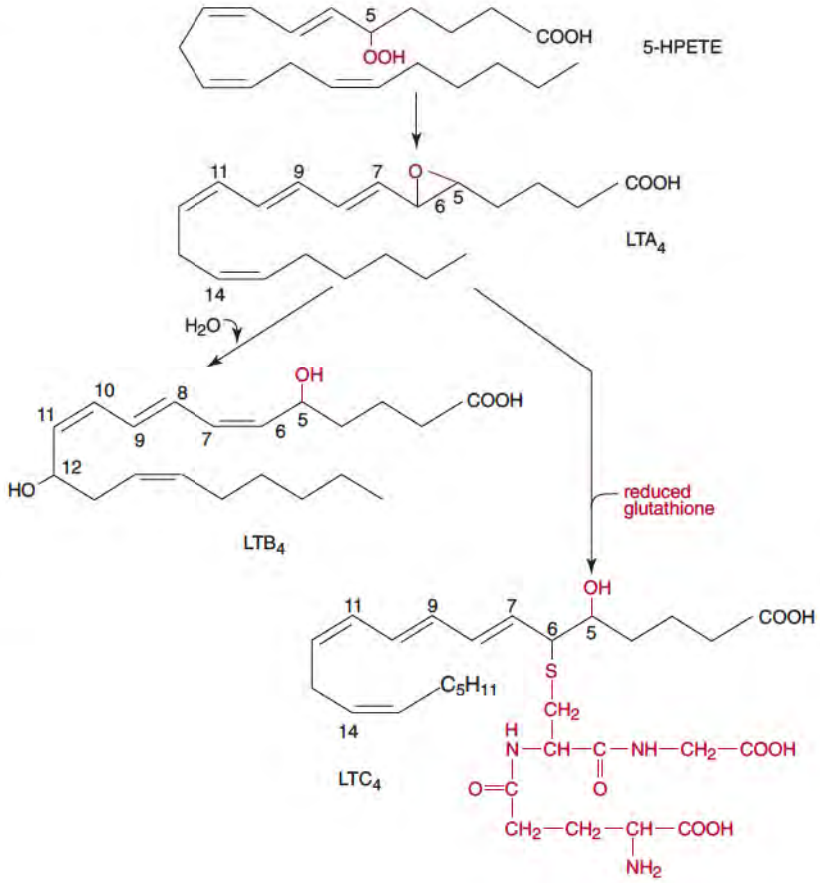

Figure 18.71 **Conversion of 5-HPETE to LTB_4 and LTC_4 through LTA_4 as intermediate.**

Lipoxins are another class of linear eicosanoids derived from arachidonic acid. They differ structurally from leukotrienes and HETEs in that they contain three hydroxyl groups and a conjugated tetraene system (Figure 18.73).

Leukotrienes and HETEs Affect Several Physiological Processes

Leukotrienes persist for up to 4 h in the body. Omega-oxidation of the methyl end followed by β-oxidation from this end inactivates LTB_4 and LTE_4. These reactions occur in mitochondria and peroxisomes. The thionyl peptides LTC_4, LTD_4, and LTE_4 constitute

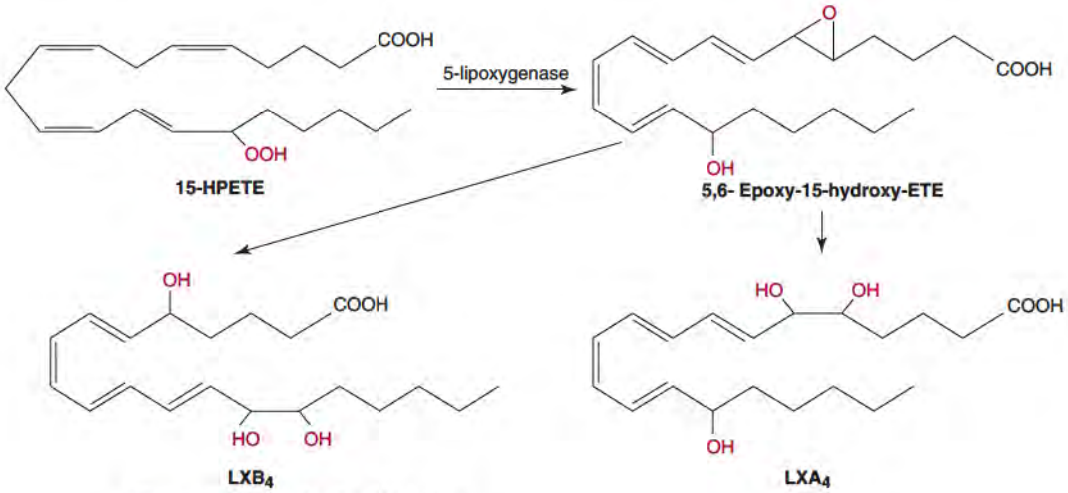

Figure 18.73 **Synthesis of Lipoxins.**

the **slow-reacting substance** of anaphylaxis (SRS-A). They cause slowly evolving but protracted contraction of smooth muscles in the airways and gastrointestinal tract. LTC_4 is rapidly converted to LTD_4 and then slowly converted to LTE_4. Enzymes in plasma catalyze these conversions. LTB_4 and the thionyl peptides LTC_4, LTD_4, and LTE_4 exert their actions through specific ligand–receptor interactions. In humans, activation of 5-LOX of leukocytes stimulates production of leukotrienes that provoke bronchoconstriction and inflammation. Current drugs for asthma include 5-LOX inhibitors and leukotriene receptor antagonists.

In general, HETEs (especially 5-HETE) and LTB_4 regulate neutrophil and eosinophil function: they mediate chemotaxis, stimulate adenylate cyclase, and induce polymorphonuclear (PMN) leukocyte cells to degranulate and release lysosomal hydrolytic enzymes. In contrast, LTC_4 and LTD_4 are humoral agents that promote smooth muscle contraction; constriction of pulmonary airways, trachea, and intestine; and increases in capillary permeability (edema). The HETEs appear to exert their effects by being incorporated into the phospholipids of membranes of target cells where the presence of fatty acyl chains containing a polar OH group may disturb lipid packing and thus the structure and function of the membrane. LTB_4 is immunosuppressive through inhibition of $CD4^+$ cells and proliferation of suppressor $CD8^+$ cells. LTB_4 also promotes neutrophil–endothelial cell adhesion.

Monohydroxy eicosatetraenoic acids of the lipoxygenase pathway are potent mediators of processes involved in allergy (hypersensitivity) and inflammation, secretion (e.g., insulin), cell movement, cell growth, and calcium fluxes. The initial allergic event, namely, the binding of IgE antibody to receptors on the surface of the mast cell, causes release of substances, including leukotrienes, referred to as mediators of immediate hypersensitivity. Lipoxygenase products are usually produced within minutes after the stimulus. The leukotrienes LTC_4, LTD_4, and LTE_4 are much more potent than histamine in contracting nonvascular smooth muscles of bronchi and intestine. LTD_4 increases the permeability of the microvasculature. LTB_4 stimulates migration (chemotaxis) of eosinophils and neutrophils, making them the principal mediators of PMN-leukocyte infiltration in inflammatory reactions.

Lipoxin A_4 (LXA4) and lipoxin B_4 (LXB4) have many physiologic functions, including inhibition of angiogenesis, promotion of clearance of pulmonary edema and protection against reperfusion injury.

Eicosatrienoic acids (e.g., dihomo-γ-linolenic acid) and eicosapentaenoic acid (see Figure 18.64, p. 739) also serve as lipoxygenase substrates. The amount of these 20 carbon polyunsaturated fatty acids with three and five double bonds in tissues is less than that of arachidonic acid, but special diets can increase their levels. The lipoxygenase products of these tri- and pentaeicosanoids are usually less active than LTA_4 or LTB_4. Since most Western diets contain about 10-fold more omega-6 fatty acids than omega-3 fatty acids, on a mass basis inflammatory prostaglandins, thromboxanes, leukotrienes, hydroxyl fatty acids, and lipoxins are produced in greater amounts than the less inflammatory products formed from omega-3 fatty acids such as eicosapentaenoic acid. Thus, a diet rich in omega-6 fatty acids shifts an individual into a state that is proinflammatory. It remains to be determined if fish oil diets rich in eicosapentaenoic acid are useful in the treatment of allergic and autoimmune diseases. Pharmaceutical research into therapeutic uses of lipoxygenase and cyclooxygenase inhibitors and inhibitors and agonists of leukotrienes in treatment of inflammatory diseases such as asthma, psoriasis, rheumatoid arthritis, and ulcerative colitis is very active.

Key Terms

phospholipids
cardiolipin
choline plasmalogen
platelet-activating factor
phosphatidylserine decarboxylase
phosphatidylinositol
phosphatidylinositol 4, 5-bisphosphate
CDP-choline
cytidyltransferase
glycerol 3-phosphate: acyltransferase
glycerol kinase
phosphatidic acid phosphatase
phosphatidylinositol synthase
cholesterol
acetoacetyl-CoA thiolase
HMG-CoA reductase
HMG-CoA synthase
farnesyl pyrophosphate
geranyltransferase
lanosterol cyclase
chylomicrons
high-density lipoprotein
low-density lipoproteins (LDL)
plasma lipoproteins
very low-density lipoproteins
cholesteryl ester transfer protein
lecithin:cholesterol acyl transferase
LDL receptors
CoA:cholesterol acyltransferase
bile acids
sphingosine
ceramide
serine palmitoyltransferase
sphingomyelin
galactocerebroside
glucocerebroside
sulfatide
gangliosides
globosides
neuraminic acid
prostaglandins
thromboxanes
cyclooxygenase
nonsteroidal anti-inflammatory drugs
lipoxygenase
leukotrienes
slow-reacting substance

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. Roles of various phospholipids include all of the following except
- **A.** cell–cell recognition.
- **B.** a surfactant function in lung.
- **C.** activation of certain membrane enzymes.
- **D.** signal transduction.
- **E.** mediator of hypersensitivity and acute inflammatory reactions.

2. CDP-X (where X is the appropriate alcohol) reacts with 1,2-diacylglycerol in the primary synthetic pathway for
- **A.** phosphatidylcholine.
- **B.** phosphatidylinositol.
- **C.** phosphatidylserine.
- **D.** all of the above.
- **E.** none of the above.

3. Plasmalogens differ from other membrane lipids in that they
- **A.** do not contain phosphorus.
- **B.** are found primarily in the inner mitochondrial membrane.
- **C.** have an alkene in ether linkage at the sn-1 position rather than a fatty acyl group.
- **D.** always contain a bound serine.
- **E.** contain a sugar molecule esterified to the phosphate.

4. Bile acids differ from their precursor cholesterol in that they
- **A.** are not amphipathic.
- **B.** contain an ionizable carboxyl group.
- **C.** contain less oxygen.
- **D.** are synthesized primarily in intestine.
- **E.** contain more double bonds.

5. A ganglioside may contain all of the following except
- **A.** a ceramide structure.
- **B.** glucose or galactose.
- **C.** phosphate.
- **D.** one or more sialic acids.
- **E.** sphingosine.

6. Phosphatidylinositols
- **A.** are neutral phospholipids.
- **B.** are found primarily in mitochondrial membrane.
- **C.** release Ca^{2+} from the endoplasmic reticulum.
- **D.** can serve to anchor glycoproteins to cell surfaces.
- **E.** are the major surfactants maintaining normal lung function.

Questions 7 and 8: Prostaglandins and leukotrienes are physiologically highly reactive compounds produced from polyunsaturated C20 acids like arachidonic acid. Both play some role in inflammatory processes. NSAIDs (nonsteroidal anti-inflammatory drugs) like aspirin are effective in inhibiting prostaglandin production but not leukotrienes.

7. Prostaglandin synthase, a bifunctional enzyme,
- **A.** catalyzes the rate-limiting step of prostaglandin synthesis.
- **B.** is inhibited by anti-inflammatory steroids.
- **C.** contains both a cyclooxygenase and a peroxidase component.
- **D.** produces PGG_2 as the end product.
- **E.** uses as substrate the pool of free arachidonic acid in the cell.

8. Leukotrienes
- **A.** synthesis begins with the addition of a hydroperoxy group to arachidonic acid.
- **B.** are inactivated by conversion to HPETEs.
- **C.** have an internal ring structure.
- **D.** are highly unstable, lasting only a few minutes.
- **E.** are converted to lipoxins.

Questions 9 and 10: Hypercholesterolemia is one of the risk factors for cardiovascular disease. Total cholesterol in blood is not as important in considering risk as distribution of cholesterol between LDL ("bad") and HDL ("good") particles. Efforts to reduce serum cholesterol are two-pronged: diet and drugs if reducing dietary cholesterol and saturated fat is not sufficient. The drugs of choice are statins, inhibitors of the rate-limiting enzyme of cholesterol biosynthesis. If necessary, bile acid-binding resins can be added.

9. In biosynthesis of cholesterol,
- **A.** 3-hydroxy-3-methyl glutaryl CoA (HMG CoA) is synthesized by mitochondrial HMG CoA synthase.
- **B.** HMG CoA reductase catalyzes the rate-limiting step.
- **C.** the conversion of mevalonic acid to farnesyl pyrophosphate proceeds via condensation of three molecules of mevalonic acid.
- **D.** condensation of two farnesyl pyrophosphates to form squalene is freely reversible.
- **E.** conversion of squalene to lanosterol is initiated by formation of the fused ring system, followed by addition of oxygen.

10. Cholesterol present in LDL (low-density lipoproteins)
- **A.** binds to a cell receptor and diffuses across the cell membrane.
- **B.** when it enters a cell, suppresses activity of ACAT (acyl CoA-cholesterol acyl transferase).
- **C.** once in the cell, is converted to cholesteryl esters by LCAT (lecithin-cholesterol acyl transferase).
- **D.** once it has accumulated in the cell, inhibits replenishment of LDL receptors.
- **E.** represents primarily cholesterol that is being removed from peripheral cells.

Questions 11 and 12: Sphingolipidoses (lipid storage diseases) are a group of diseases characterized by defects in lysosomal enzymes. Rate of synthesis of sphingolipids is normal, but un-degraded material accumulates in lysosomes. The severity of the particular disease depends, in part, on what tissues are most affected. Those affecting primarily brain and nervous tissue, like Tay–Sachs disease, are lethal within a few years of birth. Since the extent of enzyme deficiency is the same in all cells, easily accessible tissues like skin fibroblasts can be used to assay for enzyme deficiency. There are no treatments for most of the diseases so genetic counseling seems to be the only helpful approach. However, for Gaucher disease enzyme (glucocerebrosidase) replacement therapy is effective.

11. All of the following are true about degradation of sphingolipids except it
- **A.** occurs by hydrolytic enzymes contained in lysosomes.
- **B.** terminates at the level of ceramides.
- **C.** is a sequential, stepwise removal of constituents.
- **D.** may involve a sulfatase or a neuraminidase.
- **E.** is catalyzed by enzymes specific for a type of linkage rather than specific compound.

12. In Niemann–Pick disease, the deficient enzyme is sphingomyelinase. Sphingomyelins differ from other sphingolipids in that they are
- **A.** not based on a ceramide core.
- **B.** acidic rather than neutral at physiological pH.
- **C.** only types containing *N*-acetylneuraminic acid.
- **D.** only types that are phospholipids.
- **E.** not amphipathic.

Problems

13. Cells from a patient with familial hypercholesterolemia (FH) and cells from an individual without that disease were incubated with LDL particles containing radioactively labeled cholesterol. After incubation, the incubation medium was removed and the radioactivity of the cells measured. The cells were treated to remove any bound material and lysed, and internal cholesterol content was measured. Results are given below. What mutation of the gene for the LDL receptor protein could account for the results?

Cell Type	*Radioactivity of Cell*	*Cholesterol Content*
Normal	3000 cpm/mg cells	Low
FH	3000 cpm/mg cells	High

14. The distribution of fatty acids in many tissue phospholipids is different than that of the initially synthesized phospholipids. How does this redistribution occur?

Answers

1. A This function appears to be associated with complex glycosphingolipids. B: Especially dipalmitoyllecithin. C: For example, β-hydroxybutyrate dehydrogenase. D: Especially phosphatidylinositols. E: Platelet activity factor (PAF) does this.

2. A This is the main pathway for choline. B: Phosphatidylinositol is formed from CDP-diglyceride reacting with myoinositol. C: This is formed by base exchange.

3. C This linkage is formed by reaction with a long-chain alcohol. A: They are phospholipids. B: This is cardiolipin; plasmalogens are found in large amounts in myelin. D: Choline plasmalogen is the most abundant. E: They do not contain sugar; cerebrosides and gangliosides contain sugar but do not contain phosphate.

4. B This carboxyl group is often conjugated to glycine or taurine. A: Their role depends on being amphipathic. C: Hydroxylation is a major part of synthesis. D: Liver is site of synthesis. E: Primary bile acids are unsaturated.

5. C Glycosphingolipids do not contain phosphate. A and E: Ceramide, which is formed from sphingosine, is the base structure from which glycosphingolipids are formed. B: Glucose is usually the first sugar attached to the ceramide. D: By definition, gangliosides contain sialic acid.

6. D Glyceryl-phosphatidylinositols anchors have specific structural features. A: These are acidic, even more so as inositol is phosphorylated. B: Their functions reside at the plasma membrane. C: PIP_2 must be hydrolyzed to IP_3, which releases Ca^{2+}. E: This is dipalmitoyllecithin.

7. C Cyclooxygenase oxidizes arachidonic acid, and peroxidase converts PGG_2 to PGH_2. A and B: The release of the precursor fatty acid by phospholipase A_2 is the rate-limiting step and the one inhibited by

anti-inflammatory steroids. D: The peroxidase component converts the PGG_2 to PGH_2. E: Arachidonic acid is not free in the cell but is part of the membrane phospholipids or sometimes a cholesteryl ester.

8. **A** This is catalyzed by a lipoxygenase. B: HPETEs are intermediates in the synthesis. C: They are open chain derivatives of arachidonic acid. D: They can persist up to 4 h. E: Lipoxins are derived from the same intermediates (HPETEs) but are a different class of arachidonic acid derivatives.
9. **B** This enzyme is inhibited by cholesterol. A: Remember that cholesterol biosynthesis is cytosolic; mitochondrial biosynthesis of HMG CoA leads to ketone body formation. C: Mevalonic acid is decarboxylated (among other things) to produce the isoprene pyrophosphates which are the condensing units. D: Pyrophosphate is hydrolyzed which prevents reversal. E: The process is initiated by epoxide formation.
10. **D** This is one of the ways to prevent overload in the cell. A: LDL binds to the cell receptor and it is endocytosed and then degraded in lysosomes to release cholesterol. B: ACAT is activated to facilitate storage. C: LCAT is a plasma enzyme. E: The primary role of LDL is to deliver cholesterol to peripheral tissues; HDL removes cholesterol from peripheral tissues.
11. **B** Ceramides are hydrolyzed to sphingosine and fatty acid. D: Sulfogalactocerebroside contains sulfate and gangliosides contain one or more *N*-acetylneuraminic acids. E: Many sphingolipids share the same types of bonds, for example, a β-galactosidic bond, and one enzyme, for example, β-galactosidase, will hydrolyze it whenever it occurs.
12. **D** Sphingomyelins are not glycosphingolipids but phosphosphingolipids. A, B, and E: They are formed from ceramides, are amphipathic and are neutral. C is the definition of gangliosides.
13. FH cells have LDL receptors with normal binding properties as indicated by the bound radioactivity being the same as that of normal cells. They are unable to internalize the receptor–LDL complex so cholesterol synthesis is not inhibited as it is with normal cells. The mutation is most likely on the carboxy terminus of the protein that is involved in internalization. Make sure you understand why mutation in other regions would not lead to the observed results.
14. The acyltransferases in phosphatidic acid synthesis usually place a saturated fatty acid at sn-1 and unsaturated one at sn-2. Phospholipases A_1 and A_2 hydrolyze the fatty acids from these respective positions, generating either 2-acyl- or 1-acyl-lysophosphatide. The lysophosphatides can then be reacylated with the desired fatty acyl CoA.

Key Concepts

AMINO ACIDS

- Ammonia, used to synthesize amino acids and other nitrogenous compounds, is formed from nitrogen in the atmosphere by plants, bacteria, and the electrical charge from lightening.
- Humans synthesize *de novo* 11 amino acids; they are classified as *nonessential amino acids* in the diet. Metabolites of intermediary metabolism are precursors for synthesis of nonessential amino acids. Nine other amino acids are required in the diet and are classified as *essential amino acids.*
- Glutamate dehydrogenase catalyses incorporation of ammonia into an amino group, which can then be incorporated into other nonessential amino acids. Aminotransferases catalyze the

transfer of amino groups from most amino acids to an α-keto acid. Pyridoxal phosphate is the prosthetic group of aminotransferases.
- Amino group nitrogen is transported to the liver predominantly by glutamine and alanine where the urea cycle synthesizes urea from amino groups and ammonia for excretion. Glutamine is transported to kidneys for excretion of the amino group as ammonium ion or to intestines to initiate synthesis of arginine.
- Two amino acids are ketogenic, some are glucogenic, and some are both ketogenic and glucogenic. Many amino acids serve as precursors for secondary metabolites such as hormones and neurotransmitters.
- There are genetic errors in amino acid degradative and synthetic pathways.

HEME

- Heme, produced in virtually all mammalian tissues, consist of a ferrous ion and protoporphyrin IX. The organic portion of heme is derived totally from eight residues each of glycine and succinyl CoA.
- Four enzymatic steps are catalyzed by enzymes in mitochondria and four in the cytosol. Regulation of heme synthesis is at the δ-aminolevulinic acid synthase reaction, the first biosynthetic step.
- Derangements of porphyrin metabolism are known clinically as the porphyrias.
- Heme catabolism occurs in the endoplasmic reticulum of reticuloendothelial cells with the formation of bilirubin, CO, and iron. Bilirubin is transported to the liver on albumin where it is conjugated with glucuronic acid. Bilirubin glucuronide is excreted in bile into the intestines, where some is further metabolized by bacteria.

19.1 • INCORPORATION OF NITROGEN INTO AMINO ACIDS

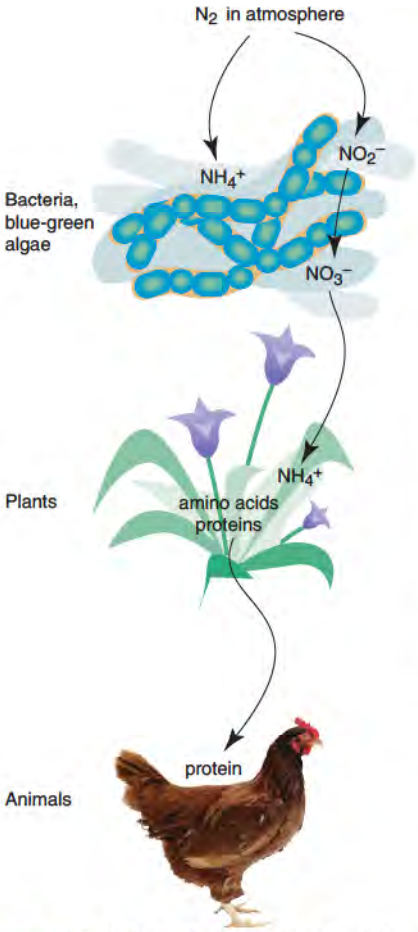

Figure 19.1 Outline of entry of atmospheric nitrogen into the animal diet. This occurs initially by reduction of nitrogen in the atmosphere to ammonia by nitrogen fixation or by reduction of nitrate to ammonia. Nitrate fixation and reduction is carried out by enzymes in microorganisms and plants. Source (photo, brown chicken): PhotoDisc, Inc.

Most Amino Acids Are Obtained from the Diet

The nitrogen found in macromolecules of the body come from the diet, after the nitrogen in the atmosphere has been made available (*fixed*) as ammonia by microorganisms and plants (Figure 19.1).

A healthy adult eating a varied and plentiful diet is generally in **nitrogen balance**, a state where the amount of nitrogen ingested each day is balanced by the amount excreted, resulting in no net change in total body nitrogen. In the well-fed condition, excreted nitrogen comes mostly from excess protein intake or from normal turnover. Protein turnover is defined as replacement of body protein by synthesis and degradation (p. 1103). Under some conditions, the body is either in negative or positive nitrogen balance. In negative nitrogen balance more nitrogen is excreted than ingested. This occurs in starvation and certain diseases. During starvation, carbon chains of amino acids from proteins are needed for gluconeogenesis; ammonia released from amino acids is excreted mostly as urea and is not reincorporated into protein. A diet deficient in essential amino acids (essential amino acids cannot be synthesized *de novo* by humans) also leads to a negative nitrogen balance, since body proteins are degraded and their essential amino acids reutilized, and the other amino acids liberated are metabolized. Negative nitrogen balance may also exist in senescence. Positive nitrogen balance occurs in growing children, who are increasing their body weight and incorporating more amino acids into proteins than they break down (A Closer Look 19.1). Cysteine, tyrosine, and arginine supplementation is sometimes required in premature infants and for people with liver disease. Positive nitrogen balance also occurs in pregnancy and during refeeding after starvation. Nonessential amino acids are synthesized from readily available intermediates (Table 19.1), and all amino acids are metabolized to intermediates of glycolysis, and the TCA cycle, and acetyl CoA (Figure 19.2).

There are many inherited metabolic diseases associated with amino acid metabolism. Information on these diseases may be found at www.ncbi.nlm.nih.gov/Omim. OMIM accession numbers associated with a disease or enzyme are indicated n the text.

Amino Groups Are Transferred from One Amino Acid to Form Another

Most amino acids used to synthesize protein or as precursors for amino acid derivatives are obtained from the diet or from protein turnover. When necessary, nonessential amino acids are synthesized from α-keto acid precursors by transfer of a preexisting amino group from another amino acid by aminotransferases, also called transaminases (Figure 19.3;

A CLOSER LOOK 19.1

Blood Urea Nitrogen and Measurement of Nitrogen Balance

Measurement of blood urea nitrogen (BUN) is a common test used to assess kidney function. It may be used in cases of kidney disease, or as part of a routine health screening. It is also useful to assess kidney function before administration of a wide range of drugs (such as allopurinol, indomethacin, thiazide diuretics, and tetracyclines) that have the potential for kidney damage. Creatinine (p. 789) may also be assessed along with BUN. Increases in BUN may be associated with heart failure, severe burns, dehydration, and obstructed urine flow. Excess protein intake also raises BUN. The normal range for the ratio of BUN to serum creatinine is 10:1 to 15:1.

Nitrogen balance is a measure of the difference between nitrogen intake (in the form of protein) and nitrogen excretion. During growth and tissue repair, especially after surgery and trauma, the body is in positive N balance; that is, intake is greater than loss. In fevers, fasting, and wasting diseases (cachexia), the loss is greater than the intake, the individual is in negative balance, and there is a net loss of protein from the body. A key relationship between protein intake and nitrogen output is the conversion of grams of protein in the diet into nitrogen equivalents. The average amino acid is considered to have a molecular weight of 120, of which 16% can be attributed (on average) to nitrogen. This allows for a comparison of protein nitrogen consumed with total urine nitrogen (TUN) output as follows:

$$N_2 \text{ balance} = (\text{protein intake (gm)} \times 0.16) - [(\text{total urine nitrogen (gm)} + 3\text{ gm})]$$

The 3-gm "fudge factor" represents the nitrogen lost in feces, skin cells, and nails.

A CLOSER LOOK 19.2

Mechanism of Aminotransferases

The carbon in the Schiff base originates in the aldehyde group of pyridoxal phosphate (PLP), and the nitrogen in the lysine residue when PLP is covalently bound to the enzyme. When a substrate amino acid approaches the active site, its amino group displaces the lysine ε-amino group and a Schiff base linkage is formed with the amino group of the amino acid substrate (Figure 19.9). At this point the pyridoxal-phosphate-derived molecule is no longer covalently attached to the enzyme but is held in the active site only by ionic and hydrophobic interactions between it and the protein. The Schiff base linkage with the substrate amino acid substrate is in tautomeric equilibrium between an aldimine, $—CH=N—CHR_2$, and a ketimine, $—CH_2—N=CR_2$. Hydrolysis of the ketimine liberates an α-keto acid, leaving the amino group as part of the pyridoxamine structure. A reversal of the process is now possible; an α-keto acid reacts with the amine group, the double bond is shifted, and then hydrolysis liberates an amino acid. Pyridoxal phosphate now reforms its Schiff base with the "resting" enzyme (Figure 19.8). Many pyridoxal-phosphate-dependent reactions involve transamination, but the ability of the Schiff base to transfer electrons between different atoms allows the cofactor to participate when other groups, such as carboxyls, are to be eliminated. Figure 19.10 (p. 755) shows the reaction of a pyridoxal-phosphate-dependent decarboxylase and an α,β-elimination.

A Closer Look 19.2). Transfer of amino groups also occurs during degradation of amino acids. Figure 19.4 shows how the amino group of alanine is transferred to α-ketoglutarate to form glutamate. The pyruvate produced then provides carbons for gluconeogenesis or for energy production via the TCA cycle. This reaction is necessary since ammonia cannot enter the urea cycle directly from alanine but the amino group of glutamate can be utilized. The reverse reaction would occur if there were a need for alanine for protein synthesis that was not being met by dietary intake or protein turnover. Transamination involving essential amino acids is normally unidirectional since the body cannot synthesize the equivalent α-keto acid. Figure 19.5 (solid line) shows removal of the nitrogen from valine, an essential amino acid, by transamination, during catabolism. The resulting α-ketoisovalerate is further metabolized to succinyl CoA. Transamination is the most common reaction involving free amino acids, and only threonine and lysine do not participate in an aminotransferase reaction. An obligate amino and α-keto acid pair in all transamination reactions is glutamate and α-ketoglutarate. This means that amino group transfer between alanine and aspartate would have to occur via coupled reactions, with a glutamate intermediate (Figure 19.6). The equilibrium constant for aminotransferases is close to 1 so that the reactions are freely reversible. When nitrogen excretion is impaired and hyperammonemia occurs, as in liver failure, amino acids, especially branched-chain amino acids, can be replaced in the diet by α-keto acid analogs. The α-keto acids are transaminated to produce the corresponding amino acids. Figure19.5 (dotted line) shows valine formation after administration of α-ketoisovalerate as therapy for hyperammonemia.

Tissue distribution of some of the aminotransferases is used diagnostically by measuring the release of a specific enzyme during tissue damage; for instance, an increase in **glutamate aspartate aminotransferase** (**AST**, aspartate transaminase; previously SGOT, serum glutamate oxaloacetate transaminase) and **glutamate alanine aminotransferase** (**ALT**, alanine transaminase; previously SGPT, serum glutamate pyruvate transaminase) in plasma is a sign of liver damage.

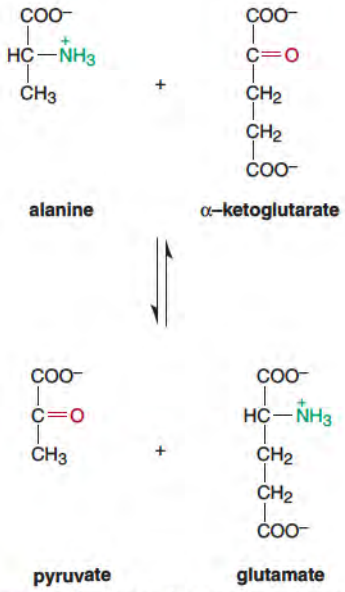

Figure 19.4 Alanine aminotransferase reaction.

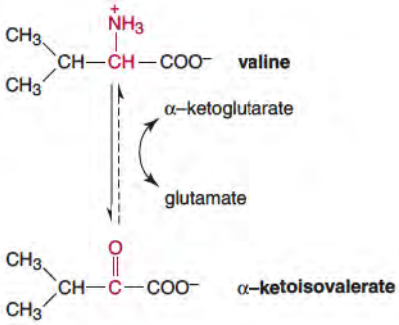

Figure 19.5 Transamination of valine. Valine can be formed from α-ketoisovalerate only when this compound is administered therapeutically.

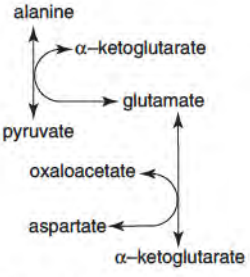

Figure 19.6 Coupled transamination reaction.

Pyridoxal Phosphate Is Cofactor for Aminotransferases

Transfer of amino groups occurs via enzyme-associated intermediates derived from **pyridoxal phosphate**, the functional form of vitamin B_6 (Figure 19.7). The active site of the "resting" aminotransferase contains pyridoxal phosphate covalently attached to a ε-amino group of a lysine residue of the enzyme (Figure 19.8). The complex is further stabilized by ionic and hydrophobic interactions. The linkage, —CH=N—, is called a Schiff base. The reaction occurs by a double-displacement (*ping-pong*) mechanism (Figure 19.9). The effective concentration of vitamin B_6 in the body may be decreased by administration of certain drugs, such as the antituberculosis drug, isoniazid, which forms a Schiff base with pyridoxal thus making it unavailable for catalysis. Pyridoxal phosphate plays an important role in many transferase reactions (Figure 19.10).

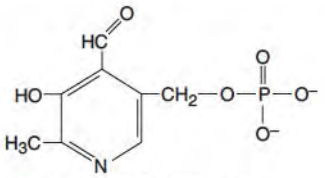

Figure 19.7 Pyridoxal phosphate.

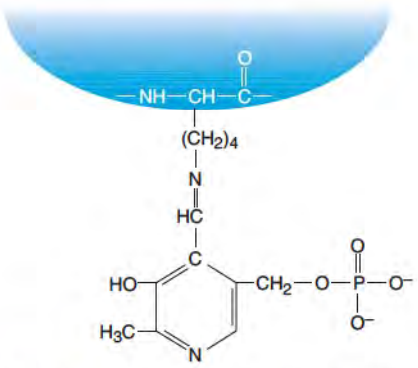

Figure 19.8 Pyridoxal phosphate in aldimine linkage to protein lysine residue.

Glutamate Dehydrogenase Incorporates and Produces Ammonia

In liver ammonia is incorporated into glutamate by glutamate dehydrogenase (Figure 19.11), which also catalyzes the reverse reaction. Glutamate always serves as one of the amino acids in transaminations and is thus the "gateway" between amino groups of most amino acids and free ammonia (Figure 19.12). NADPH is used in the synthetic reaction, whereas NAD^+ is used in liberation of ammonia, a degradative reaction. The enzyme produces ammonia from amino acids when these are needed as glucose precursors or for energy. Formation of NADH during the oxidative deamination reaction is a welcome bonus, since it can be reoxidized by the respiratory chain with formation of ATP. The reaction as shown is readily reversible in the test tube but it probably occurs more frequently in the direction of ammonia formation. The concentration of ammonia needed for production of glutamate is toxic and under normal conditions would rarely be attained except in the perivenous region of the liver.

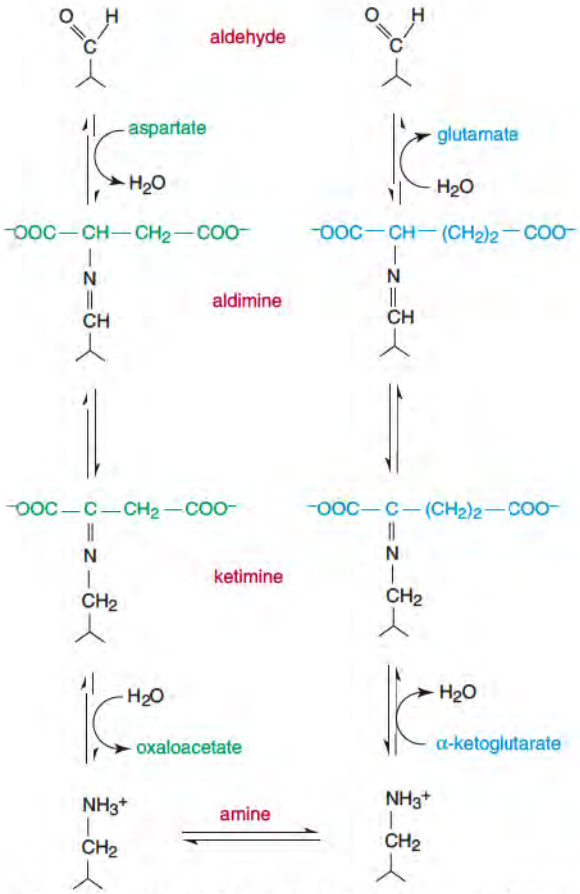

Figure 19.9 Different forms of pyridoxal phosphate during a transamination reaction.

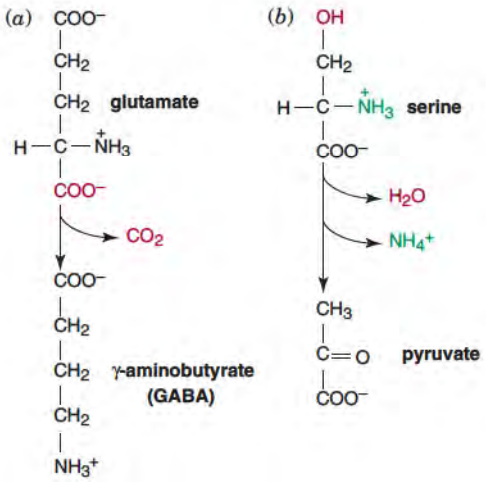

Figure 19.10 Pyridoxal-phosphate-dependent reactions. (*a*) Glutamate decarboxylase. (*b*) Serine dehydratase.

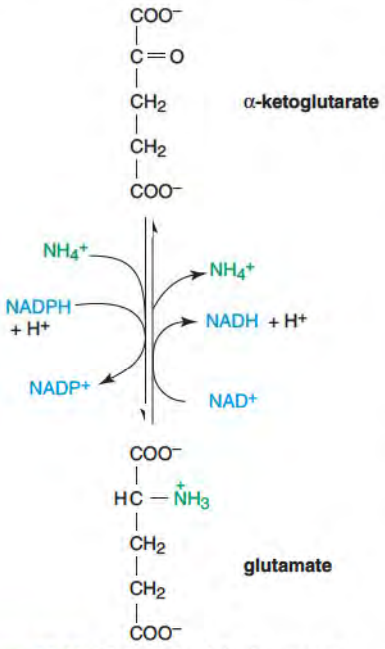

Figure 19.11 Glutamate dehydrogenase reaction.

A major source of ammonia is bacterial metabolism in the intestinal lumen from where it is transported to the liver. The enzyme's dominant role in ammonia removal is emphasized by its location in liver mitochondria, where the initial reactions of the urea cycle occur.

Glutamate dehydrogenase is regulated allosterically by purine nucleotides. When there is need for oxidation of amino acids for energy, the activity is increased in the direction of glutamate degradation by ADP and GDP, which are indicative of a low cellular energy level. GTP and ATP, indicative of an ample energy level, are allosteric activators in the direction of glutamate synthesis (Figure 19.13).

Free Ammonia Is Incorporated into and Produced from Glutamine

Free ammonia is toxic and is preferentially transported in blood in the form of amino or amide groups. The most abundant circulating amino acid is glutamine, an ammonia transporter. The amide group of glutamine is a nitrogen donor for several classes of molecules, including purine bases, and the amino group of cytosine. Glutamate and ammonia are substrates for glutamine synthetase (Figure 19.14). ATP is needed for activation of the γ-carboxyl group to make the reaction energetically favorable.

Congenital glutamine synthetase deficiency leads to severe brain malformations and death. Removal of the amide group is catalyzed by glutaminase (Figure 19.15) that has tissue-specific isozymes.

Amide Group of Asparagine Is Derived from Glutamine

The amide group of asparagine comes from that of glutamine (Figure 19.16), and not from free ammonia, as in the synthesis of glutamine. ATP is needed to activate the receptor carboxyl group. Asparagine is readily synthesized in most cells, but some leukemic cells

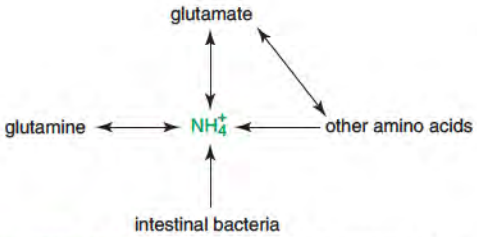

Figure 19.12 Role of glutamate in amino acid synthesis, degradation, and interconversion.

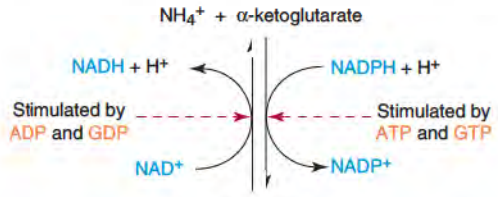

Figure 19.13 Allosteric regulation of glutamate dehydrogenase.

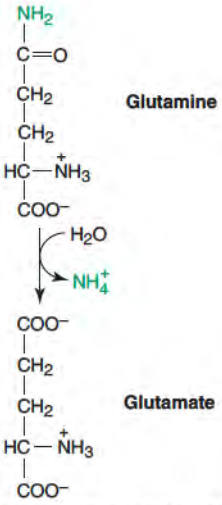

Figure 19.15 Reaction catalyzed by glutaminase.

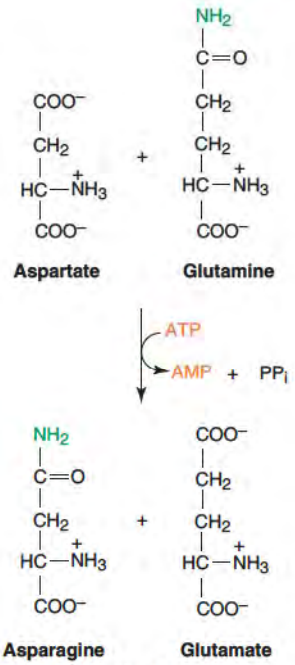

Figure 19.16 **Synthesis of asparagine.**

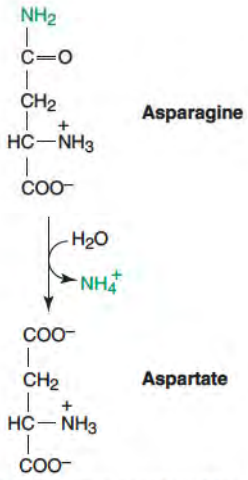

Figure 19.17 **Reaction catalyzed by asparaginase.**

seem to have lost this ability. A therapeutic approach that has been used for over 30 years in patients with asparagine synthetase-deficient leukemia is treatment with exogenous asparaginase to hydrolyze the blood-borne asparagine on which these cells rely (Figure 19.17).

Amino Acid Oxidases Remove Amino Groups

Many amino acids are substrates for **L-amino acid oxidase** (Figure 19.18). The significance of this reaction in metabolism is uncertain, but appears to be small. The enzyme contains flavin mononucleotide (FMN) and produces hydrogen peroxide. Catalase metabolizes the hydrogen peroxide to oxygen and water. The final products are an α-keto acid, ammonia, and water, the same products as for the glutamate dehydrogenase reaction. In the amino acid oxidase reaction, unlike the glutamate dehydrogenase reaction, there is no production of NADH, and therefore no production of ATP.

A D-amino acid oxidase occurs in human cells. Very little of the D-amino acid isomer is found in humans and the enzyme may degrade D-amino acids derived from intestinal bacteria.

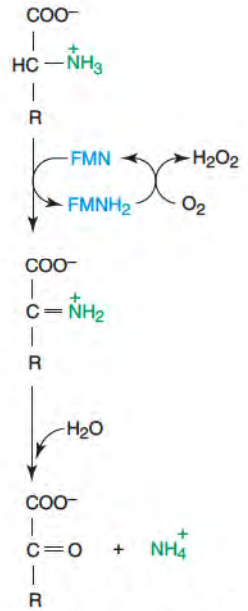

Figure 19.18 **Reaction of L-amino acid oxidase, a flavoprotein.**

19.2 • TRANSPORT OF NITROGEN TO LIVER AND KIDNEY

Protein Is Degraded Constantly

Cells die by necrosis and by programmed cell death, a process termed apoptosis (p. 1010), and their component molecules are metabolized. Individual proteins also undergo regular turnover under normal conditions (p. 248). Regulation of protein degradation is described in Chapter 6. The half-life of a protein can be an hour or less, such as for ornithine decarboxylase, phosphokinase C, and insulin, several months, such as for hemoglobin, collagen, and histones, or the life of the organism, such as for the crystallins of the lens. The majority, however, turn over every few days.

The majority of body protein, and consequently of amino acids, is in skeletal muscle. Under conditions of energy need, this protein is degraded and amino groups from the amino acids are transferred to glutamine and alanine. Some glutamine is transported directly to kidney or liver, but most glutamine is transported to the intestines where it is converted to alanine and ammonia. The alanine from the intestines, muscle, and other extrahepatic tissues is taken to liver. Urea is produced in liver and ammonia (from glutamine)

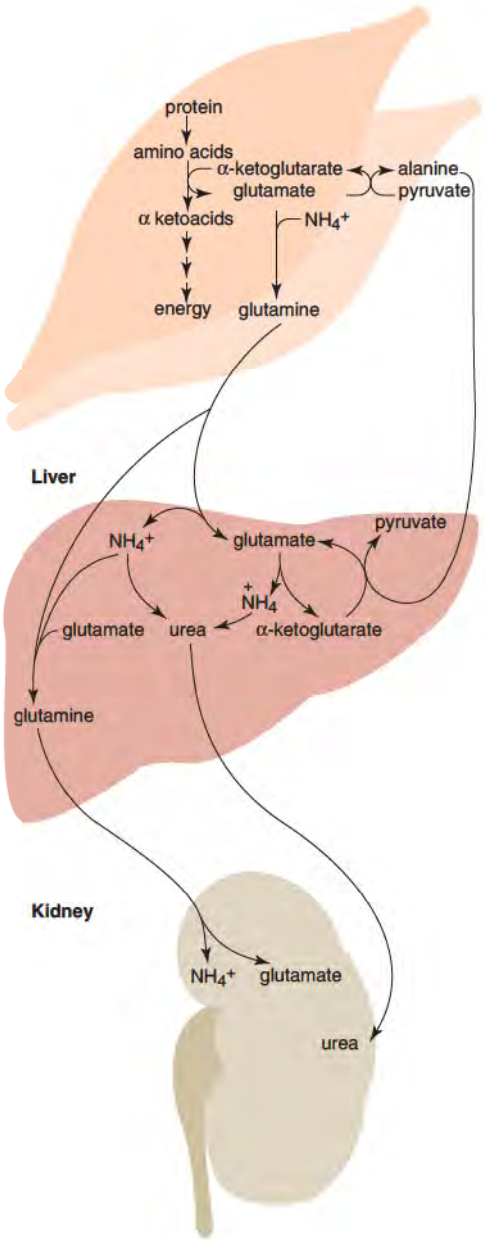

Figure 19.19 Major pathways of interorgan nitrogen transport following muscle proteolysis. Most glutamine goes directly to kidney

in kidneys (Figure 19.19). Carbon skeletons are used for energy or transported to the liver for gluconeogenesis. Muscle protein responds to conditions such as starvation, trauma, burns, and septicemia by undergoing massive degradation. Of the amino acids released, most important as a source of fuel are branched-chain amino acids (valine, leucine, and isoleucine) because steps in their degradation also produce large amounts of NADH and $FADH_2$. The first step in their degradation is transamination, which occurs almost exclusively in muscle. Protein, of course, is degraded throughout the body, but muscle is by far the greatest source of free amino acids for metabolism.

Ammonia Is Released in Liver and Kidney

Ammonia formed in muscle and other extrahepatic organs is transported through the blood circulation in nontoxic form as amino acids, predominantly glutamine and alanine. These two amino acids are the result of addition of ammonia to α-ketoglutarate and pyruvate.

The main destination of blood alanine is the liver (Figure 19.19), where ammonia is released by transamination and by action of glutamate dehydrogenase that releases ammonia, NADH, and α-ketoglutarate, a glucogenic intermediate. Under conditions of energy need,

these products are very beneficial. A high circulating glucagon concentration, a signal for the liver to increase gluconeogenesis, increases amino acid uptake by this organ. Some glutamine is also transported to the liver, some is taken up by the kidneys and ammonia is released, protonated to ammonium ion, and excreted. Much of this amino acid is destined for the intestines, where it is converted to alanine and ammonia. Acidosis causes the body to shunt more glutamine to kidneys for excretion as ammonia by suppressing uptake in the liver. This helps to restore pH homeostasis by removing excess hydrogen ions and also by conserving bicarbonate that would otherwise be used in the liver for urea synthesis.

19.3 • UREA CYCLE

Nitrogen Atoms of Urea Come from Ammonia and Aspartate

The urea cycle and the tricarboxylic acid (TCA) cycle were discovered by Sir Hans Krebs and coworkers; the former being described before the latter. In land-dwelling mammals, the urea cycle is the mechanism of choice for nitrogen excretion. The two nitrogens in each urea molecule (Figure 19.20) are derived from free ammonia and the amino group of aspartate respectively. The cycle starts and finishes with ornithine. Unlike the TCA cycle, where carbons of oxaloacetate at the start are different from those at the end, the carbons in the original and the final ornithine are the same. Ammonia (first nitrogen for urea) enters the cycle after condensation with bicarbonate to form carbamoyl phosphate (Figure 19.21), which reacts with ornithine to form **citrulline**. Aspartate (donor of the second urea nitrogen) and citrulline react to form argininosuccinate, which is then cleaved to arginine and fumarate. Arginine is hydrolyzed to urea and ornithine is regenerated. The liver has an intercellular glutamine cycle that serves to scavenge any unused ammonia (A Closer Look 19.3)

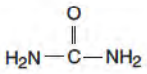

Figure 19.20 Urea.

Synthesis of Urea Requires Five Enzymes

Carbamoyl phosphate synthetase I (CPSI) is technically not a part of the urea cycle, although it is essential for urea synthesis. Ammonia and bicarbonate are condensed, at the expense of two ATPs, to form carbamoyl phosphate. One ATP activates bicarbonate, and the other donates the phosphate group of carbamoyl phosphate (Figure 19.21). CPSI is found in the mitochondrial matrix, uses ammonia as nitrogen donor, and is absolutely dependent on ***N*-acetylglutamate** for activity (Figure 19.22). Carbamoyl phosphate synthase II (CPSII) is cytosolic, uses the amide group of glutamine, and is not affected by *N*-acetylglutamate. By having separate enzymes in different cellular compartments urea formation can be regulated independently without effect on pyrimidine biosynthesis (p. 821).

Formation of citrulline is catalyzed by **ornithine transcarbamoylase** (Figure 19.23) in the mitochondrial matrix. Citrulline is transported out of the mitochondria into the cytosol where the other reactions of the cycle occur. Argininosuccinate production by argininosuccinate synthetase requires hydrolysis of ATP to AMP and PP_i. This is the equivalent of hydrolysis of two molecules of ATP since PP_i is irreversibly cleaved to 2 P_i. Although this step is very energy requiring, it apparently serves the purpose of maintaining the urea cycle

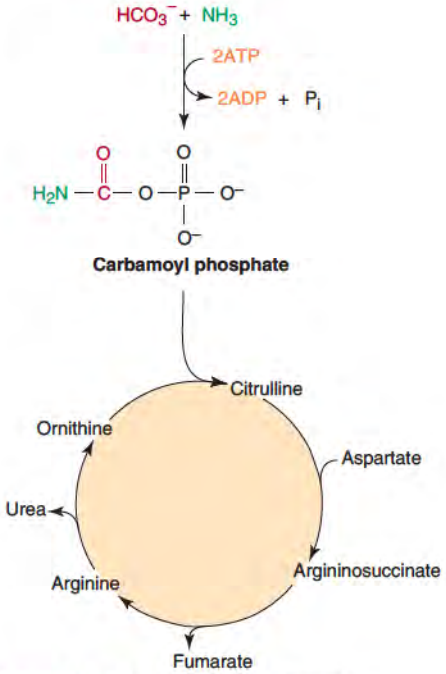

Figure 19.21 Synthesis of carbamoyl phosphate and entry into urea cycle.

A CLOSER LOOK 19.3

Intercellular Glutamine Cycle

Liver contains glutamine synthetase and glutaminase but is neither a net consumer nor a net producer of glutamine. The two enzymes are present in parenchymal cells in different segments of the liver. Blood enters the liver lobules through sinusoids that originate in the portal vein. The cells in this periportal area contain glutaminase (and the urea cycle enzymes) and are in contact with blood coming from skeletal muscle. Blood flows along the sinusoids to the central vein of each lobule, from where it flows into the central vein and then to the vena cava and eventually to the kidney. The cells of the perivenous area represent 5% of parenchymal cells and contain glutamine synthetase. This *intercellular glutamine cycle* may be a mechanism for scavenging ammonia that has not been incorporated into urea. The enzymes of urea synthesis are found in the same periportal cells as glutaminase, whereas the uptake of glutamate and α-ketoglutarate for glutamine synthesis predominates in the perivenous region. The intercellular glutamine cycle makes it possible to control flux of ammonia to urea or glutamine, and then to excretion of ammonia by the kidney under different pH conditions (p. 876).

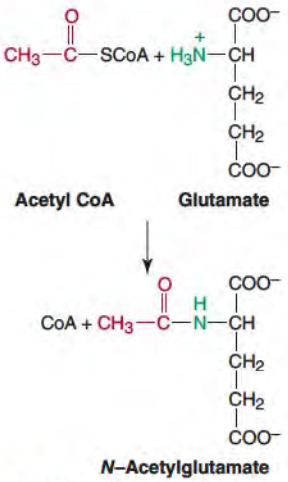

Figure 19.22 Reaction catalyzed by *N*-acetylglutamate synthase. The enzyme is allosterically stimulated by arginine.

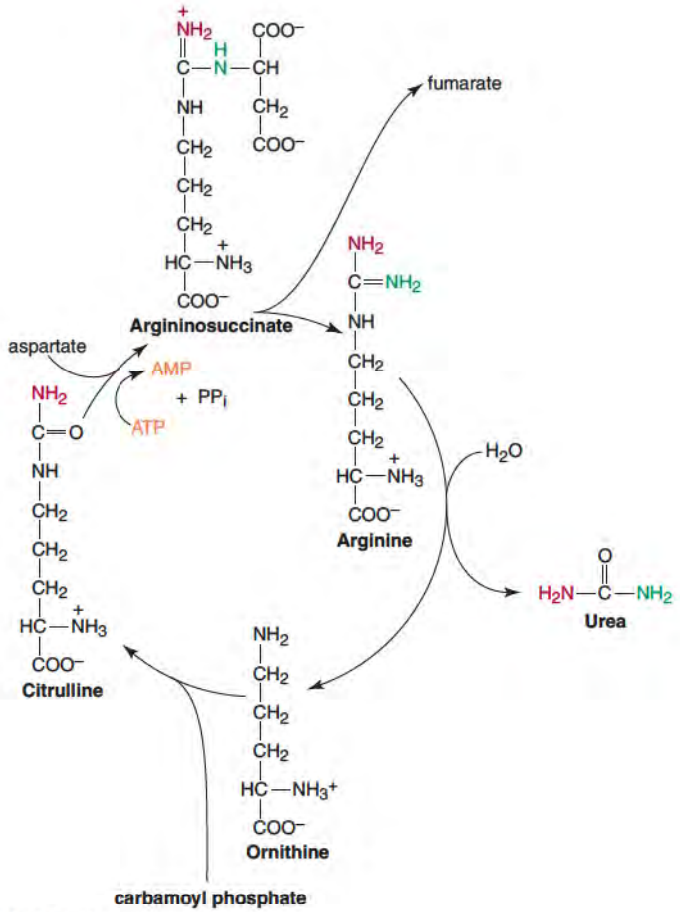

Figure 19.23 Urea cycle.

in the forward direction. Cleavage of argininosuccinate by argininosuccinate lyase produces fumarate and arginine. Arginine is cleaved by **arginase** to ornithine and urea. Ornithine reenters the mitochondrial matrix for another turn of the cycle. The inner mitochondrial membrane contains a citrulline/ornithine exchange transporter.

Fumarate released from the cleavage of argininosuccinate, as mentioned above, may be converted to malate in the cytosol and transported into mitochondria, where it be metabolized to oxaloacetate in the TCA cycle. Oxaloacetate may then be transaminated and transported to the cytosol where it can enter another turn of the urea. Thus the citric acid cycle and the urea cycle are linked.

About two-thirds of the oxaloacetate derived from fumarate is metabolized via oxaloacetate to aspartate or via phosphoenolpyruvate to glucose (Figure 19.24). The amount of fumarate used to form ATP is approximately equal to that required for the urea cycle and gluconeogenesis, meaning that the liver itself gains no net energy. Since humans cannot utilize urea, it is transported to the kidneys for filtration and excretion. Any urea that enters the intestinal tract is cleaved by urease-containing bacteria in the intestinal lumen and the ammonia is absorbed back into the body.

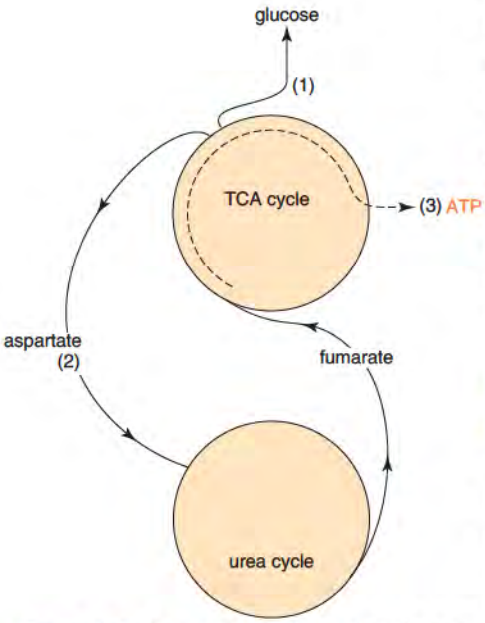

Figure 19.24 Fumarate from the urea cycle is a source of glucose (1), aspartate (2), or energy (3).

Urea Synthesis Is Regulated by an Allosteric Effector and by Enzyme Induction

CPSI requires the allosteric activator *N*-acetylglutamate (see Figure 19.22). This compound is synthesized from glutamate and acetyl CoA by *N*-acetylglutamate synthase (still sometimes called synthetase), that is in turn activated by arginine. Acetyl CoA, glutamate, and arginine are needed to supply intermediates or energy for the urea cycle, and the presence of *N*-acetylglutamate indicates that they are available. Tight regulation is desirable for a pathway that controls the plasma level of ammonia that is potentially toxic, and that is also highly energy dependent.

Induction of urea cycle enzymes (10–20 fold) occurs when delivery of ammonia or amino acids to liver rises. Concentration of intermediates also regulates activity through mass action. A high-protein (net-excess amino acids) diet and starvation (need to metabolize body protein in order to provide carbons for energy production) result in induction of urea cycle enzymes. A deficiency of essential amino acids also promotes excess protein degradation. *N*-acetylglutamate activation is short-term regulation and enzyme induction is long term.

Metabolic Disorders of Urea Synthesis Have Serious Consequences

Metabolic disorders that arise from abnormal function of enzymes of urea synthesis are potentially fatal and cause coma when ammonia concentrations become high. Loss of consciousness may be a consequence of ATP depletion. The major source of ATP is oxidative phosphorylation, which is linked to transfer of electrons from the TCA cycle down the electron transport chain (p. 561). A high concentration of ammonia sequesters α-ketoglutarate as glutamate, thus depleting the TCA cycle of important intermediates and reducing ATP production.

Urea cycle enzyme deficiencies are usually fatal in infants, but adults with a partial deficiency in one or other of the urea cycle enzymes have been found. Therapy for these deficiencies has a fourfold basis: (1) to limit protein intake and potential buildup of ammonia, (2) to remove excess ammonia, (3) to replace any intermediates missing from the urea cycle, and (4) to undergo a liver transplant. The first is accomplished by limiting ingestion of amino acids, replacing them if necessary with the equivalent α-keto acids to be transaminated *in vivo*. The bacterial source of ammonia in the intestines can be decreased by a compound that acidifies the colon, such as lactulose, a poorly absorbed synthetic disaccharide that is metabolized by colonic bacteria to acidic products. This promotes excretion of ammonia in feces as protonated ammonium ions. Antibiotics can also be administered to kill ammonia-producing bacteria. The second is achieved by compounds that bind covalently to amino acids and produce nitrogen-containing molecules that are excreted in urine. Figure 19.25 shows condensation of benzoate and glycine to form hippurate and of phenylacetate and glutamine to form phenylacetylglutamine. Phenylacetate is extremely unpalatable and is given as the precursor sodium phenylbutyrate. Both reactions require energy for activation of the carboxyl groups by addition of CoA. Clin. Corrs. 19.1 and 19.2 give examples of therapy for specific enzyme deficiencies, which often includes administration of urea cycle intermediates.

Gene therapy has been tried to correct urea cycle enzyme deficiencies. However, in 1999 this resulted in the death of a patient, who had only partial ornithine transcarbamoylase activity (p. 759). Gene therapy for urea cycle enzyme has subsequently been halted.

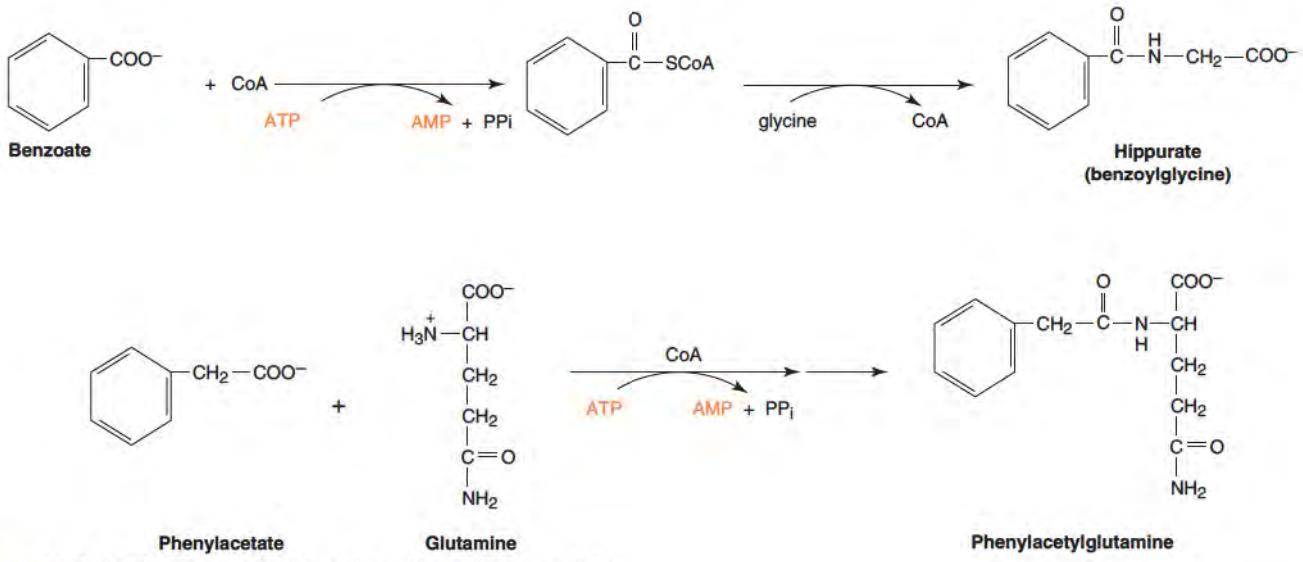

Figure 19.25 Detoxification reactions as alternatives to the urea cycle.

CLINICAL CORRELATION 19.1

Carbamoyl Phosphate Synthetase and *N*-Acetylglutamate Synthetase Deficiencies

Deficiencies in these enzymes, as for deficiencies in enzymes of the urea cycle, result in hyperammonemia, encephalopathy, and respiratory alkalosis. Carbamoyl phosphate synthetase (CPSI) (OMIM 237300) deficiency exists in two forms. The first is neonatal and fatal, and the second is delayed onset that may manifest itself in childhood or later, frequently by seizures, vomiting, and abdominal pain. The mutations leading to this disease are autosomal recessive, and exist at many loci in the gene. CPSI is allosterically activated by *N*-acetylglutamate, and cases of apparent CPSI deficiency are caused by inactivity of *N*-acetylglutamate synthase (NAG) (OMIM 237310 and 608310). This latter enzyme is activated severalfold by arginine, and arginine therapy has been shown in some cases to ameliorate the inability to make adequate carbamoyl phosphate. NAG deficiency is so uncommon that no incidence data is available.

S. *N*-Acetyl Synthetase Deficiency 2003, http://www.emedicine.com/ped/topic10.htm.

CLINICAL CORRELATION 19.2

Deficiencies of Urea Cycle Enzymes

Ornithine Transcarbamoylase Deficiencies

The most common deficiency of a urea cycle enzyme is lack of ornithine transcarbamoylase (OMIM 300461 and 311250). Mental retardation and death often result, but the occasional finding of normal development in treated patients suggests that the mental retardation is caused by excess ammonia before adequate therapy. Many different mutations exist. The gene for ornithine transcarbamoylase is on the X-chromosome, and males are generally more seriously affected than heterozygotic females, most of who show inactivation of one of the X-chromosomes and occasionally exhibit cellular mosaicism. In some cases mutations have been found in the coding region for the leader sequence of the protein, which prevents incorporation of the enzyme in the mitochondria. In addition to ammonia and amino acids appearing in the blood in increased amounts, orotic acid also increases, presumably because carbamoyl phosphate that cannot be used to form citrulline diffuses into the cytosol, where it condenses with aspartate, ultimately forming orotate and pyrimidines (p. 821).

Argininosuccinate Synthetase and Lyase Deficiency

The inability to condense citrulline with aspartate results in accumulation of citrulline in blood and its excretion in urine (citrullinemia). Inheritance is autosomal recessive and about 50% of cases are severe, due to hyperammonemia. There are heterogeneous mutations that cause this deficiency, and three distinct types. In Type I the enzyme usually has an altered Michaelis constant, and the enzyme is affected in both liver and kidney. In Type II the kidney is not affected, and the residual enzyme in liver is kinetically normal. Type III argininosuccinate synthetase (OMIM 215700, 603471, and 605814) deficiency is caused by lack of transcription of the gene. Impaired ability to split argininosuccinate (OMIM 207900 and 608310) to form arginine is also autosomal recessive, and due to a multiplicity of mutations. In patients with early-onset disease therapy with a low-protein diet and arginine supplementation has resulted in good outcomes.

Arginase Deficiency

Arginase (OMIM 207800, 608313, and 107830) deficiency is rare but causes many abnormalities in development and function of the central nervous system. Arginine accumulates and is then excreted. Precursors of arginine and products of arginine metabolism may also be excreted. In severe cases spastic paraplegia may result. Type I affects liver, but not kidney, brain, or intestinal tract. The enzyme involved in Type I argininemia is the enzyme found in cytosol and contributes to the production of urea. The enzyme identified as responsible for Type II argininemia is found in kidney mitochondrial matrix. The formation of nitric oxide from arginine and polyamines from ornithine are affected by a deficiency in this enzyme.

Mitochondrial Ornithine Transporter Deficiency (OMIM 603861 and 608157)

This disease is also called hyperornithemia, hyperammonemia, homocitrullinemia syndrome (HHH Syndrome.) The symptoms include mental retardation, cerebellar, ataxia, and episodic coma. The disease is caused by many different mutations in the gene, including nonsense, missense, and frameshift.

Hypoargininemia in Preterm Infants

Premature births occur before the burst of cortisol production that occurs late in pregnancy. Cortisol is an inducer of arginine-synthetic enzymes, and it is suggested that addition of cortisol to enteral and parenteral feeding of premature infants may improve survival and growth.

19.4 • BIOSYNTHESIS OF NONESSENTIAL AMINO ACIDS

Synthesis of glutamate, glutamine, aspartate, asparagine, and alanine has been described (p. 752).

Arginine: Arginine is synthesized by sequential reactions starting in the intestinal epithelial cells, and continuing in proximal tubules of the kidneys (Figure 19.26). In these cells arginase is not expressed. Any deficiencies in the enzymes needed for the urea cycle (except arginase) will also affect synthesis of arginine, hence the necessity of dietary arginine supplementation in urea cycle deficiencies.

Ornithine: The precursor of citrulline and arginine, and proline is synthesized from glutamate. Synthesis starts from glutamate by a reaction that uses ATP and NADH (Figure 19.27) and forms **glutamic semialdehyde**. This spontaneously cyclizes to form a Schiff base between the aldehyde and amino groups, which is then reduced by NADPH to proline. When semialdehyde is transaminated, it forms ornithine (Figure 19.28).

Serine: Synthesis of serine from 3-phosphoglycerate uses phosphorylated intermediates (Figure 19.29). Loss of the phosphate is the last step in the production of this amino acid. Serine plays a significant role in the central nervous system because of its role as a precursor of glycine and D-serine, which are neurotransmitters.

Serine is a precursor of the cofactor-like group in pyruvoyl enzymes (A Closer Look 19.4).Serine is converted reversibly to **glycine** in a reaction that requires pyridoxal

Figure 19.30 **Formation of selenocysteinyl tRNA from seryl tRNA is via a phosphoseryl tRNA intermediate.**

phosphate and tetrahydrofolate (p. 1079). N^5,N^{10}-methylenetetrahydrofolate (N^5,N^{10}-THF) is produced (Figure 19.30). The demand for serine or glycine and the amount of N^5,N^{10}-THF available determine the direction of this reaction.

Selenocysteine: Serine is the precursor of an unusual but important amino acid, selenocysteine, which is present in some proteins, notably glutathione peroxidase (Figure 19.31). In mRNA for selenoproteins the codon UGA, which usually serves as a termination codon, codes for selenocysteine (Clin. Corr. 19.3). This amino acid is formed from serine after formation of the seryl-tRNA^{Ser} (p. 212).

Pyrrolysine: A 22nd DNA-encoded amino acid, pyrrolysine, was discovered recently. It also is incorporated in response to a stop codon and is found only in methanogenic bacteria.

19.5 • DEGRADATION OF AMINO ACIDS

Nonessential Amino Acids

Glutamate, Alanine, and Aspartate: Glutamate dehydrogenase, a reversible enzyme, deaminates glutamate. The amide groups of glutamine and asparagine are removed by the hydrolytic activity of glutaminase and asparaginase. Arginine is metabolized by arginase to ornithine. Transamination of alanine, aspartate, and glutamate yield pyruvate, oxaloacetate, and α-ketoglutarate respectively.

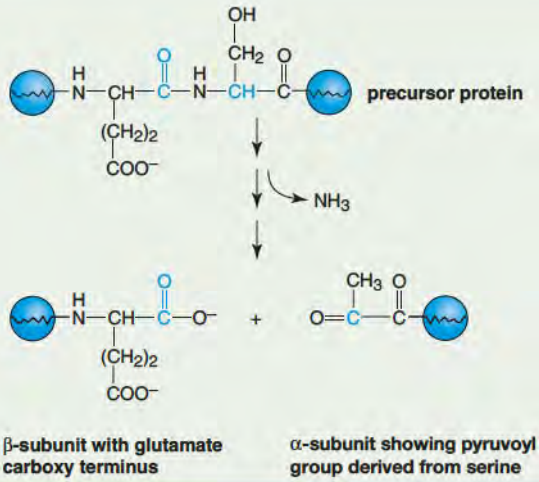
Glycine: A glycine cleavage complex degrades glycine to CO_2 and ammonia (Figure 19.32). This reaction is reversible in vitro, but not *in vivo*, as the K_m values for ammonia and N^5,N^{10}-THF are much higher than their respective physiological concentrations. The enzyme system for cleavage of glycine (glycine cleavage system) has several component enzymes and is confined to the mitochondria. Glycine encephalopathy, also called nonketotic hyperglycinemia (NKH), may be due to a defect in any one of these enzymes (Clin. Corr. 19.4, p. 766).

A CLOSER LOOK 19.4

Pyruvoyl Enzymes

A serine residue in some enzymes is modified to form a prosthetic group (see figure). In humans, the only example found so far is *S*-adenosylmethionine decarboxylase. The enzyme is synthesized in precursor form that is then cleaved autocatalytically between a glutamate and a serine residue to form two polypeptides. During cleavage the new N-terminal serine is converted into a pyruvoyl group that functions in decarboxylation by forming a Schiff base with the amino group of *S*-adenosylmethionine.

The figure shows the formation of *S*-adenosylmethionine decarboxylase with covalently bound pyruvoyl prosthetic group.



CLINICAL CORRELATION 19.3

Selenoproteins

Human selenoproteins include glutathione peroxidase-1, thioredoxin reductase, glutathione peroxidase-2, glutathione peroxidase-3, thyroxine deiodinase type 1, and mitochondrial capsule selenoprotein. Most of the known selenoproteins are members of the glutathione peroxidase or iodothyronine deiodinase families. Selenoprotein P (SEPP1) (OMIM 601484) is a major selenoprotein that is not a member of those families. It is an extracellular glycoprotein that is present in several isoforms and is the only selenoprotein known to contain multiple selenocysteine residues. It acts as a heparin-binding protein that appears to be associated with endothelial cells. Bifunctional SEPP1 serves to provide selenium to proliferating cells and also for glutathione-dependent reduction of phosphatidylcholine hydroperoxide in the extracellular space. The shift in usage of the UGA codon from a stop codon to a signal for selenocysteine incorporation is mediated by at least five different components. Two of these are cis sequences, one a region in the 3'UTR of the mRNA and the other the UGA codon itself. Three are trans-acting factors, a selenocysteine-specific translation elongation factor (eEFSec), a binding protein for the sequence in the 3'UTR (SBP2), and the selenocysteinyl-tRNA. Statin drugs used as therapy for hypercholesterolemia inhibit the cholesterol synthetic pathway, and therefore reduce synthesis of isopentyl groups. The myopathy and other side effects caused by statins resemble the symptoms of selenium deficiency. This suggests that the mechanism of tissue damage caused by statins may be inhibition of selenoprotein synthesis since selenocysteinyl-tRNA$^{[Ser]Sec}$ requires isopentylation for activity. Chronic inflammation has a pathologic role in many common diseases and is influenced by both genetic and environmental factors. SEPS1 (OMIM 607918) is associated with both TNF-alpha and IL1-beta and there is a direct mechanistic link between SEPS1 and the production of inflammatory cytokines that suggests that SEPS1 has a role in mediating inflammation.

Curran, J. E., Jowett, J. B. M., Elliott, K. S., Gao, Y., et al. Genetic variation in selenoprotein *S* influences inflammatory response. *Nature Genet.* 37:1234, 2005, and Kryukov, G. Characterization of mammalian selenoproteomes. *Science* 300:1439, 2003; and Moosmann, B., and Behl, C., Selenoprotein synthesis and side effects of statins. *Lancet* 363:2000, 2004.

Serine: Degradation of serine to 3-phosphoglycerate is similar to its synthesis except that degradation uses unphosphorylated intermediates, addition of a phosphate being the last step. The enzymes of these two pathways, however, are not the same (Figure 19.33). Alternatively serine may be metabolized to pyruvate from serine by **serine dehydratase** with loss of the amino group as NH_4^+ (Figure 19.34). Serine is also metabolized to glycine. Serine is one of the amino acids with various degradative pathways that are determined by physiological needs and conditions.

Ornithine and **Proline**: These two amino acids are degraded via glutamic semialdehyde (Clin. Corrs. 19.5 and 19.6) These reactions, together with the reactions that synthesize proline and ornithine, result in these three amino acids being readily interconvertible (see Figure 19.28, p. 763). Proline is converted back to the Schiff base intermediate, δ-1-pyrroline 5-carboxylate, which is in equilibrium with glutamic

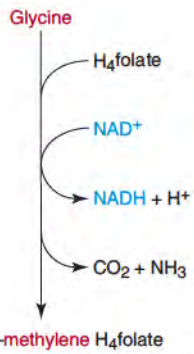


Figure 19.32 Glycine cleavage is pyridoxal-phosphate-dependent.

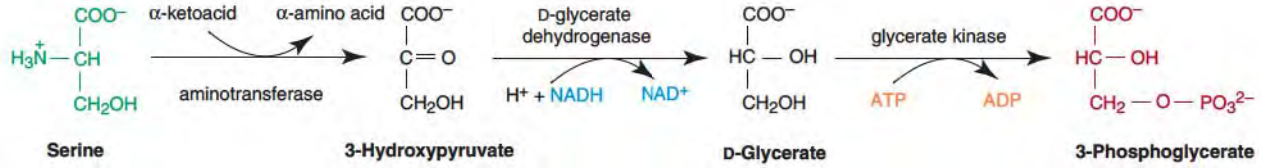

Figure 19.33 **Metabolism of serine for gluconeogenesis.**

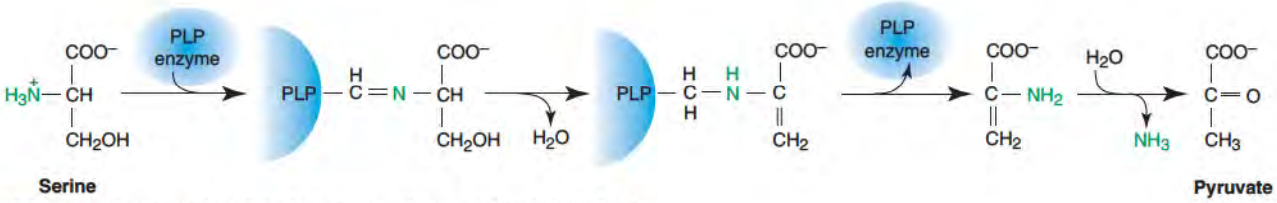

Figure 19.34 **Reaction of serine dehydratase requires pyridoxal phosphate.**

semialdehyde. The transaminase reaction in the ornithine synthetic pathway is freely reversible and forms glutamic semialdehyde from ornithine. Proline residues that have been post-translationally modified by hydroxylation to form 3-hydroxyproline or 4-hydroxyproline (Figure 19.35) produce glyoxalate and pyruvate, and 4-hydroxy-2-ketoglutarate, respectively.

CLINICAL CORRELATION 19.4

Nonketotic Hyperglycinemia: Glycine Encephalopathy

Neonatal nonketotic hyperglycinemia is characterized by severe mental deficiency and seizures. Many patients do not survive infancy. This very serious disease is to be distinguished from ketoacidosis in abnormalities of branched-chain amino acid metabolism in which the glycine level in the blood is also elevated. Deficiency of glycine cleavage complex has been demonstrated in homogenates of liver from several patients, and isotopic studies *in vivo* have confirmed that this enzyme is not active. Glycine encephalopathy (OMIM 605899) can present at about 6 mon of age or later. The late-onset disease is characterized by mild mental retardation and problems with the central nervous system. The severity of this disease suggests that glycine cleavage is of major importance in the catabolism of glycine. Glycine is a major inhibitory neurotransmitter, which probably explains some neurological complications of the disease. Treatment with ketamine or dextromethorphan, antagonist of the NMDA receptor, has been helpful in some cases.

Hamosh, A., and Johnston, M. V. Nonketotic hyperglycinemia. In Scriver, C. R., Beaudet, A. L., Sly, W. S., Valle, D. *The Metabolic and Molecular Bases of Inherited Disease,* 8th ed. New York: McGraw Hill, 2001. 2:2065.

CLINICAL CORRELATION 19.5

Proline Dehydrogenase Deficiency

A deficiency in proline dehydrogenase (oxidase) (PRODH1), which converts proline back to pyrroline-5-carboxylate, results in high concentrations of proline, glycine, and ornithine in serum and is generally benign, but is sometimes associated with seizures (OMIM 606810 and 237000). There are many allelic variants. The gene is expressed most strongly in human lung, skeletal muscle, and brain, but also in heart, kidney, liver, placenta, and pancreas. Recent studies have found a strong association between this enzyme deficiency and schizophrenia. PRODH2 deficiency causes an increase in hydroxyproline, a metabolite of collagen degradation in plasma and urine (the latter concentration can be up to 100-fold the normal value).

Baron, M. Genetics of schizophrenia and the new millennium: progress and pitfalls. *Am. J. Hum. Genet.* 68:299, 2001; Chakravarti, A. USA* 99:4755, 2002; and Kamoun, P., Aral, and Saudubray, J., A new inherited metabolic disease: δ-Pyrroline-5-carboxyl synthetase deficiency. *Bull. Natl. Acad. Med.* 182:131, 1998.

CLINICAL CORRELATION 19.6

Deficiencies in the Glutamic Semialdehyde Pathway

Pyrroline-5-Carboxylate Synthetase

A deficiency in the enzyme that forms glutamic semialdehyde from glutamate by transamination, pyrroline-5-carboxylate synthetase (also found as synthase) (OMIM 138250) has serious symptoms. Hyperprolinemia, hypoornithinemia, and hyperammonemia lead to cataracts, mental retardation, joint lability, and skin hyperelasticity. This latter deficiency is called hyperprolinemia II. The elevated concentration of pyrroline-5-carboxylate in this disease inactivates pyridoxal phosphate, and this leads to neurological complications.

Ornithine Keto Acid Aminotransferase

Ornithine keto acid aminotransferase (OAT or OKT) (OMIM 258870) is a pyridoxal-phosphate-dependent reversible enzyme that converts glutamic semialdehyde to ornithine. A deficiency in the enzyme results in hyperornithemia and gyrate atrophy leading to night blindness. Eventual loss of muscle fibers may be linked to loss of creatine phosphate in muscle, since ornithine deficiency would lead to arginine deficiency. Arginine is necessary for synthesis of creatine. Some types of this enzyme deficiency respond to vitamin B_6 therapy. Protein restriction in the diet is advised.

Baumgartner, M. R., Hu, C. A., Almashanu, S., Steel, G., et al. Hyperammonemia with reduced ornithine, citrulline, arginine and proline: a new inborn error caused by a mutation in the gene encoding delta-1-pyrroline-5-carboxylate synthase. *Hum. Molec. Essential Amino Acids

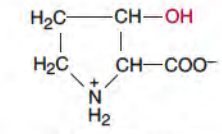
Threonine: Threonine is sometimes metabolized to pyruvate (Figure 19.36), but an intermediate in this pathway can undergo thiolysis with CoA to acetyl CoA and glycine. Thus, the α-carbon atom of threonine can contribute to the one-carbon pool through formation of glycine. In a more common pathway, serine dehydratase (p. 766) converts threonine to α-ketobutyrate. A complex similar to pyruvate dehydrogenase metabolizes this to propionyl CoA, which is converted to succinyl CoA (p. 776).

Phenylalanine: Phenylalanine and tyrosine are discussed together since tyrosine is produced by hydroxylation of phenylalanine and is the first product in phenylalanine degradation. Because of this, tyrosine is not usually considered to be essential, whereas phenylalanine is. Normally three-quarters of ingested phenylalanine is hydroxylated to tyrosine by **phenylalanine hydroxylase** (Figure 19.37) an irreversible liver enzyme that is **tetrahydrobiopterin** dependent (Figure 19.38). Biopterin resembles folic acid in containing a pteridine ring but is not a vitamin. It is synthesized from GTP.

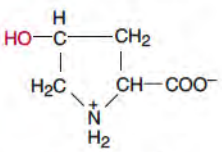
Individuals with phenylketonuria (Clin. Corr. 19.7) are unable to convert phenylpyruvate to tyrosine. As a result phenylalanine may accumulate to approximately 20 times the normal level. Some of the excess is transaminated to phenylpyruvate that is in turn converted to phenyllactate and phenylacetate (Figure 19.39). These metabolites are formed in very small amounts in people without phenylketonuria.

Tyrosine: The metabolism of tyrosine starts with transamination by tyrosine aminotransferase to produce *p*-hydroxyphenylpyruvate (Figure 19.40). The enzyme is inducible by glucocorticoids and dietary tyrosine (Clin. Corr. 19.8). Further oxidation of *p*-hydroxyphenylpyruvate leads to homogentisate (Clin. Corr. 19.9). The aromatic ring is next cleaved by the iron-containing homogentisate oxidase to maleylacetoacetate. This is isomerized from *cis* to *trans* to give fumarylacetoacetate by maleylacetoacetate isomerase, an enzyme that seems to require glutathione for activity. Fumarate can be utilized in the TCA cycle for energy or for gluconeogenesis. Acetoacetate can be used as acetyl CoA for lipid synthesis or energy.

Methionine: Methionine is an essential amino acid and therefore no net synthesis occurs, although, as described later, it can be produced in a salvage pathway from **homocysteine**. Cysteine, however, is synthesized by transfer of the sulfur atom derived from methionine to the hydroxyl group of serine. As long as the supply of methionine is adequate, cysteine is nonessential. The disposition of individual atoms of methionine and cysteine is a prime example of how cells regulate pathways to fit their immediate needs for energy or for other purposes.



3–Hydroxyproline



4–Hydroxyproline

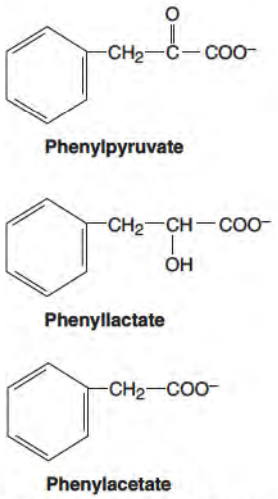

Figure 19.39 Minor products of phenylalanine metabolism.

CLINICAL CORRELATION 19.7

Phenylketonuria

Phenylketonuria (PKU) (OMIM 261600) is the most common disease caused by a deficiency of an enzyme of amino acid metabolism and has been widely studied. The name comes from the excretion of phenylpyruvic acid, a phenylketone, in the urine. Phenyllactate (Figure 19.39), the reduced form of phenylpyruvate, and phenylacetate are also excreted. The latter gives the urine a "mousey" odor. These three metabolites are found only in trace amounts in urine in the healthy person. The disease is autosomal recessive, and over 200 allelic variants have been described. The symptoms of mental retardation, possibly caused by the inhibition of pyruvate carboxylase in brain by high levels of phenylpyruvic acid, associated with this disease can be prevented by a diet low in phenylalanine. Another approach to treatment that has been tried is inclusion of the plant enzyme, phenylalanine ammonia lyase, in the diet. This is an unusually stable enzyme that can metabolize dietary phenylalanine in the digestive tract. Routine screening for PKU is required by governments in many parts of the world. Classical PKU is an autosomal recessive deficiency of phenylalanine hydroxylase. Untreated PKU almost always results in severe neurological symptoms and very low IQ. Babies born to mothers with untreated PKU also show these symptoms.

The characteristic light color of skin and eyes is due to under pigmentation because of tyrosine deficiency. Hypotyrosinemia may also lead to a decrease in catecholamine synthesis. Conventional treatment is by a synthetic diet low in phenylalanine, but including tyrosine, for about 4 to 5 years, followed by dietary protein restriction for several more years or for life. Aspartame, an artificial sweetener, is usually avoided, although it has been shown to increase blood phenylalanine only moderately. About 3% of infants with high levels of phenylalanine have normal hydroxylase but are defective in either synthesis of biopterin or reduction of the oxidized form of the coenzyme.

Platt, B. A., and Clarke, J. T. R. "Hypotyrosinemia" in phenylketonuria. *Molec. Genet. Metab.* 69:286, 2000; Koch, R., Burton, B., Hoganson, G., Peterson, R., et al. A different approach to treatment of phenylketonuria: phenylalanine degradation with recombinant phenylalanine ammonia lyase. *Proc. Nat. Acad. Sci. USA* 96: 2339, 1999.

CLINICAL CORRELATION 19.8

Tyrosinemias

Tyrosinemia Type I

Tyrosinemia Type I (OMIM 276700) is a defect in fumarylacetoacetase (also called fumarylacetoacetate hydroxylase [FAH]). It is known as hepatorenal tyrosinemia because of the severe liver and kidney damage associated with the disease. The abnormal metabolites produced in this deficiency, succinyl acetone (SA) and succinyl acetoacetone, form Schiff bases with amino acids, primarily lysine. Resulting chromosomal damage is also resistant to repair because SA appears to inhibit DNA ligase I. There is high risk for hepatocarcinoma and chromosome damage. One of the common symptoms of tyrosinemia type I is acute hepatic porphyria. This results from inhibition of porphobilinogen synthetase by SA and is recognized by excretion of δ-aminolevulinic acid. The disease often leads to a need for liver transplantation, but 2-(2-nitro-4-trifluoromethylbenzoyl)-1, 3-cyclohexanedione (NTBC), a strong inhibitor of 4-hydroxyphenylpyruvate dioxygenase, has been shown to reverse the symptoms of tyrosinemia type I by diminishing formation of maleylacetoacetate and fumarylacetoacetate.

Tyrosinemia Type II

Tyrosinemia Type II (OMIM 276600) is an absence or deficiency of tyrosine aminotransferase leads to accumulation and excretion of tyrosine and metabolites. This disease is also known as oculocutaneous tyrosinemia and results in eye and skin lesions and mental retardation. The ulcerated skin lesions can be particularly severe on the soles of the feet. It is treated primarily by a diet low in phenylalanine and tyrosine. Both tyrosinemias types I and II are autosomal recessive and rare.

Tyrosinemia Type III

Tyrosinemia Type III (OMIM 276710) is caused by a deficiency in a recessively inherited disease, caused by a mutation in 4-hydroxyphenylpyruvate dioxygenase (HPD). This results in very high concentrations of tyrosine metabolites in urine. Patients have mild retardation, but no liver damage.

Aponte, J. L., Sega, G. A., Hauser, L. J., Dhar, M. S., et al. Mutations in the 4-hydroxyphenylpyruvic acid dioxygenase gene are responsible for tyrosinemia type III and hawkinsinuria. *Molec. Genet. Metab.* 71:506, 2000.

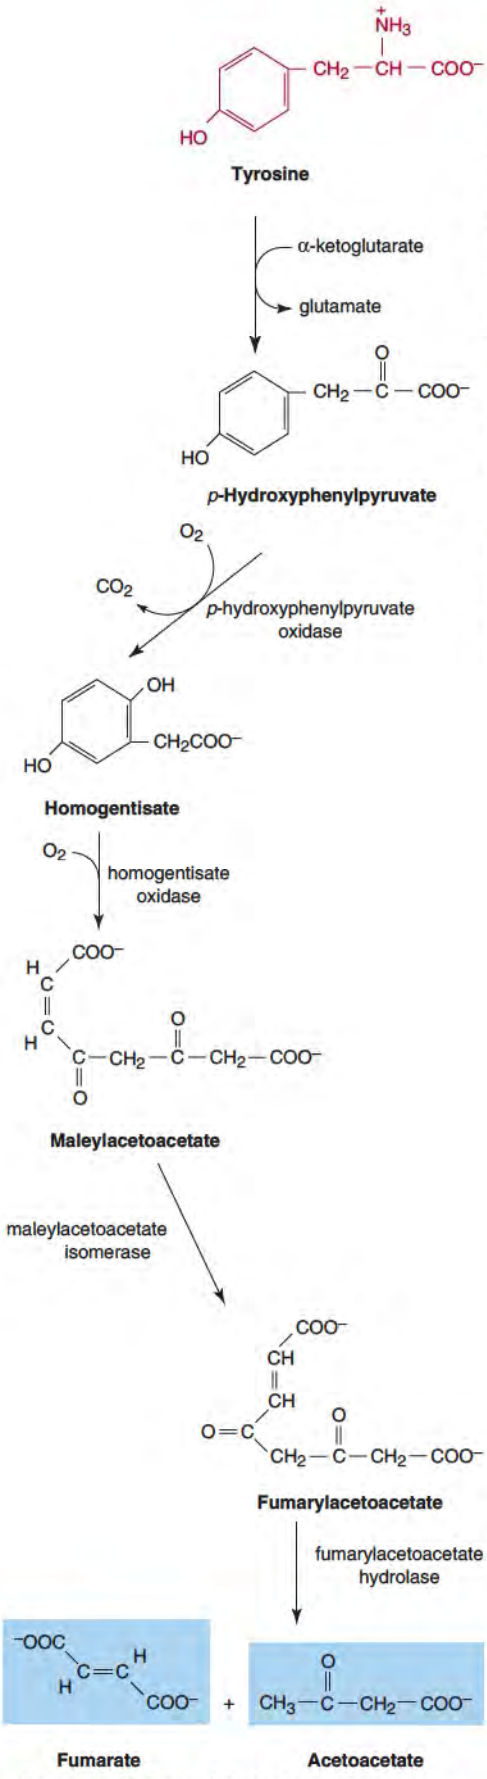

Figure 19.40 **Degradation of tyrosine.**

When excess methionine is present its carbons can be used for energy or for gluconeogenesis, and the sulfur retained as the sulfhydryl of cysteine. Figure 19.41 shows the first step in methionine metabolism, catalyzed by methionine adenosyltransferase. All phosphates of ATP are removed, the product being ***S*-adenosylmethionine** (abbreviated **AdoMet**, or **SAM**). The sulfonium ion is highly reactive, and the methyl is a good leaving group. AdoMet as a methyl group donor will be described below. After a methyltransferase removes the methyl group, the resulting *S*-adenosylhomocysteine is cleaved to produce homocysteine (Figure 19.42). Note that homocysteine is one carbon longer than cysteine (Clin. Corr. 19.10). Although the carbons are destined for intermediary metabolism, the sulfur is conserved through transfer to serine to form cysteine. This requires the pyridoxal-phosphate-dependent cystathionine synthase and cystathionase. Since the bond to form cystathionine is made on one side of the sulfur and that cleaved is on the other side, the result is a transsulfuration. Homocysteine can also directly produce α-ketobutyrate and ammonia (Figure 19.43). α-Ketobutyrate is decarboxylated by a multienzyme complex resembling pyruvate dehydrogenase to yield propionyl CoA, which is then converted to succinyl CoA.

When cells need to resynthesize methionine (Figure 19.44), homocysteine methyltransferase catalyzes the transfer. This is one of two enzymes known to require vitamin B_{12} as cofactor (p. 1082). The methyl group comes from N^5-methyltetrahydrofolate. This is the only reaction known that uses this particular form of tetrahydrofolate as a methyl donor. A minor salvage pathway uses a methyl group from betaine instead of N^5-methyltetrahydrofolate.

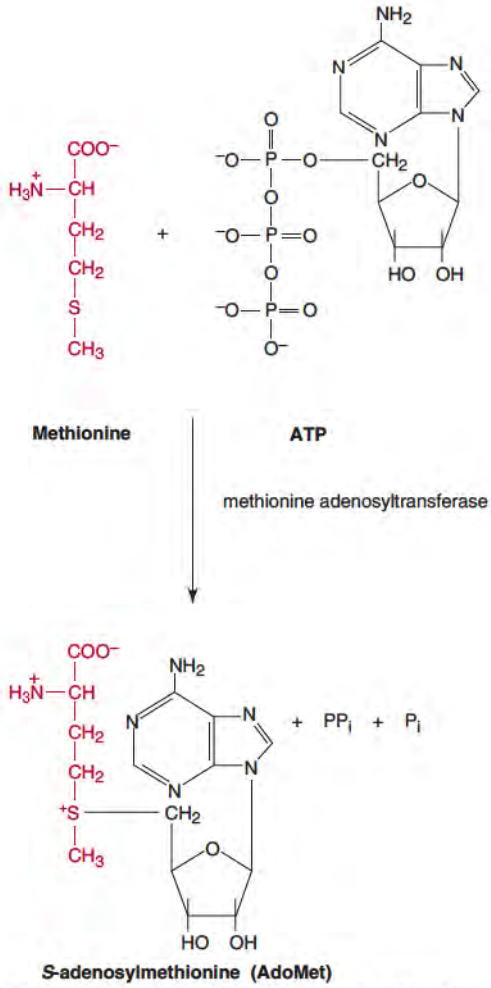

Figure 19.41 **Synthesis of *S*-adenosylmethionine.**

CLINICAL CORRELATION 19.9

Alkaptonuria (OMIM 203500)

The first identified "inborn error of metabolism" was alcaptonuria. Individuals deficient in homogentisate 1,2-dioxygenase (HGD) excrete almost all ingested tyrosine as the colorless homogentisic acid in their urine. Homogentisic acid autooxidizes to the corresponding quinone, which polymerizes to form an intensely dark color. Concern about the dark urine is the only consequence of this condition early in life. Homogentisate in body fluids is slowly oxidized to pigments that are deposited in bones, connective tissue, and elsewhere, a condition called ochronosis because of the ochre color of the deposits. This is thought to be responsible for the associated arthritis, especially of the spine. Nitisinone, a triketone herbicide that inhibits 4-hydroxphenylpyruvate dioxygenase, has been approved for therapy of alkaptonuria. Another inhibitor of this enzyme, 2(-2-nitro-4-trifluoromethylbenzoyl)-1, 3-cyclohexanedione (NTBC) has also been used as therapy. Dietary intervention is also recommended. The study of alkaptonuria by Archibald Garrod, who first indicated its autosomal recessive genetic basis, includes an unusual historical description of the iatrogenic suffering of the first patient treated for the condition, which is frequently benign.

CLINICAL CORRELATION 19.10

Homocysteinemia and Homocysteinuria

Deficiency of cystathionine synthase or lack of pyridoxal phosphate causes homocysteinuria (OMIM 236200). Homocysteine (Hyc) accumulates, and its methylation leads to high levels of methionine (Met). Many minor products of Hyc and Met are formed and excreted. Other causes of increased homocysteine in plasma (homocysteinemia) are folate and vitamin B_{12} deficiency. These vitamin deficiencies prevent salvage of methionine by remethylation of homocysteine. Homocysteinemia (OMIM 603174) may lead to dislocation of the lens of the eye in early life, and other ocular abnormalities often occur. Osteoporosis may develop during childhood, and high homocysteine is a risk factor for osteoporotic fractures in the elderly. Mental retardation is frequently the first indication of high plasma homocysteine, and this has been linked to Alzheimer disease later in life. No mechanism has been firmly established to explain why accumulation of homocysteine should lead to some of the pathological changes. It has, however, been suggested that the associated atherosclerosis results from damage to blood vessels. Homocysteine injures the cells that line arteries and stimulates the growth of smooth muscle cells. Excess homocysteine can form homocysteine thiolactone, a highly reactive intermediate which thiolates free amino groups in low-density lipoproteins (LDL), and causes them to aggregate and be endocytosed by macrophages. The lipid deposits form atheromas. Homocysteine can have other effects, including lipid oxidation and platelet aggregation, which in turn lead to fibrosis and calcification of atherosclerotic plaques. Hyc can also disrupt normal blood-clotting mechanisms, increasing the risk of clots that can bring on a heart attack or stroke. Homocysteine may react with and block lysyl aldehyde groups on collagen and bind to fibrillin-1, producing Marfan-like symptoms. It increases DNA synthesis in vascular smooth muscle cells and in endothelial cells induces cyclins that promote quiescent cells to divide. About one quarter of patients with atherosclerosis who exhibit none of the other risk factors (such as smoking or oral contraceptive therapy) have been found to be deficient in cystathionine synthase activity. Attempts at treatment include restriction of methionine intake and feeding of betaine (or its precursor, choline). In some cases significant improvement has been obtained by feeding pyridoxine (vitamin B_6), suggesting that the deficiency may be caused by more than one type of gene mutation; one type may affect the K_m for pyridoxal phosphate and others may alter the K_m for other substrates, the V_{max}, or the amount of enzyme.

Cysteine: Cysteine sulfinate is the major metabolite of cysteine (Figure 19.45). This is converted to sulfite and pyruvate, or to hypotaurine and taurine (secondary metabolites, p. 774; Clin. Corr. 19.11).

Tryptophan: Metabolism of tryptophan has many branch points. The major or oxidative pathway of tryptophan metabolism in humans (Figure 19.46, p. 773) starts with oxidation to *N*-formylkynurenine by a heme-containing enzyme, **tryptophan dioxygenase**. Tryptophan dioxygenase is induced in liver by glucocorticoids and glucagon.

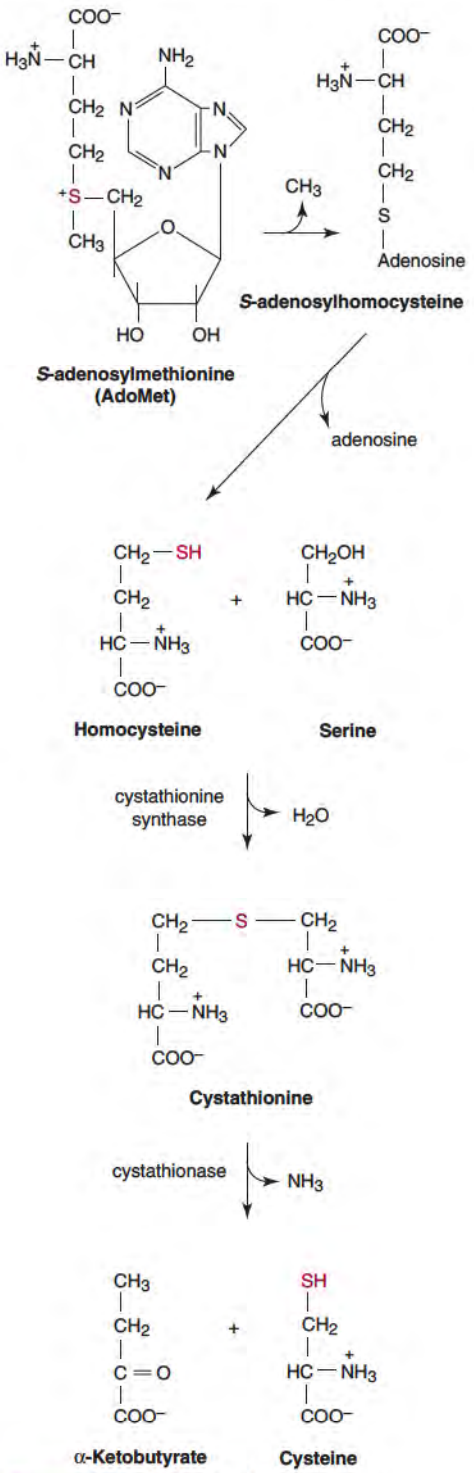

Figure 19.42 **Synthesis of cysteine from *S*-adenosylmethionine.**

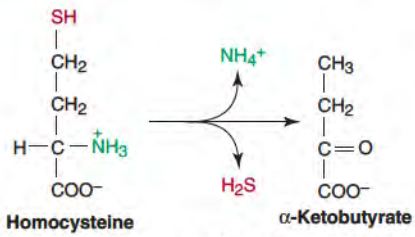

Figure 19.43 **Homocysteine desulfhydrase.**

Other tissues contain a similar enzyme called indolamine dioxygenase, which is less substrate specific. Formamidase then hydrolyzes formylkynurenine to formate and kynurenine. At this point the pathway begins to branch. The dominant pathway leads to 3-hydroxykynurenine, 3-hydroxyanthranilic acid and alanine, amino-carboxymuconic semialdehyde and, by decarboxylation, to aminomuconic semialdehyde. This can be further metabolized in several steps to glutaryl CoA (Clin. Corr. 19.12) and eventually acetoacetyl CoA or recyclized nonenzymatically to picolinic acid, which is excreted in the urine.

Tryptophan has been implicated in the postprandial "Thanksgiving nap" (A Closer Look 19.5, p. 775).

Many enzymes in this lengthy pathway are pyridoxal phosphate dependent. One of these is kynureninase. This enzyme is very sensitive to vitamin B_6 deficiency resulting in excess kynurenine and xanthurenate excretion, which gives urine a greenish-yellow color. This is a diagnostic symptom of vitamin B_6 deficiency.

Lysine: Lysine like leucine is entirely ketogenic. The carbon skeleton enters intermediary metabolism as acetoacetyl CoA. Lysine has an ε- and an α-amino group, which is transferred to α-ketoglutarate by a bifunctional enzyme with an intermediate called

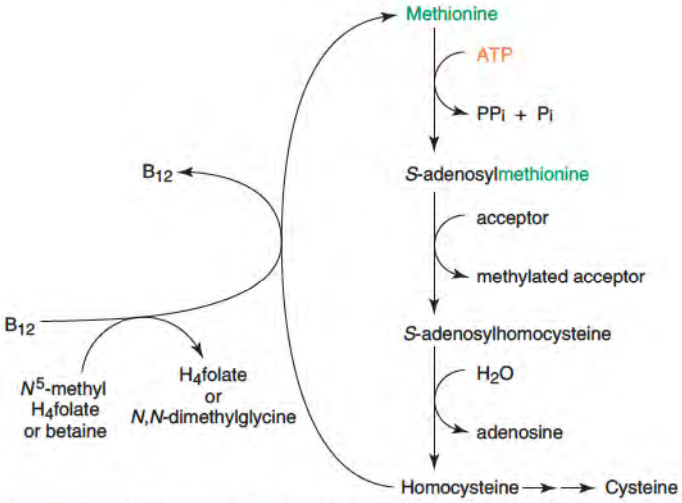

Figure 19.44 **Resynthesis of methionine.** The methyl group goes from folate to methionine via a cobalamin-dependent reaction.

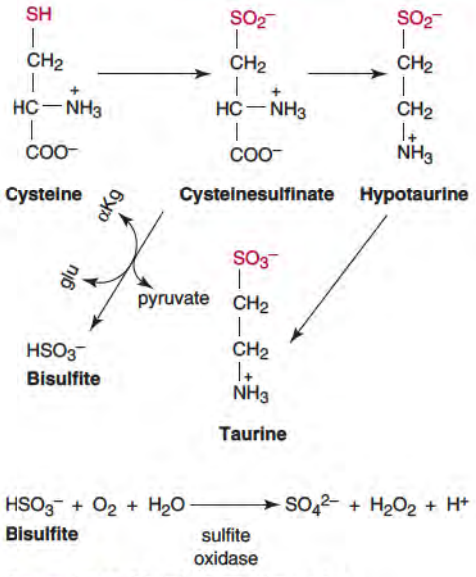

Figure 19.45 **Metabolism of cysteine.**

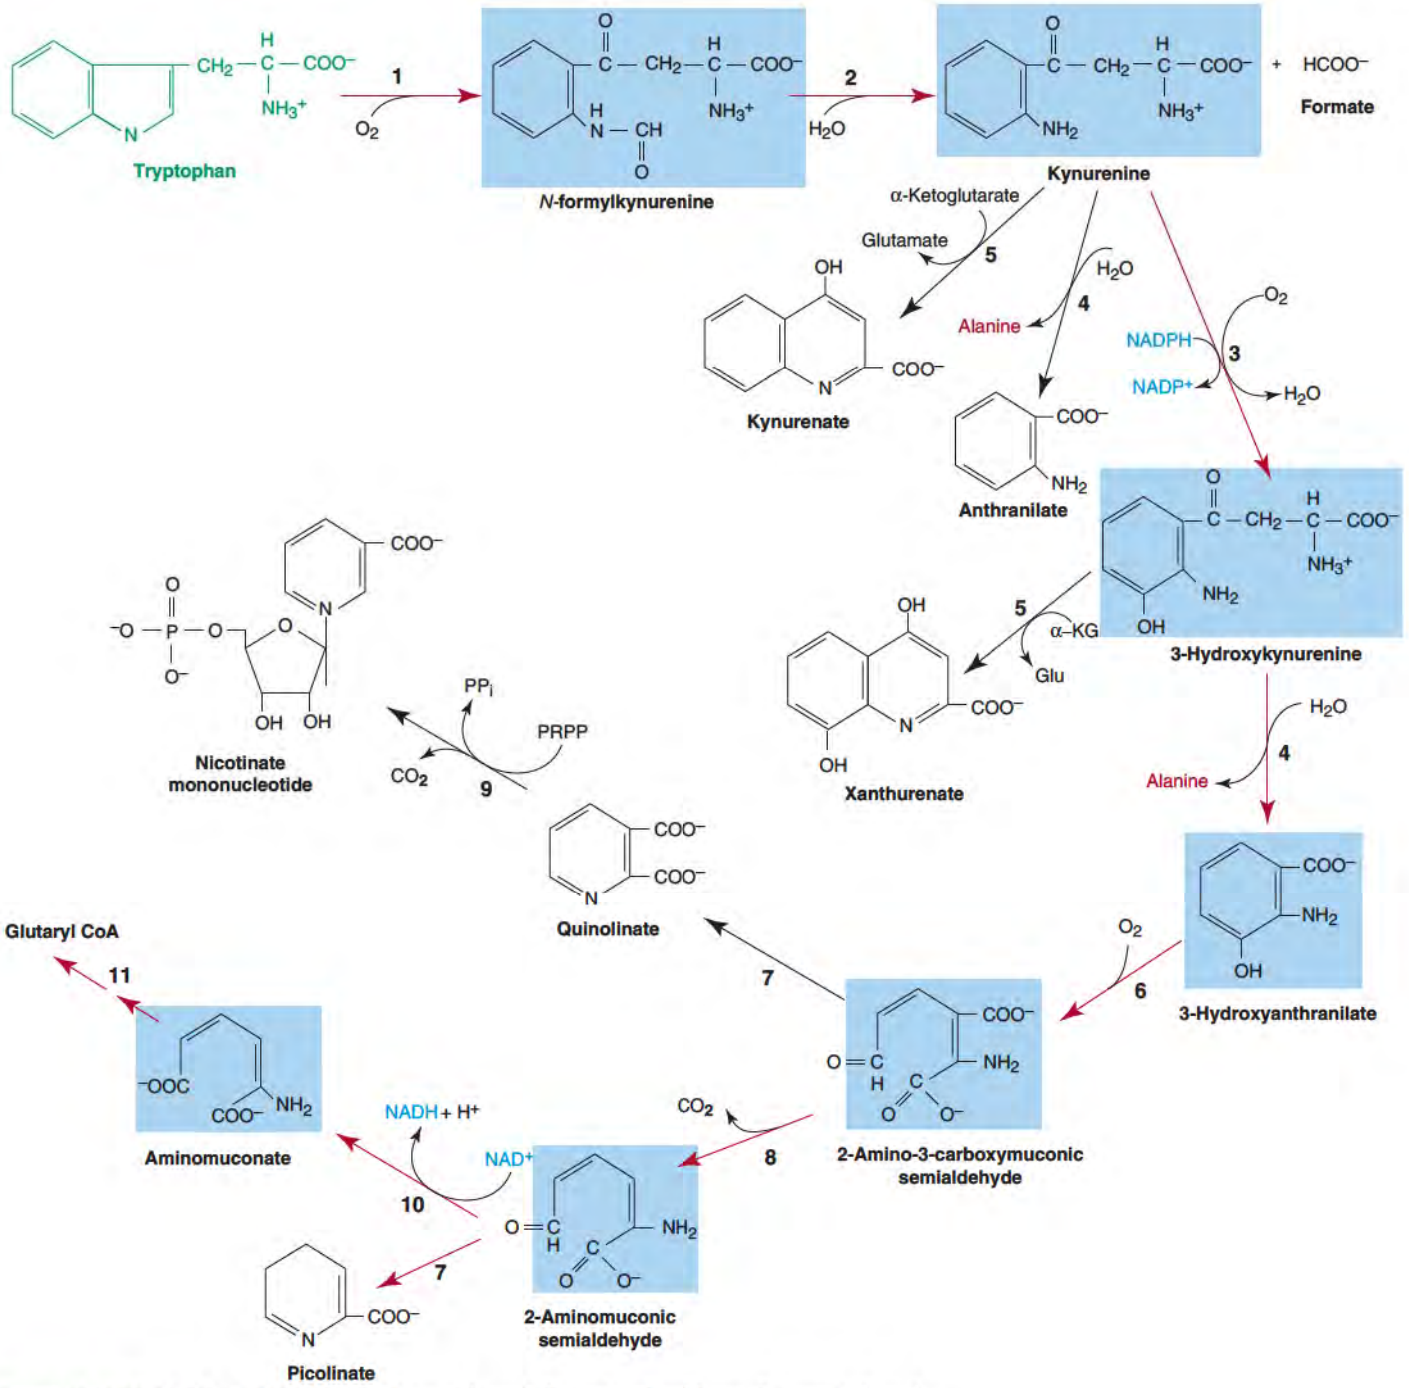

Figure 19.46 Metabolism of tryptophan. Major pathway is shown in colored boxes. Enzymes indicated by number are (1) tryptophan oxygenase, (2) kynurenine formamidase, (3) kynurenine hydroxylase, (4) kynureninase, (5) aminotransferase, (6) 3-hydroxyanthranilate oxidase, (7) spontaneous nonenzymatic reaction, (8) picolinate carboxylase, (9) quinolinate phosphoribosyltransferase, (10) aldehyde dehydrogenase, and (11) complex series of reactions.

saccharopine (Clin. Corr. 19.13, p. 776, and Figure 19.47). Glutamate and a semialdehyde compound are formed. The semialdehyde is then oxidized to a dicarboxylic amino acid, and a transamination of the α-amino group occurs in a pyridoxal-dependent manner. Further reactions lead to glutaryl CoA that is in turn metabolized to acetoacetyl CoA. A minor pathway leads to pipecolate (Figure 19.48, p. 776; A Closer Look 19.6, p. 778).

Histidine: Histidase releases free ammonia from histidine and leaves a compound with a double bond called urocanate (Figure 19.49, p. 776). Two other reactions lead

CLINICAL CORRELATION 19.11

Diseases Involving Cystine

Cystinuria (OMIM 220100), one of the most common of genetic disorders with a prevalence of about 1 in 7000, is a defect of membrane transport of cystine and basic amino acids (lysine, arginine, and ornithine) that results in their increased renal excretion. Extracellular sulfhydryl compounds are quickly oxidized to disulfides. Low solubility of cystine results in crystals and formation of renal calculi, a serious feature of this disease. Treatment is limited to removal of stones, prevention of precipitation by drinking large amounts of water or alkalinizing the urine to solubilize cystine or formation of soluble derivatives by conjugation with drugs. If these treatments do not work, penicillamine is used.

Much more serious is cystinosis (OMIM 219800) in which cystine accumulates in lysosomes. The stored cystine forms crystals in many cells, with a serious loss of function of the kidneys, usually causing renal failure within 10 years. The defect is believed to be in the cystine transporter of lysosomal membranes. Cystinosis is often treated by cysteamine therapy and, when serious enough, by kidney transplant.

CLINICAL CORRELATION 19.12

Diseases of Glutaric Acid Metabolism

Glutaric Aciduria (OMIM 231670)

Glutaryl CoA is produced from the metabolism of tryptophan and lysine and is further metabolized by the mitochondrial enzyme glutaryl-CoA dehydrogenase to glutaconyl CoA. The earliest sign of a deficiency in this enzyme is microencephalic macrocephaly at birth with subdural hematoma and acute retinal hemorrhage. It may be diagnosed by increasing lysine intake, which makes the aciduria worse, and decreasing protein intake, which reduces the amount of glutaric acid excreted. Tissue degeneration and behavioral arrest follow in the first 2 years of life, often triggered by infection. Glutaric acid causes modulation of glutamatergic and GABAergic neurotransmission, and this may explain the mechanism of neural damage. Newborn screening by enzymatic assay of asymptomatic infants can identify this deficiency, and careful monitoring and treatment with a low lysine/tryptophan diet with carnitine supplementation during crises can prevent about two-thirds of dystonia and dyskinesis. It is believed that some cases of *postencephalitic* cerebral palsy result from glutaryl-CoA dehydrogenase deficiency.

Multiple Acyl-CoA Dehydrogenase Deficiency (MADD) (Glutaric Aciduria II) (OMIM 231680)

Many different acids are excreted due to deficiencies of these flavoprotein deficiencies. They include glutaric, isovaleric, and butyric acids. Mutations have been found in two of the subunits for the flavoprotein found in electron transport, and in flavoprotein dehydrogenase. Any one of these mutations can be responsible for the symptoms found in this disease. These mutations affect fatty acid degradation, metabolism of branched-chain amino acids and lysine, and degradation of choline, as well as metabolism of glutaric acid. Symptoms, which include hypoglycemia, appear in early childhood, and resemble those of poisoning caused by ingestions of unripe ackee fruit. Unripe ackee contains a substance called hypoglycin, which inhibits many acyl-CoA dehydrogenases.

Glutaryl-CoA Oxidase Deficiency (Glutaric Acidemia III) (OMIM 231690)

Excess glutaric acid in the urine usually indicates one of the two diseases just described. Some cases, however, have been observed where tests for these conditions have ruled them out as the cause of the aciduria. In these cases administration of lysine or pipecolic acid increased the excretion of glutaric acid and led to the discovery of a peroxisomal glutaryl-CoA oxidase deficiency. There are often no overt symptoms connected to this condition.

to formation of forminoglutamate (FIGLU). The formimino group of FIGLU must then be transferred to tetrahydrofolate before the final product, glutamate, can be produced. When there is insufficient tetrahydrofolate available, this reaction decreases and FIGLU is excreted in urine. This is a diagnostic sign of folate deficiency if it occurs after a test dose of histidine is ingested (Clin. Corr.19.14).

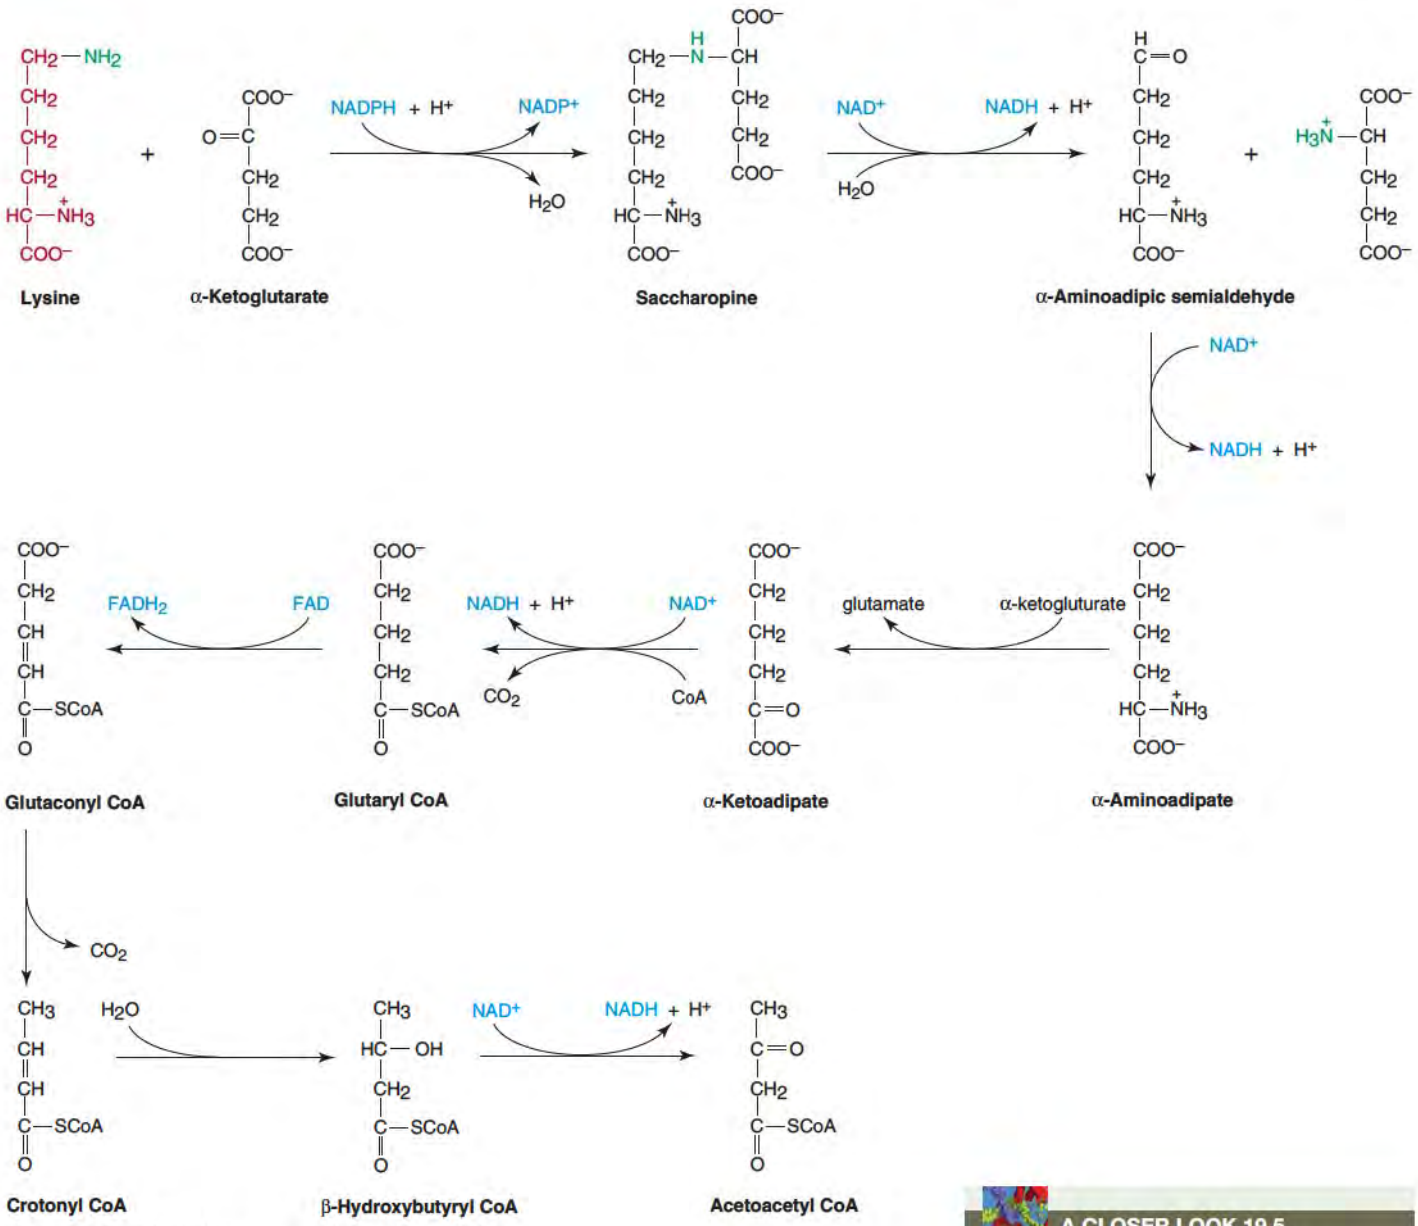

Figure 19.47 **Principal pathway of lysine degradation.**

Branched-Chain Amino Acids

Metabolism of the **branched-chain amino acids** (**BCAAs**) valine, isoleucine, and leucine is unusual, being initiated in muscle. NADH and $FADH_2$ are formed during their metabolism, making them an excellent source of energy. BCAA aminotransferase activity is higher in muscle than in liver. Although these amino acids produce different products, the initial steps in their metabolism are shared. BCAA aminotransferase exists in three isozymes with different tissue distributions. Some are found in cytosol and some in mitochondria (Figure 19.50, p. 777). Two of these isozymes metabolize all three BCAAs, and one is specific for leucine. Starvation induces the muscle BCAA aminotransferases. The resulting α-keto branched-chain acids are oxidatively decarboxylated by an inner mitochondrial membrane enzyme complex similar to the pyruvate dehydrogenase complex, producing NADH and CO_2. All three α-keto branched-chain acids are oxidized by the same enzyme. The more active form occurs in liver in the fed state and in muscle during starvation, reflecting the metabolism of dietary BCAAs by liver and of muscle BCAAs to provide energy during fasting. The resulting CoA compounds are one carbon shorter than the amino acids and are next acted on by an enzyme that resembles the first dehydrogenase of fatty acid β-oxidation (Clin. Corr. 19.15, p. 778).

A CLOSER LOOK 19.5

Tryptophan, Carbohydrates, and Sleep

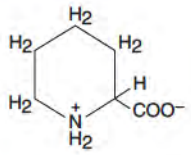
Tryptophan availability is reduced when other amino acids compete with it for transport through the blood–brain barrier. Elevated plasma concentrations of other amino acids, after a high-protein meal, diminish transport of tryptophan and induce wakefulness. The sleep-inducing effect of carbohydrates is due to decreased plasma amino acid levels, since carbohydrate stimulates release of insulin, and insulin causes removal of amino acids from plasma and uptake into muscle. This alleviates competition and increases the amount of tryptophan that can enter the brain.

CLINICAL CORRELATION 19.13

Hyperlysinemia and Lysinuric Protein Intolerance

The enzyme α-aminoadipic semialdehyde synthase is deficient in a small number of patients who excrete lysine and smaller amounts of saccharopine. This has led to the discovery that the enzyme has both lysine-α-ketoglutarate reductase and saccharopine dehydrogenase activities. In saccharopinuria some of the reductase activity is retained. Hyperlysinemia (OMIM 238700) can cause lax ligaments and muscles, convulsions, and anemia. Lysine is an inhibitor of arginase, and hyperammonemia may also occur. More serious is familial lysinuric protein intolerance (OMIM 222700) due to failure to transport dibasic amino acids across intestinal mucosa and renal tubular epithelium. Plasma lysine, arginine, and ornithine are decreased to one-third or one-half of normal. Patients may be undiagnosed as infants, but develop gastrointestinal symptoms and hyperammonemia after being changed to a meat-containing diet. Citrulline excretion is enhanced. This is thought to arise from deficiency of urea cycle intermediates ornithine and arginine in liver, limiting the capacity of the cycle. Consistent with this view, oral supplementation with citrulline prevents hyperammonemia. Other features are thin hair, muscle wasting, and osteoporosis, which may reflect protein malnutrition due to lysine and arginine deficiency.

Lysinuric protein intolerance: update and extended mutation analysis of the SLC7A7 gene. *Hum. Mutat.* 29:14, 2008.



Pipecolate

Figure 19.48 Pipecolate, a minor product of lysine metabolism.

Valine and **isoleucine**: These two amino acids continue down a common pathway, with addition of water across the double bond to form a hydroxylated intermediate (Figure 19.51). The hydroxyl group on the isoleucine derivative is oxidized by NAD^+ followed by thiolysis to give acetyl CoA and propionyl CoA. The valine derivative loses CoA and is then oxidized by NAD^+ to methylmalonate semialdehyde, which is converted to propionyl CoA.

Leucine: At this point, the metabolism of leucine diverges from that of the other two BCAAs. β-Methylcrotonyl CoA is carboxylated, hydroxylated, and cleaved to acetoacetate and acetyl CoA (Figure 19.52). One intermediate is β-hydroxy-β-methylglutaryl CoA, an intermediate in cytoplasmic sterol synthesis (p. 719). Since BCAA degradation occurs in mitochondria the two pools do not mix. Leucine also has a minor alternative pathway (not shown), which results in excretion of 3-hydroxyvaleric acid and can be utilized in the case of blockage in the leucine degradative pathway.

Propionyl CoA Is Metabolized to Succinyl CoA

An end product of isoleucine, valine, threonine, and methionine metabolism, odd-chain fatty acid oxidation, and degradation of the side chain of cholesterol is **propionyl CoA**. The first step in conversion of propionyl CoA to succinyl CoA is catalyzed by **propionyl-**

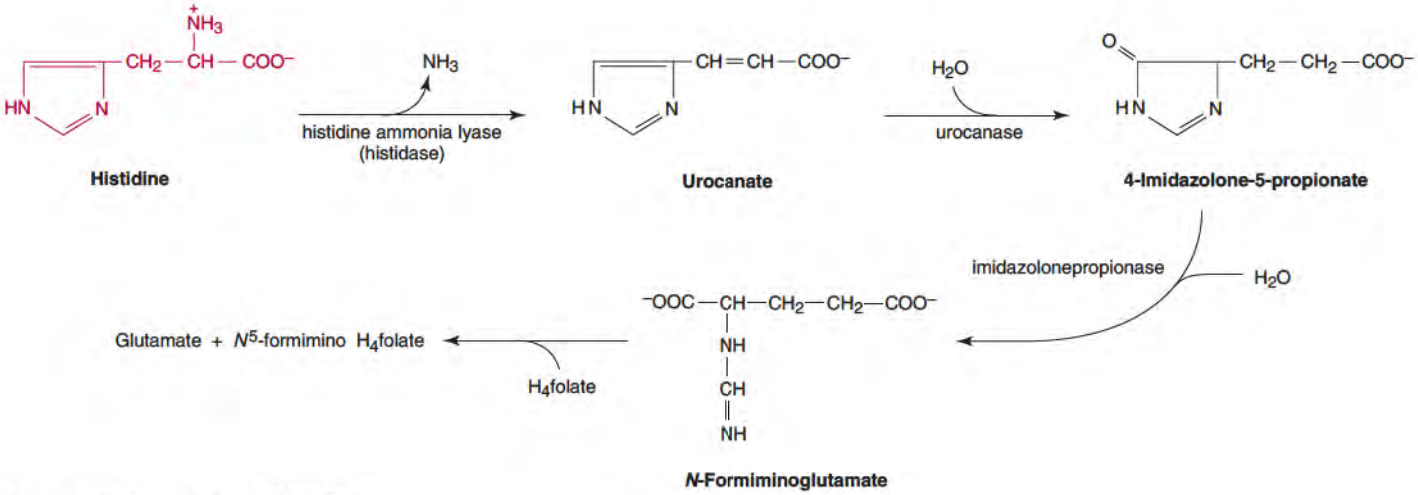


Figure 19.49 Degradation of histidine.

CLINICAL CORRELATION 19.14

Histidinemia and Formiminotransferase Deficiency

Histidinemia (OMIM 235800) is due to histidine ammonia-lyase (histidase) deficiency. A convenient assay for this enzyme uses skin, which produces urocanate as a constituent of sweat; urocanase and other enzymes of histidine catabolism in liver do not occur in skin. Histidase deficiency can be confirmed from a skin biopsy. Incidence of the disorder is high, about 1 in 10,000 newborns screened. Most reported cases of histidinemia show normal mental development. Restriction of dietary histidine normalizes the biochemical abnormalities but is not usually required. Glutamate formiminotransferase (OMIM 229100) deficiency is the second most common error of folate metabolism. In mild cases the only symptom is excretion of formiminoglutamate (FIGLU), but in severe cases mental retardation may occur. The difference between lack of activity of this enzyme and folic acid deficiency may be established by measuring folic acid in plasma.

Hilton, J. F., Christensen, K. E., Watkins, D., Raby, B. A., et al. The molecular basis of glutamate formiminotransferase deficiency. *Hum. Mutat.* 22:67, 2003; and Levy, H. L., Taylor, R. G., and McInnes, R. R. Disorders of histidine metabolism. In Scriver, C. R., Beaudet, A. L., Sly, W. S., Valle, D. (Eds.), *The Metabolic and Molecular Bases of Inherited Disease,* 8th ed. New York: McGrawHill, 2001, 2:1807.

CoA carboxylase that contains a biotin covalently linked to the ε-amino group of a lysine residue (Figure 19.53) and yields D-methylmalonyl CoA. A racemase converts this to a mixture of D- and L-methylmalonyl CoA. Methylmalonyl mutase, which requires 5′-deoxyadenosylcobalamin (a derivative of vitamin B_{12}), converts the L-isomer to succinyl CoA. This is the second enzyme known to be dependent on vitamin B_{12} (p. 1082). The reaction is very unusual, removing a methyl side chain and inserting it as a methylene group into the backbone of the compound (Clin. Corr. 19.16, p. 780).

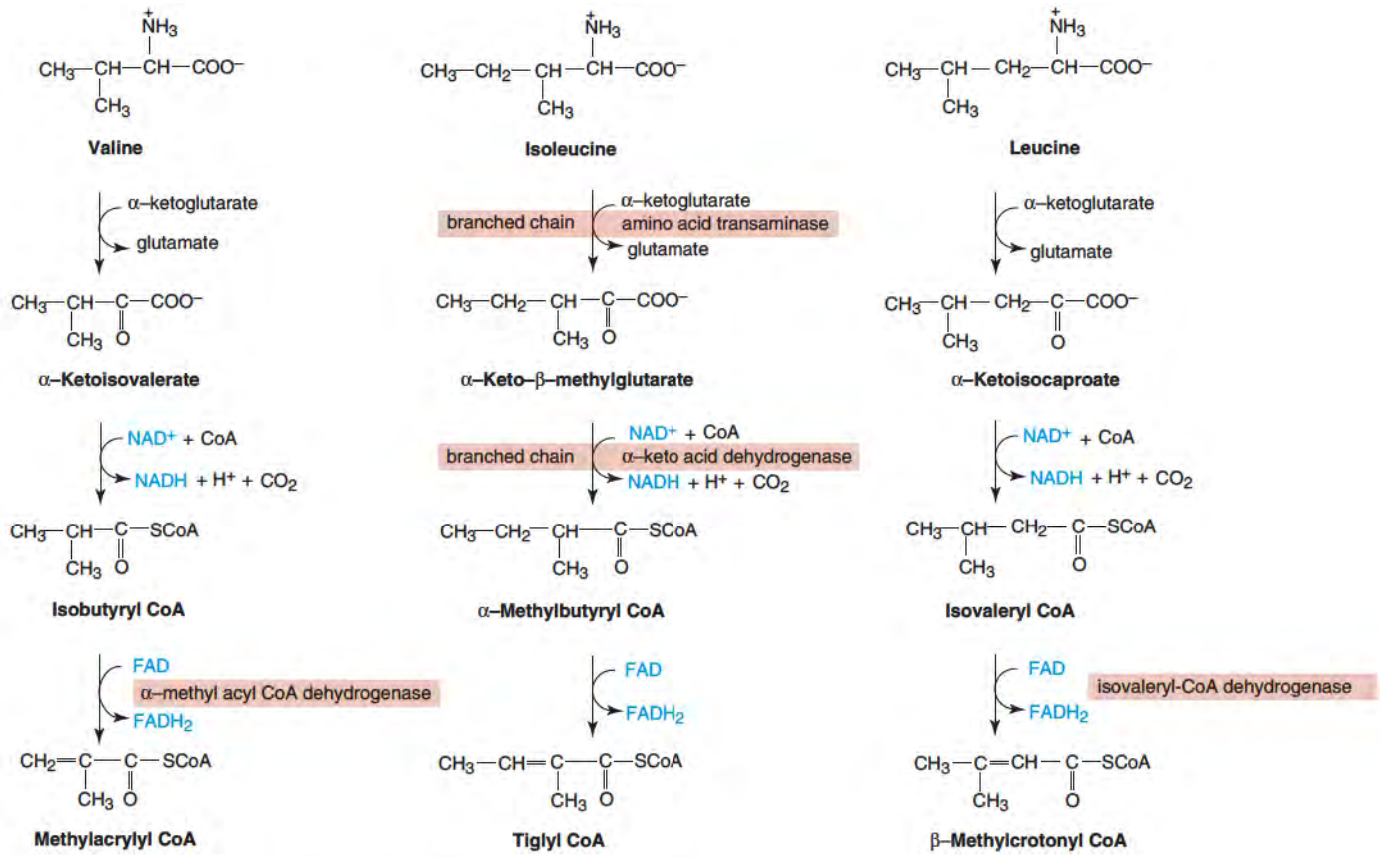

Figure 19.50 **Common reactions in degradation of branched-chain amino acids.**

CLINICAL CORRELATION 19.15

Maple Syrup Urine Disease (OMIM 248600) and Other Diseases in the Branched-Chain Amino Acid Degradative Pathways

Enzyme deficiency in catabolism of branched-chain amino acids is not common and results in acidosis in newborns or young children. Very rare instances have been reported of hypervalinemia, isovaleric acidemia, and hyperleucine-isoleucinemia. It has been suggested that these conditions indicate existence of specific aminotransferases for valine, leucine, and isoleucine. Alternatively, mutation could alter the specificity of a single enzyme. The most common abnormality is deficiency of branched-chain keto acid–dehydrogenase complex which contains four catalytic components as well as regulatory proteins. Some of the mutations appear to involve protein misfolding, and trimethylamine-amine oxide, a chemical chaperone, has been found to improve dehydrogenase activity. There are several variations, but all patients excrete the branched-chain α-keto acids, corresponding hydroxy acids, and other side products; an unidentified product imparts the characteristic odor as indicated by the name maple syrup urine disease. Some cases respond to high doses of thiamin, and these are caused by a mutation in the thiamin-binding site on one of the proteins. Many show serious mental retardation, ketoacidosis, and short life span. Severity of the disease appears to be linked to the identity of the protein carrying the mutation. Dietary treatment to reduce the branched-chain ketoacidemia is effective in some cases. Deficiency of enzymes in later reactions of branched-chain amino acids include a blockage of oxidation of isovaleryl CoA with accumulation of isovalerate (which gives urine a smell of sweaty feet: OMIM 607036), β-methylcrotonyl-CoA carboxylase deficiency (in which urine smells like that of a cat: OMIM 609010), deficiency of β-hydroxy-β-methylglutaryl-CoA lyase (OMIM 246450), and deficiency of β-ketothiolase that splits β-methylacetoacetyl CoA (with no defect in acetoacetate cleavage: OMIM 203750). In the latter condition, development is normal and symptoms appear to be related only to episodes of ketoacidosis.

2-Methyl-3-hydroxybutyryl-CoA dehydrogenase deficiency results in excretion of the substrate and glycylglycine. At about the age of 1 year motor and mental deterioration occurs and without dietary treatment the mental retardation becomes severe.

A CLOSER LOOK 19.6

Lysine and Pipecolate

A minor pathway of lysine metabolism starts with removal of the α-amino group and goes via the cyclic compound pipecolate (see Figure 19.48, p. 776) to join the major pathway at the level of the semialdehyde intermediate. This does not replace the major pathway even in a deficiency of enzymes in the early part of the pathway (see Figure 19.47, p. 775).

19.6 • IMPORTANT METABOLITES DERIVED FROM AMINO ACIDS

Glutamate: Glutamate is a component of glutathione, which is discussed at the end of this chapter (p. 789). It is also a precursor of **γ-amino butyric acid (GABA)**, a neurotransmitter (see Figure 19.10, p. 755), and of proline and ornithine (p. 763).

Serine: Serine is itself a head group for phospholipids. Ethanolamine, choline, and betaine (Figure 19.54, p. 780) are derivatives of serine. It should be noted that choline is now classified as a vitamin. Ethanolamine (decarboxylated serine) and choline (*N*-trimethylethanolamine) are components of phospholipids, and betaine (an oxidized derivative of choline) is a methyl donor in a minor pathway leading to methionine salvage (p. 767). Metabolism of choline and **carnitine** (see Figure 19.68, p. 788) leads to trimethylamine, which is normally oxidized for excretion. Loss of the enzyme for the further metabolism of trimethylamine leads to a condition called fish malodor syndrome. Serine also provides the carbon skeleton of cysteine, the sulfur being transferred from homocysteine (see Figure 19.42, p. 772).

A serine residue in some enzymes is metabolized in pyruvoyl enzymes (see A Closer Look 19.4, p. 765).

Arginine: Arginine is a precursor for nitric oxide (p. 447) in brain; agmatine (Figure 19.55, p. 780), a compound with properties of a neurotransmitter, is derived by decarboxylation of arginine and may have antihypertensive properties.

Glycine: Glycine is the precursor of glyoxalate, which can be transaminated back to glycine or oxidized to oxalate (Figure 19.56, p. 780). Excessive production of oxalate

CLINICAL CORRELATION 19.16

Propionic Acidemia and Methylmalonic Aciduria

Deficiency of any of the three enzymes shown in Figure 19.53 contributes to ketoacidosis. Propionate is formed in the degradation of valine, isoleucine, methionine, threonine, the side chain of cholesterol, and odd-chain fatty acids. The amino acids appear to be the main precursors since decreasing or eliminating dietary protein immediately minimizes acidosis. A defect in propionyl-CoA carboxylase (OMIM 606054) results in accumulation of propionate, which is diverted to alternative pathways including incorporation into fatty acids in place of the first acetyl group to form odd-chain fatty acids. Its hallmark diagnostic criteria are hyperglycinemia and hyperglycinuria that are accompanied by symptoms such as vomiting, lethargy, and ketosis. A low-protein diet can ameliorate these symptoms. In one case, large amounts of biotin were reported to produce beneficial effects, suggesting that more than one defect decreases propionyl-CoA carboxylase activity. Possibilities are a lack of intestinal biotinidase that liberates biotin from ingested food for absorption (OMIM 253260) or a lack of biotin holocarboxylase that incorporates biotin into biotin-dependent enzymes (OMIM 253270). Acidosis in children may be caused by high levels of methylmalonate, which is normally undetectable in blood. Liver taken at autopsy or cultured fibroblasts showed in some cases deficiency of methylmalonyl-CoA mutase. Some samples were unable to convert methylmalonyl CoA to succinyl CoA under any conditions, but other samples carried out the conversion when 5′-adenosylcobalamin was added. Clearly, those with an active site defect cannot metabolize methylmalonate, but those with defects in handling vitamin B_{12} respond to massive doses of the vitamin. Other cases of methylmalonic aciduria have a more fundamental inability to use vitamin B_{12} that leads to methylcobalamin deficiency (coenzyme of methionine salvage) and 5′-adenosylcobalamin deficiency (coenzyme of methylmalonyl CoA isomerization). Methylmalonic aciduria (OMIM 251000) can be anywhere from benign to fatal, often causing mental retardation and kidney failure. An interesting case of false accusation of murder is that of Patricia Stalling, who was jailed for causing the death of her infant son by feeding him ethylene glycol. While in jail, she gave birth again, and the baby was diagnosed with methylmalonic academia. Reexamination of the first infant's blood showed that the compound that had originally been identified as ethylene glycol was in fact propionic acid.

forms the insoluble calcium oxalate salt, which may lead to kidney stones (Clin. Corr. 19.17). The role of glycine as a neurotransmitter is described on page 942.

Methionine: The vast majority of methyltransferase reactions utilize ***S*-adenosylmethionine** (see Figure 19.41, p. 770, and Clin. Corr. 19.18). Methyl group transfer from AdoMet (also called SAM, for *S*-adenosylmethionine), a methyl acceptor, is

CLINICAL CORRELATION 19.17

Primary Hyperoxaluria

Idiopathic hyperoxaluria is caused by excess oxalate production. About 50% of the oxalate comes from the diet and may be related to changes in the ability of the intestines to absorb oxalate. Primary hyperoxaluria is a rare disease and a result of enzyme deficiency. It has serious consequences. More than 50% of people with this genetic defect have renal failure by age 15, and 80% by age 30. The amount of excess serum oxalate is so great that even dialysis (the normal treatment for high oxalic acid) is ineffective. Calcium oxalate stones in the kidney are the cause of the damage, and the oxalate buildup is due to the deficiency in either one of two enzymes. Type I primary hyperoxaluria (OMIM 259900) results from a loss of activity of alanine: glyoxylate aminotransferase. This enzyme is liver specific and found in peroxisomes. Its function is the conversion of glyoxylate to glycine. The aminotransferase is pyridoxal-phosphate-dependent, and the disease sometimes responds to vitamin B_6 therapy. Children with kidney stones are usually screened for this enzyme deficiency because, when identified, any younger siblings can start therapy as early as possible to avoid eventual kidney damage. Early liver transplantation is sometimes successful in preventing further damage. Later symptoms are caused by blockage of the circulatory system by oxalate and include uremia, Raynaud syndrome, spasms of large arteries, gangrene, and vision-associated problems.

Type II primary hyperoxaluria (OMIM 260000), is characterized by a loss of D-glyceric dehydrogenase. This enzyme catalyzes the conversion of glyoxalate to oxalate. It is less serious than type I.

The clinical outcome of both diseases is related to the degree of loss of enzyme activity.

Results of long-term treatment with orthophosphate and pyridoxine in patients with primary hyperoxaluria. *N. Engl. J. Med.* 331:1553, 1994.

irreversible. An example is shown in Figure 19.57. A butylamino group derived from AdoMet is used for posttranslational modification of a specific lysine residue in eIF-4D, an initiation factor that promotes formation of the first peptide bond in eukaryotic protein synthesis. The group is first added to putrescine to make spermidine, and then cleaved to form deoxyhypusine. It is then hydroxylated, and the modified residue that results is called hypusine (Figure 19.58). Use of the iron chelator desferrioxamine, a strong inhibitor of hypusine synthesis, has been shown to potentiate apoptosis in cancer cells and shows promise as an anticancer agent.

Cysteine: Cysteine is metabolized in several ways as determined by the needs of the cell. The major metabolite is cysteine sulfinate (see Figure 19.45, p. 772). This is converted to bisulfite and pyruvate or to hypotaurine and taurine. Taurine is an abundant intracellular free amino acid. It appears to play a necessary role in brain development. It forms conjugates with bile acids (p. 1058) and may enhance bile flow and increase cholesterol clearance by the liver. Taurine may also play a role as an antioxidant in salvaging toxic intermediates, in immunity, in regulating intracellular calcium, in controlling hypertension, and, because of its abundance, in osmoregulation.

Sulfite produced from cysteine metabolism is oxidized to sulfate (see Figure 19.45, p. 772) and used in formation of 3′-phosphoadenosine-5′-phosphosulfate (PAPS), the source of sulfate groups for addition to biological molecules (Figure 19.59).

Another reaction of cysteine metabolism catalyzed by cystathionase moves the sulfur from one cysteine to another cysteine (Figure 19.60) to form thiocysteine. Thiosulfate is formed from cysteine as shown in Figure 19.61. An enzyme called rhodanese (named for the deep red color of thiocyanate) can incorporate a sulfur from thiosulfate or thiocysteine into other molecules such as cyanide ion (Figure 19.62). Cyanide-related compounds occur in some plant material, notably those of the genus *Brassica.*

Tyrosine: Most tyrosine not incorporated into proteins is metabolized to acetoacetate and fumarate but some is used for the synthesis of the catecholamines: **dopamine**, **norepinephrine**, and **epinephrine**. The eventual metabolic fate of tyrosine carbons is determined by the first step in each pathway. Catecholamine synthesis (Figure 19.63) starts with tyrosine hydroxylase, which, like phenylalanine and tryptophan hydroxylase, is dependent on tetrahydrobiopterin. All three are affected by biopterin deficiency or a defect in dihydrobiopterin reductase (see Figure 19.38,

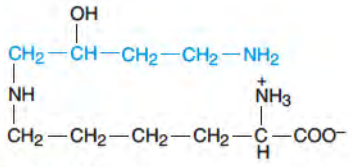

Figure 19.58 Hypusine.

CLINICAL CORRELATION 19.18

Methionine Adenosyltransferase (MAT) Deficiency (OMIM 250850)

This inborn error of metabolism is probably more prevalent than reported, since it is generally symptom free and therefore remains undiagnosed. Only a severe loss of enzyme activity results in symptoms that include growth retardation, digestive problems, and anorexia. Frequent manifestations of the condition are halitosis or other unpleasant body odors due to buildup of dimethylsulfide.

MAT deficiency can cause hypermethioninemia (over 1500 μM; normal is 35 μM), and is differentiated from that caused by cystathionine synthase deficiency, tyrosinemia-associated liver failure, and liver disease by liver biopsy. At extremely high levels of methionine it can be transaminated, and the transaminated metabolites are found in blood. Treatment is a low methionine diet, but a severe lack of AdoMet that can result from MAT inactivity is associated with neurological symptoms and must be treated with AdoMet therapy.

The disease is believed to be inherited in an autosomal recessive manner, but heterozygotes exhibiting truncation, missense, and splicing mutations have been found. The defect may be an example of a dominant negative mutant where one defective subunit of the dimeric or tetrameric enzyme can cause inactivation of the other subunits.

Chamberlin, M. E., Ubagai, T., Mudd, S. H., Thomas, J., et al. Methionine adenosyltransferase I/III deficiency: novel mutations and clinical variations. *Am J Hum Genet.* 66(2): 347, 2000; and Ubagai, T., Lei, K.-J., Huang, S., Mudd, S. H., et al. Molecular mechanisms of an inborn error of methionine pathway: methionine adenosyltransferase deficiency. *J. Clin. Invest.* 96: 1943, 1995.

p. 768). Tyrosine hydroxylase produces **dihydroxyphenylalanine** (dioxophenylalanine, **DOPA**). DOPA decarboxylase, with pyridoxal phosphate as cofactor, forms dopamine, the active neurotransmitter. Because dopamine is metabolized primarily by monoamine oxidase B in humans, and Parkinson disease (Clin. Corr. 19.19, p. 785) is characterized by a reduction in the brain dopamine concentration, selective inactivation of MAO-B has been shown to be effective in increasing the dopamine concentration and thus treat the disease.

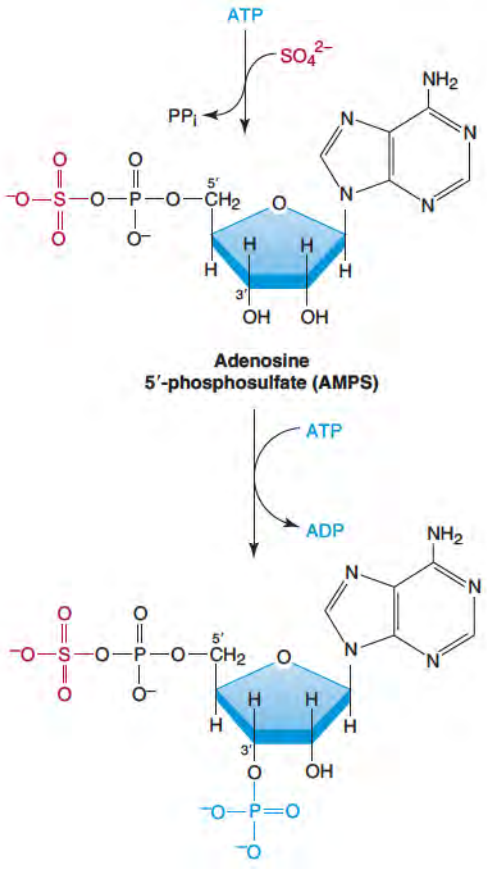

Figure 19.59 **Synthesis of PAPS.**

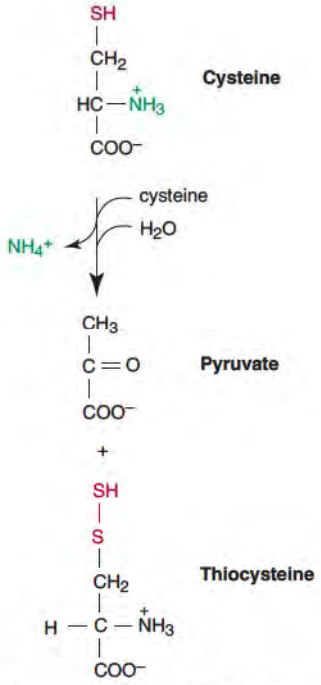

Figure 19.60 **Synthesis of thiocysteine.**

In the substantia nigra and some other parts of the brain, this is the end of this pathway. The adrenal medulla converts dopamine to norepinephrine and epinephrine (adrenaline). The methyl group of epinephrine is derived from *S*-adenosylmethionine (see Figure 19.41, p. 770).

Tyrosine in brain cells regulates norepinephrine formation. Estrogens decrease tyrosine concentration and increase tyrosine aminotransferase activity, diverting tyrosine into the catabolic pathway. Estrogen sulfate competes for the pyridoxal phosphate site on DOPA decarboxylase. These effects combined may help explain mood variations during the menstrual cycle. Tyrosine is therapeutic in some cases of depression and stress. Its transport appears to be reduced in skin fibroblasts from schizophrenic patients, indicating other roles for tyrosine derivatives in mental disorders. Catecholamines are metabolized by monoamine oxidase and catecholamine *o*-methyltransferase. Major metabolites are shown in Figure 19.64. Absence of these metabolites in urine is diagnostic of a deficiency in synthesis of catecholamines. Lack of synthesis of serotonin is indicated by lack of 5-hydroxyindole-3-acetic acid in urine. Biopterin deficiency is described in Clin. Corr. 20.

Tyrosine is also required for synthesis of **melanin**, thyroid hormone, and quinoproteins.

Conversion of tyrosine to melanin requires tyrosinase, a copper-containing protein (Figure19.65*a*). The reaction produces dopaquinone. During melanogenesis, following exposure to UVB light, tyrosinase and tyrosinase-related protein, which may function

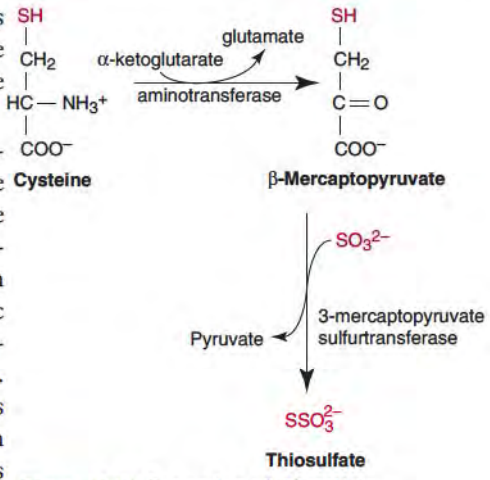

Figure 19.61 Formation of thiosulfate.

in posttranslational modification of tyrosinase, are induced. A lack of tyrosinase activity produces albinism (Clin. Corr. 19.21). There are various types of melanin (Figure 19.65*b*). All are aromatic quinones in which the conjugated bond system gives rise to color. The dark pigment that is usually called melanin is eumelanin, from the Greek for "good melanin." Other melanins are yellow or colorless. The role of tyrosine residues of thyroglobulin in thyroid hormone synthesis is presented on page 896.

Some proteins use a modified tyrosine residue as a prosthetic group in oxidation–reduction reactions. The only example reported in humans is topaquinone (trihydroxyphenylalanylquinone) or dihydroxyphenylalanine (TOPA), which is present in some plasma amine oxidases (Figure 19.66).

Tryptophan: Tryptophan is the precursor of approximately 50% of the body's pyridine nucleotides. The rest is obtained from the diet. The branch point leading to

CLINICAL CORRELATION 19.19

Parkinson Disease

Idiopathic Parkinson disease (PD) (OMIM 168600 and 168601) generally manifests itself in people over the age of 60 years but occasionally earlier. Tremors may develop that gradually interfere with motor function and muscular rigidity of various muscle groups. Prominent symptoms include a loss of dopaminergic neurons in the substantia nigra (SN) and the presence of Lewy bodies (see the following) in cells in other areas of the brain. Of neurological diseases only Alzheimer occurs more frequently.

Parkinsonism is made up of diseases that mimic the symptoms of PD. These conditions may or may not exhibit Lewy bodies. PD can be definitively diagnosed only after postmortem pathological examination, with a finding of degeneration of cells in certain small nuclei of the cells of substantia nigra. These cells normally produce dopamine as a neurotransmitter, the amount released being proportional to the number of surviving cells.

Many causes have been suggested for PD. Among them are mutations of the alpha-synuclein (SNCA) gene. These mutations may cause deficiencies in vesicle movement, and consequent accumulation of dopamine in cytoplasm. Free dopamine in cytosol is subject to metabolism and excretion. Other possibilities for the etiology of PD include disruption in the ubiquitin system and interaction with factors leading to cell death. Some mutations appear to be mitochondrial and some present as X linked. In most cases of PD Lewy bodies, accumulated bits of alpha-synuclein protein, inside the nuclei of neurons, are seen in various parts of the brain.

A dramatic outbreak of parkinsonism occurred in young adult drug addicts using a derivative of pyridine (methylphenyltetrahydropyridine [MPTP]). It (or a contaminant produced during its manufacture) appears to be directly toxic to dopamine-producing cells of the substantia nigra. Symptomatic relief from PD, often dramatic, is obtained by administering DOPA, the precursor of dopamine. Clinical problems developed when DOPA (L-DOPA, levo-DOPA) was used for treatment of many people who have Parkinson disease. Side effects included nausea, vomiting, hypotension, cardiac arrhythmias, and various central nervous system symptoms. These were explained as effects of dopamine produced outside the central nervous system. Administration of DOPA analogs, such as carbidopa, that inhibit DOPA decarboxylase in peripheral organs but are unable to cross the blood–brain barrier has been effective in decreasing side effects and increasing effectiveness of the DOPA. The interactions of the many brain neurotransmitters are very complex, cell degeneration continues after treatment, and elucidation of the major biochemical abnormality has not yet led to complete control of the disease. Limited trials with injection of the brain glial cell line-derived neurotrophic factor (GDNF) into the putamen have been found to have a beneficial effect. A recent discovery suggests that loss of norepinephrine-producing cells in the locus coeruleus may contribute to symptoms of PD.

nicotinate mononucleotide (see Figure 19.46, p. 773) is at amino-carboxymuconic semialdehyde. Picolinate carboxylase forms 2-aminomuconic semialdehyde; this enzyme has a low K_m and is easily saturated with substrate. Since picolinate carboxylase has low activity in liver, some amino-carboxymuconic semialdehyde is spontaneously cyclized to quinolinic acid. Phosphoribosyl pyrophosphate provides a ribonucleotide moiety, and the final step is a decarboxylation leading to nicotinate mononucleotide. Note that the nicotinic acid ring is synthesized as a part of a nucleotide. Because kynurenine hydroxylase is inhibited by estrogen, women are more susceptible to pellagra, the disease produced by niacin deficiency (from the Italian pelle, "skin," and agra, "rough").

Several intermediates in the tryptophan degradative pathway are neuroactive, including L-kynurenine, kynurenate and quinolinate, and some of their derivatives. They function frequently by binding to the *N*-methyl D-aspartate (NMDA) receptor.

Serotonin and melatonin are tryptophan derivatives. Serotonin (5-hydroxytryptamine) results from hydroxylation of tryptophan by a tetrahydrobiopterin-dependent enzyme (Clin. Corr. 19.22) and decarboxylation by a pyridoxal-phosphate-containing enzyme (Figure 19.67*a*). It is a neurotransmitter in brain and causes contraction of smooth muscle of arterioles and bronchioles. It occurs widely in the body and may have other physiological roles. Melatonin, a sleep-inducing molecule, is *N*-acetyl-5-methoxytryptamine (Figure 19.67*b*). The acetyltransferase needed for its synthesis is present in pineal gland and retina. Melatonin is involved in regulation of circadian rhythm, being synthesized mostly at night. It appears to function by inhibiting

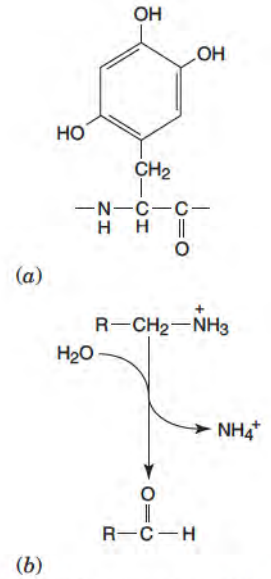

Figure 19.66 (*a*) Trihydroxyphenylalanine (TOPA). (*b*) Amine oxidase reaction.

CLINICAL CORRELATION 19.20

Tetrahydrobiopterin

A general test for biopterin deficiency is measurement of pterin metabolites in the urine.

An indirect test for biopterin deficiency measures loss of urinary metabolites resulting from the activity of the three aromatic amino acid hydroxylases and is diagnosed by a reduction in the urinary metabolites of these pathways (Figure 19.65). Studies with cultured skin fibroblasts can allow for determination of the source of the deficiency. Possible enzyme deficiencies are GTP cyclohydrolase (OMIM 233910), 6-pyruvoyltatrahydrobiopterin synthase (OMIM 261640), sepiapterin reductase (OMIM 182125), and dihydropteridine reductase (OMIM 261630). The first two of these enzymes are involved in the synthesis of biopterin, and the other two in its regeneration. Symptoms include red hair, psychomotor retardation, and progressive neurological deterioration. Some cases of biopterin deficiency respond well to supplementation of the diet with biopterin, and some are very difficult to treat. Neurotransmitter precursors (L-DOPA and hydroxytryptophan) can be administered. A compound called quinonoid dihydrobiopterin is also synthesized by enzymes that are encoded by different genes from those needed for synthesis of tetrahydrobiopterin. Addition of a methyl group from N^5,N^{10}-tetrahydrofolate to quinonoid dihydrobiopterin forms dihydrobiopterin. Supplementation with folinic acid can therefore sometimes be a successful treatment for biopterin deficiency.

In some cases of vitiligo it has been noted that there is a low level of catalase in the affected cells, leading to a buildup of hydrogen peroxide. The peroxide inactivates enzymes involved in regeneration of tetrahydrobiopterin, and therefore to reduction in amounts of tyrosine, the precursor of melanin.

The oxygenase domain of each nitric oxide synthase isoform also contains tetrahydrobiopterin. Unlike other enzymes where tetrahydrobiopterin is used as a source of reducing equivalents and is recycled by dihydrobiopterin reductase, in this case tetrahydrobiopterin activates heme-bound O_2 by donating a single electron. A combination of NO depletion and loss of synthesis of catecholamines and serotonin have been blamed on tetrahydrobiopterin deficiency.

CLINICAL CORRELATION 19.21

Albinism (OMIM 203100)

Skin and hair color are controlled by numerous genetic loci in humans and exist in infinite variation. There are many cases in which the skin has little or no pigment. The chemical basis for classical oculocutaneous albinism (OCA1) results from a lack of tyrosinase ("tyrosinase-negative"). Lack of pigment in the skin makes albinos sensitive to sunlight, increasing the incidence of skin cancer in addition to burns; lack of pigment in the eyes may contribute to photophobia. In OCA1B the enzyme is partially missing. Other forms of albinism can be attributed to a deficiency in tyrosinase-related protein (TRP) or membrane-associated transporter protein (MATP). The skin of albinos with OCA1 has been found to contain melanocytes, the cells where melanin synthesis occurs. It is suggested that any residual tyrosinase in these is not available to metabolize tyrosine.

(Eds.), *The Metabolic and Molecular Bases of Inherited Disease*, 8th ed. New York: McGraw Hill, 2001, 2:5587; and Witkop, C. J., Jr., Quevedo, W. C., Jr., Fitzpatrick, T. B., and King, R. A. Albinism. In Scriver, C. R., Beaudet, A. L., Sly, W. S., Valle, D. (Eds.), *The Metabolic and Molecular Bases of Inherited Disease*, 6th ed. New York: McGraw Hill, 1989, 2:2905.

synthesis and secretion of other neurotransmitters such as dopamine and GABA (see A Closer Look 19.5, p. 775).

Lysine: Medium- and long-chain fatty acids are transported into mitochondria for β-oxidation as carnitine conjugates (p. 691). **Carnitine** is synthesized from lysine residues in certain proteins. The first step is trimethylation of the ε-amino group of the lysine side chain, with AdoMet as the methyl donor (Figure 19.68). Free trimethyllysine is released by hydrolysis of these proteins and is converted in four steps to carnitine.

Histidine: Histamine (Figure 19.69), released from cells as part of an allergic response, is produced from histidine by histidine decarboxylase. Histamine has many physiological roles, including dilation and constriction by interacting with different types of

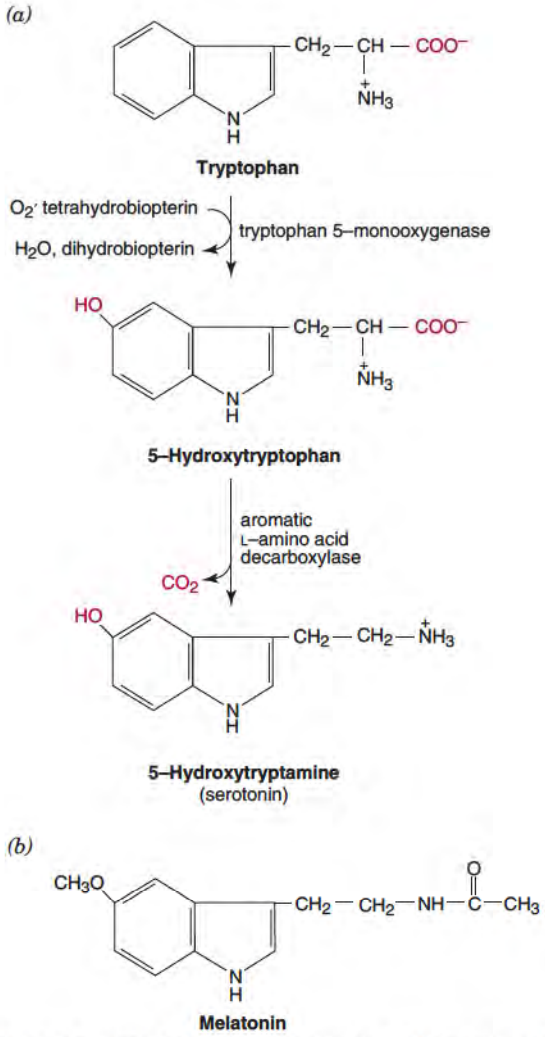

Figure 19.67 ***(a)*** **Synthesis of serotonin (5-hydroxytryptamine).** ***(b)*** **Structure of melatonin.**

receptors on endothelium of blood vessels. An overreaction to histamine can lead to asthma and other allergic reactions.

Metabolites Made from More than One Amino Acid

Carnosine and **Anserine**: Carnosine (Figure19.70) is a dipeptide of the amino acids histidine and β-alanine. It is highly concentrated in muscle and brain tissues. Several roles have been proposed for this dipeptide, but only its role as an antioxidant has been well documented. Anserine (Figure19.70) is a dipeptide of β-alanine and *N*-methylhistidine. It is also an antioxidant.

Polyamines: Ornithine is a precursor of putrescine, the foundation molecule of the polyamines, highly cationic molecules that interact with DNA. Ornithine decarboxylase (Figure 19.71) is regulated by phosphorylation at several sites, presumably in response to specific hormones, growth factors, or cell cycle regulatory signals. It can also be induced, often the first easily measurable sign that cell division is imminent, since polyamines must be synthesized before mitosis can occur. Propylamine derived from AdoMet, leaving methylthioadenosine, is added to putrescine to form spermidine and spermine. Putrescine is formed by decarboxylation of ornithine and, with propylamine, forms spermidine. Addition of another propylamine gives spermine (Figure 19.72). The methylthioadenosine that remains can be used to regenerate methionine. Much of the polyamine needed by the body is provided by microflora in the gut or from the diet and is carried by the enterohepatic circulation. Meat has a high content

CLINICAL CORRELATION 19.22

Tryptophan Hydroxylase Deficiency

Unipolar major depression is associated with a low level in serotonin in the synaptic cleft (p. 943). In order to prevent reuptake into the presynaptic neuron, where it is degraded, a class of drugs called selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine (Prozac), have been developed. A significant number of patients with unipolar depression do not respond to therapy with SSRIs. In some of these cases the defect is not in increased degradation of serotonin but in the loss of activity of the first enzyme in the synthetic pathway for this neurotransmitter, tryptophan hydroxylase. The two isozymes, tryptophan hydroxylases (TPH) 1 (OMIM 191060) and 2 (OMIM 607478), are coded on different chromosomes. TPH 1 is expressed in raphe neurons, pinealocytes, mast cells, mononuclear leukocytes, β cells of the pancreas, and intestinal and pancreatic enterochromaffin cells. TPH 1 controls several neural processes, including mammary homeostasis and liver regeneration. Mutations in TPH 1 have been associated with unipolar depression and suicidal ideation. The other isozyme, TPH2, is known as neuronal TPH, and mutations in this enzyme are related to unipolar major depression. Bipolar disorder does not seem to be associated with loss of either isozyme.

of putrescine, but other foods contain more spermidine and spermine. Inhibition of polyamine synthesis is being investigated as a therapy for cancer.

Creatine: Storage of high-energy phosphate, particularly in cardiac and skeletal muscle, occurs by transfer of the phosphate group from ATP to creatine (p. 979). Creatine is synthesized by transfer of the guanidinium group of arginine to glycine, followed by addition of a methyl group from AdoMet (Figure 19.73). The amount of creatine in the body is related to muscle mass, and a certain percentage of this undergoes turnover each day. About 1% to 2% of preexisting creatine phosphate is cyclized nonenzymatically to creatinine (Figure 19.74) and excreted in urine, and new creatine is synthesized to replace it. The amount of creatinine excreted by an individual is therefore constant from day to day. When a 24-h urine sample is requested, the amount of creatinine in the sample can be used to determine whether the sample truly represents a whole day's urinary output.

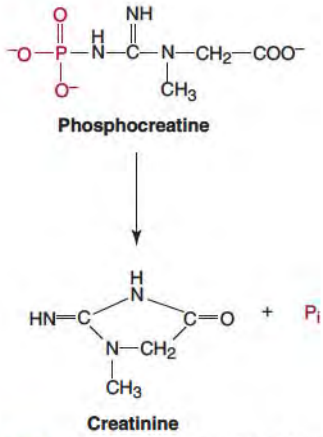

Figure 19.74 Spontaneous reaction forming creatinine.

Glutathione

The tripeptide γ-glutamylcysteinylglycine, glutathione, has several important functions. It is a reductant, is conjugated with drugs to make them more water soluble (p. 431), is involved in transport of amino acids across cell membranes, is part of some leukotriene structures (p. 743), is a cofactor for some enzymatic reactions, and participates in the rearrangement of protein disulfide bonds. Glutathione as reductant is very important in maintaining stability of erythrocyte membranes. Its sulfhydryl group can be used to reduce peroxides formed during oxygen transport (p. 583). The resulting oxidized form consists of two molecules of GSH joined by a disulfide bond. This is reduced by glutathione reductase to two molecules of GSH at the expense of NADPH (Figure 19.75). The usual steady-state

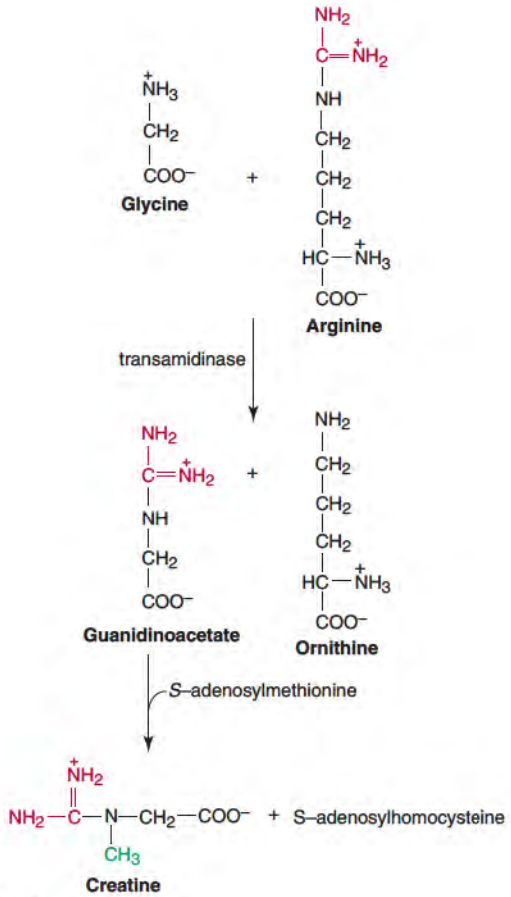

Figure 19.73 Synthesis of creatine.

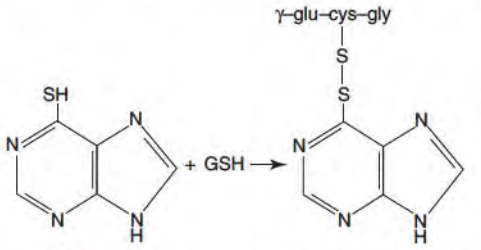

Figure 19.76 **Conjugation of a drug by glutathione transferase.**

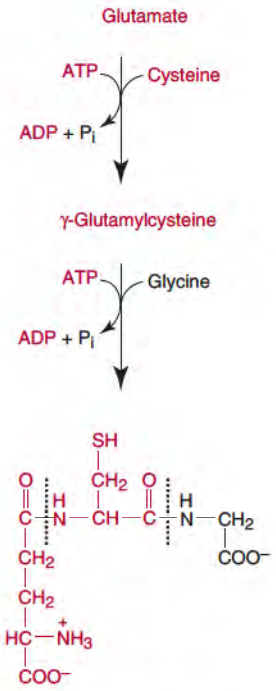

Glutathione
(γ-glutamylcysteinylglycine)

Figure 19.77 **Synthesis of glutathione.**

ratio of GSH to GSSG in erythrocytes is 100:1. Conjugation of drugs such as 6-thiopurine with glutathione renders them more polar for excretion (Figure 19.76).

Glutathione is synthesized by formation of the dipeptide γ-glutamylcysteine and the subsequent addition of glycine. Both reactions require activation of carboxyl groups by ATP (Figure 19.77). Synthesis of glutathione is largely regulated by cysteine availability.

The γ-Glutamyl Cycle Transports Amino Acids

There are several mechanisms for transport of amino acids across cell membranes. Many are symport or antiport mechanisms (p. 486) coupled to sodium transport. The γ-glutamyl cycle for transmembrane transport of amino acids functions in kidneys and some other tissues but is of particular importance in renal epithelial cells. It is more energy-requiring than other mechanisms, but is rapid and has high capacity. The cycle involves several enzymes. The γ-glutamyl transpeptidase, located in the plasma membrane, adds glutamate from GSH to an extracellular amino acid. The resulting γ-glutamyl amino acid is transported into the cell by an amino acid transporter, where the γ-glutamyl amino acid is hydrolyzed to liberate the amino acid (Figure 19.78) and 5-oxoproline. Cysteinylglycine formed in the transpeptidase reaction is cleaved to its component amino acids. To regenerate GSH, glutamate is reformed from oxoproline in an ATP-requiring reaction, and GSH is resynthesized from its three component parts. Three ATPs are used in the regeneration of glutathione, one in formation of glutamate from oxoproline and two in formation of the peptide bonds.

Glutathione Concentration Affects Response to Toxins

When the body encounters toxic conditions such as peroxide formation, ionizing radiation, alkylating agents, or other reactive intermediates, it is beneficial to increase the level of GSH. Cysteine and methionine have been administered as GSH precursors, but they have the disadvantage of being precursors of an energy-expensive pathway to GSH. A more promising approach is administration of a soluble diester of GSH, such as γ-(α-ethyl) glutamylcysteinylethylglycinate. Very premature infants have a very low concentration of cysteine because of low cystathionase activity in liver. This keeps the GSH concentration low and makes them more susceptible to oxidative damage, especially from hydroperoxides formed in the eye after hyperbaric oxygen treatment. Under certain circumstances, such as rendering tumor cells more sensitive to radiation or parasites more sensitive to drugs, it is desirable to lower GSH levels. This can be achieved by administration of the glutamate analog buthionine sulfoximine (Figure 19.79) as a competitive inhibitor of GSH synthesis.

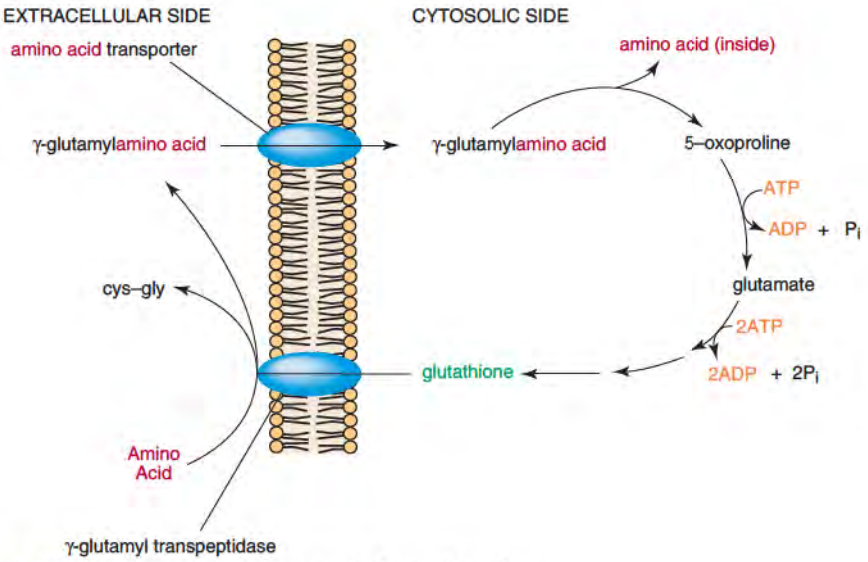

Figure 19.78 **γ-Glutamyl cycle for transporting amino acids.**

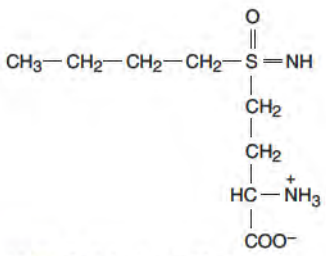

Figure 19.79 **Buthionine sulfoximine.**

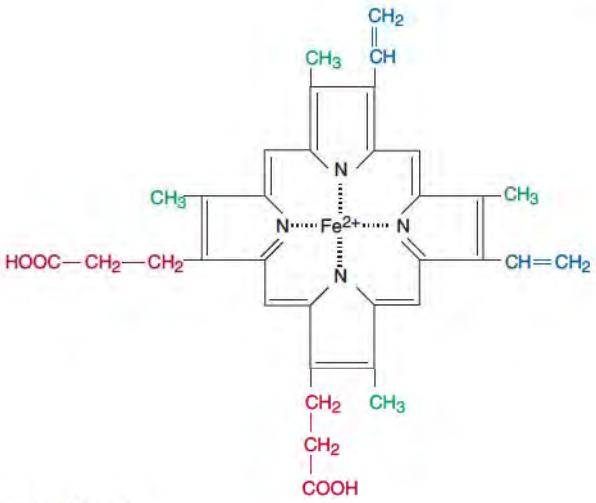

Figure 19.80 **Structure of heme.**

19.7 • HEME BIOSYNTHESIS

Heme is produced in virtually all mammalian tissues. Synthesis is most pronounced in the bone marrow and liver because of the requirements for incorporation into hemoglobin and the cytochromes, respectively. As depicted in Figure 19.80, heme is a largely planar molecule. Heme is one of the most stable of compounds, reflecting its strong resonance features.

Figure 19.81 depicts the pathway for heme biosynthesis. Porphyrinogens are unstable and can be readily oxidized, especially in the presence of light, by nonenzymatic means to their stable porphyrin products. In the latter cases, resonance between pyrrole groups is established by oxidation of the four methylene bridges. Figure 19.82, p. 793, depicts the enzymatic conversion of protoporphyrinogen to protoporphyrin by this oxidation mechanism. This is the only enzyme-catalyzed oxidation of a porphyrinogen in humans; all other porphyrinogen–porphyrin conversions are nonenzymatic and catalyzed by light.

Enzymes Involved in Heme Biosynthesis

δ-Aminolevulinic Acid Synthase: δ-Aminolevulinic acid (ALA) synthase controls the rate-limiting step of heme synthesis in all tissues studied. The synthesis of the enzyme occurs in the cytosol, being directed by mRNA derived from the nucleus. The enzyme is transferred into the matrix of the mitochondrion, where it interacts with succinyl CoA, an intermediate of the tricarboxylic acid cycle. In the cytosol, each subunit is in the unfolded state, the only form that can pass into mitochondria directed by a basic N-terminal signaling sequence. An ATP-dependent cytosolic molecule, known as a chaperone protein, maintains it in the unfolded extended state. Thereafter, the N-terminal sequence is cleaved by a metal-dependent protease in the mitochondrial matrix, to yield an ALA synthase subunit of 65 kDa. Within the matrix another oligomeric chaperon protein catalyzes the correct folding in a second ATP-dependent pro-cess (Figure 19.83, p. 793). The ALA synthase has a short biological half-life (~60 min). Both the synthesis and the activity of the enzyme are subject to regulation by a variety of substances; 50% inhibition of activity occurs in the presence of 5 mM hemin, and virtually complete inhibition at a 20 mM concentration. The enzymatic reaction involves the condensation of glycine with succinyl CoA to produce δ-aminolevulinic acid. The reaction has an absolute requirement for pyridoxal phosphate. Two isoenzymes exist for ALA synthase; only the mRNA of the erythrocytic form contains an iron response element (IRE). Mutations in the erythrocytic form give rise to sideroblastic anemia, where excess iron is found in the mitochondria of developing red blood cells, but heme synthesis is defective. The condition can be X linked or acquired.

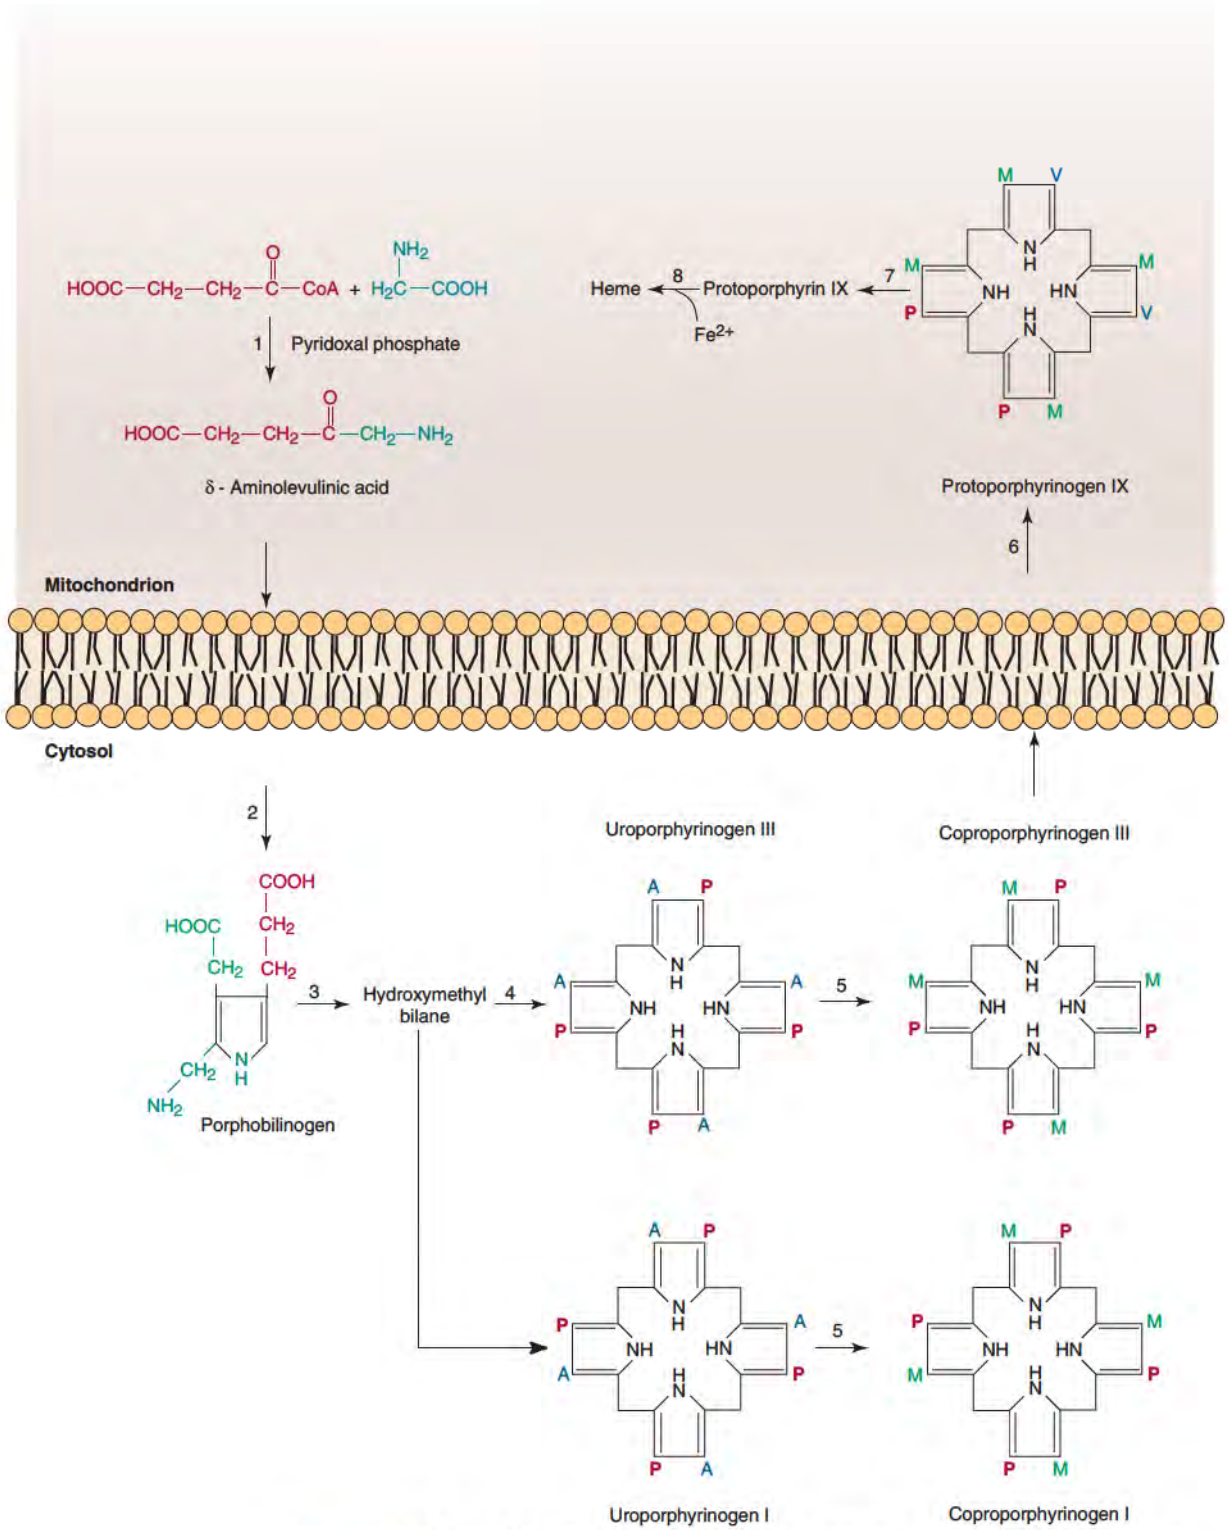

Figure 19.81 Pathway for heme biosynthesis. Numbers indicate enzymes involved in each step as follows: 1. ALA synthase, 2. ALA dehydratase (porphobilinogen synthase), 3. porphobilinogen deaminase (hydroxymethylbilane synthase), 4. uroporphyrinogen III synthase, 5. uroporphyrinogen decarboxylase, 6. coproporphyrinogen III oxidase, 7. protoporphyrinogen IX oxidase, and 8. ferrochelatase. Pyrrole ligands are indicated as follows: P = propionic, A = acetic, M = methyl, and V = vinyl.

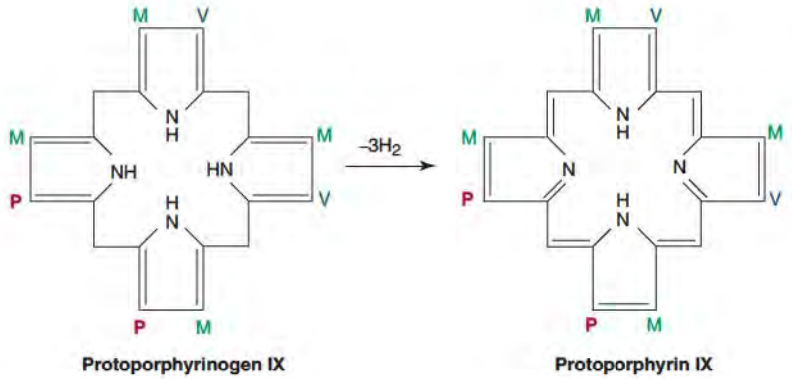

Figure 19.82 **Action of protoporphyrinogen IX oxidase, an example of the conversion of a porphyrinogen to a porphyrin.**

Aminolevulinic Acid Dehydratase: The second enzyme in the pathway, aminolevulinic acid dehydratase (porphobilinogen synthase), is cytosolic and consists of eight subunits, of which only four interact with the substrate. This protein interacts with the substrate to form a Schiff base, but in this case the ε-amino group of a lysine residue binds to the carbonyl carbon of the substrate molecule (Figure 19.84). Two molecules of ALA condense asymmetrically to form porphobilinogen, a five member heterocyclic ring structure with three side chains, two of which are acetic acid and propionic acid. The ALA dehydratase is a zinc-containing enzyme and is very sensitive to inhibition by heavy metals, particularly lead. A characteristic of **lead poisoning** is the elevation of ALA in the absence of an elevation of porphobilinogen.

Porphobilinogen Deaminase and Uroporphyrinogen III Synthase: The synthesis of the porphyrin ring is a complicated process. A sulfhydryl group on porphobilinogen deaminase (hydroxymethylbilane synthase) (Clin. Corr. 19.23) forms a thioether bond with a porphobilinogen residue through a deamination reaction. Thereafter, five additional porphobilinogen residues are deaminated successively to form a linear hexapyrrole adduct with the enzyme. The adduct is cleaved hydrolytically to form both an enzyme–dipyrrolomethane complex and the linear tetrapyrrole, hydroxymethylbilane. The enzyme–dipyrrolomethane complex is then ready for another cycle to generate another tetrapyrrole. Thus, dipyrrolomethane is the covalently attached cofactor for the enzyme. Porphobilinogen deaminase has no ring-closing function; hydroxymethylbilane closes spontaneously in an enzyme-independent step to form uroporphyrinogen I, a structure consisting of four linked pyrrole rings, if no additional factors are present. However, the deaminase is closely associated with a second protein, **uroporphyrinogen III synthase**, which directs the synthesis of the III isomer. The formation of the latter involves an intermediate where the rings are linked by only one atom (a spiro structure) generated from hydroxymethylbilane; this allows the inversion of one of the pyrrole groups (Figure 19.85, p. 795). In the absence of the uroporphyrinogen III synthase, uroporphyrinogen I is synthesized slowly; in its presence, the III isomer is synthesized rapidly. The uroporphyrinogens have two different substituents for each pyrrole group. Going clockwise around the ring, the substituents can be arranged as ABABABAB (where A and B are different substituents), forming a type I porphyrinogen, or the arrangement can be ABABABBA, forming a type III porphyrinogen. In principle, two other arrangements can occur to form porphyrinogens II and IV, and these can be synthesized chemically; however, they do not occur naturally. Later in the heme synthetic pathway are **protoporphyrinogen** and **protoporphyrin** with three types of substituents, and the classification becomes more complicated; type IX is the only form that is synthesized naturally. A rare recessively inherited disease, erythropoietic porphyria, associated with marked cutaneous light sensitization, is due to an abnormality of reticulocyte uroporphyrinogen III synthase. Here large amounts of the type I isomers of uroporphyrinogen and coproporphyrinogen are synthesized in the bone marrow.

Uroporphyrinogen Decarboxylase: The reactions occurring on the side groups attached to the tetrapyrrole ring involve the colorless intermediates known as **porphyrinogens**. Though exhibiting resonance features within each pyrrole ring, these do not demonstrate resonance between the pyrrole groups. Hence, the porphyrinogens are

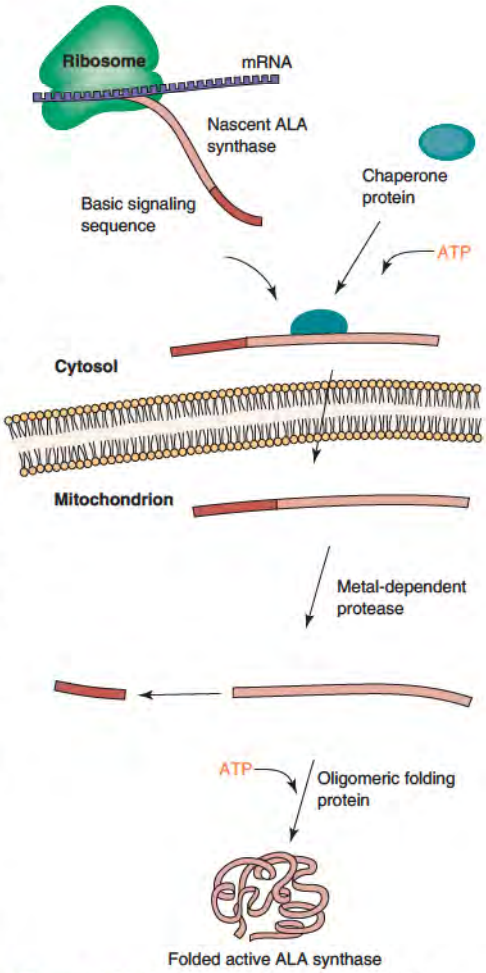

Figure 19.83 **Synthesis of δ-aminolevulinic acid (ALA) synthase.**

CLINICAL CORRELATION 19.23

Acute Intermittent Porphyria

Acute intermittent porphyria (AIP) (OMIM 176000) is caused by mutation in the gene encoding hydroxymethylbilane synthase (HMBS), also referred to as porphobilinogen deaminase (PBGD). First attacks usually occur after puberty and are frequently precipitated by drugs such as barbiturates, by alcohol, and by infection. This is due to induction of hepatic 5-aminolevulinate synthase. Women are more prone to AIP. AIP is characterized by increased urinary excretion of the HMBS precursors, delta-aminolevulinic acid (ALA) and porphobilinogen (PBG). It is inherited as an autosomal dominant trait, so even heterozygotes may exhibit symptoms. Only about 10% to 20% of AIP gene carriers become symptomatic during their lifetime. Prevention consists of notification of family members so that they may avoid the precipitating factors.

Symptoms include marked weakness in the arms and legs, a slightly rapid heart rate, and moderate hypertension. There may have been have been earlier episodes of severe abdominal pain without a diagnosis. High levels of porphobilinogen are often noted in urine.

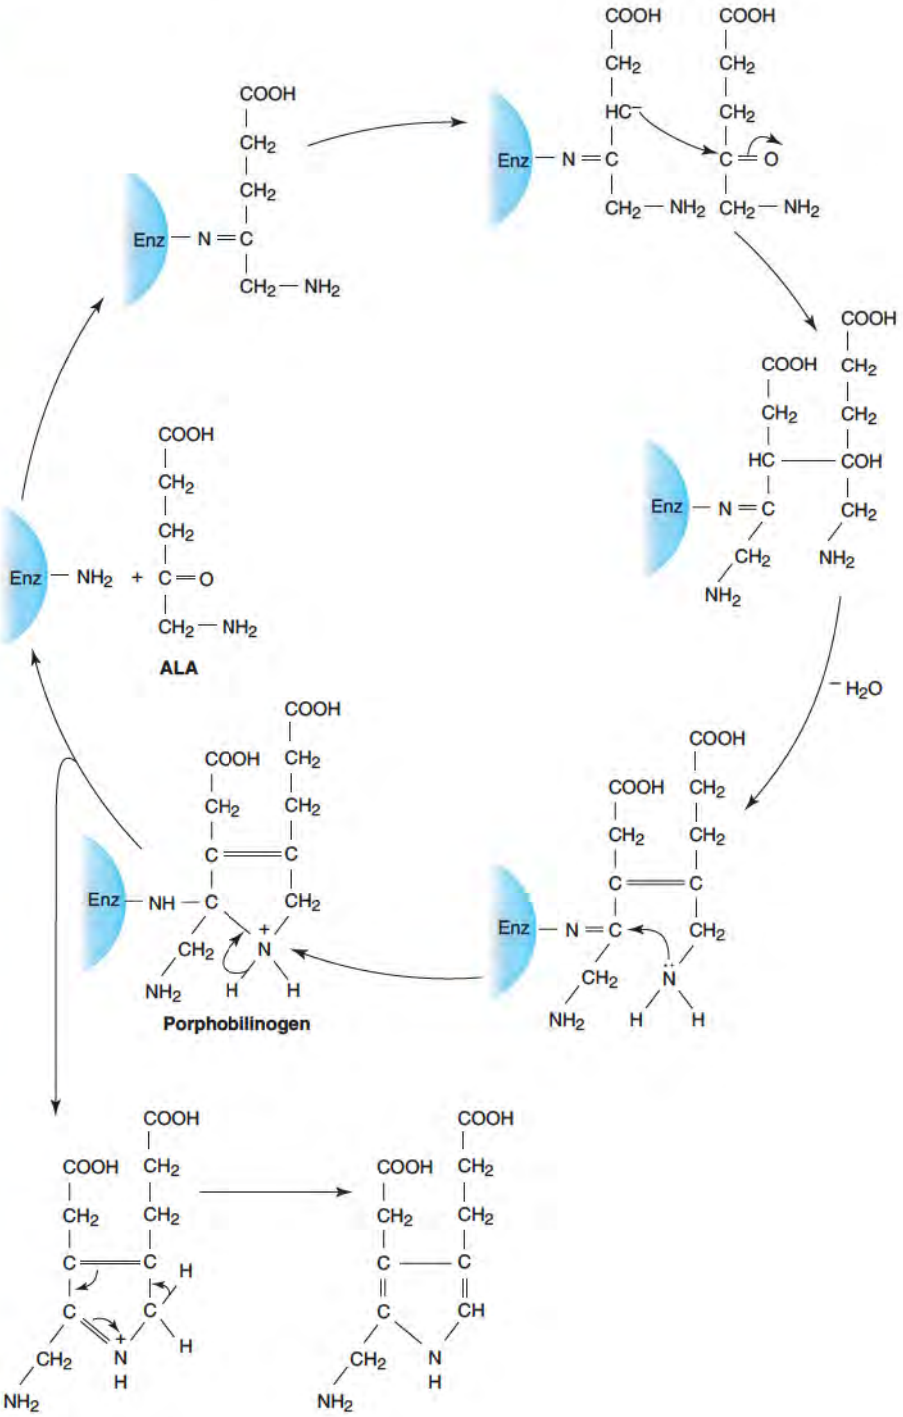

Figure 19.84 **Synthesis of porphobilinogen.**

unstable and can be readily oxidized, especially in the presence of light, by nonenzymatic means to their stable **porphyrin** products. In the latter cases, resonance between pyrrole groups is established by oxidation of the four methylene bridges. Figure 19.82 (p. 793) depicts the enzymatic conversion of protoporphyrinogen to protoporphyrin by this oxidation mechanism. This is the only enzyme-catalyzed oxidation of a porphyrinogen in humans; all other porphyrinogen–porphyrin conversions are nonenzymatic and catalyzed by light.

Uroporphyrinogen decarboxylase acts on the side chains of uroporphyrinogens to form coproporphyrinogens, where acetic acid groups have been decarboxylated to leave methyl groups. The protein catalyzes the conversion of both I and III isomers of

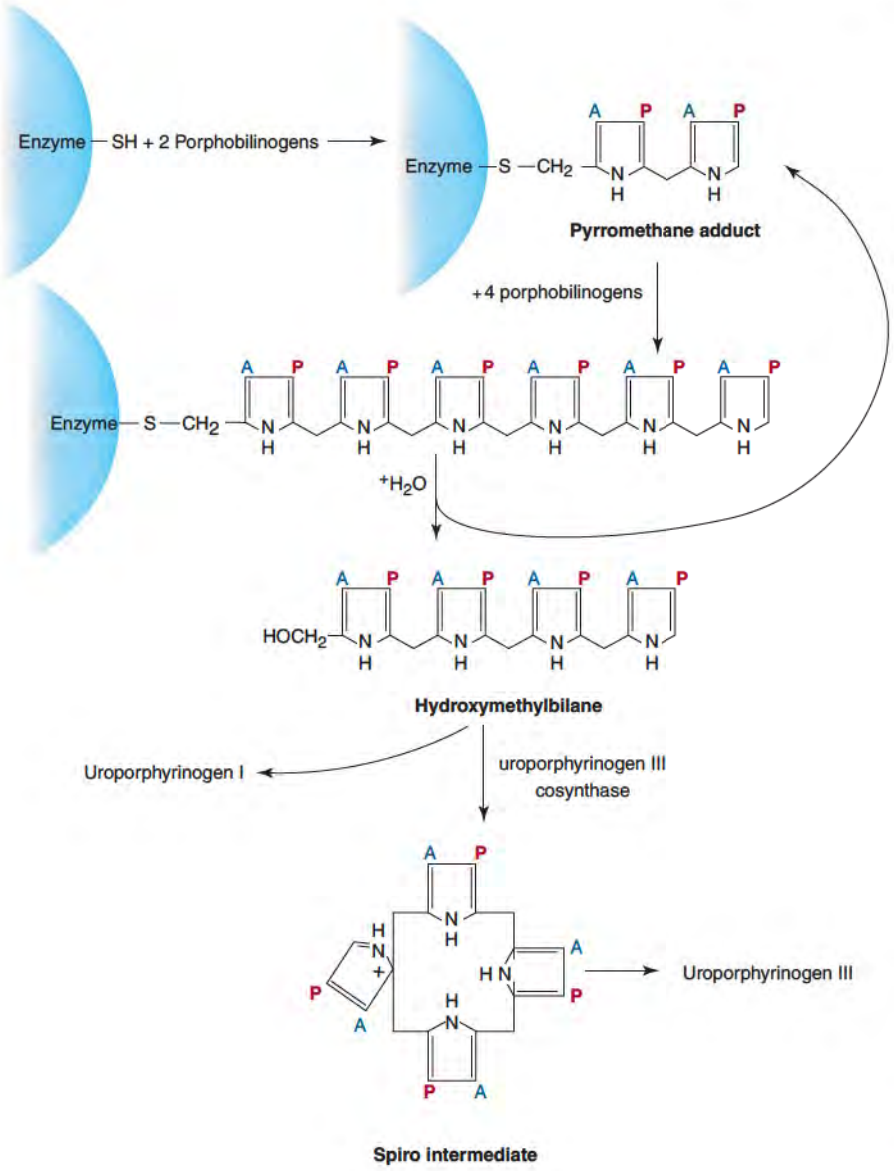

Figure 19.85 Synthesis of uroporphyrinogens I and III. Enzyme in blue is uroporphyrinogen I synthase.

uroporphyrinogen to the respective coproporphyrinogen isomers. Uroporphyrinogen decarboxylase is inhibited by iron salts. Clinically the most common cause of porphyrin derangement is associated with patients who have a single gene abnormality for uroporphyrinogen decarboxylase, leading to 50% depression of the enzyme's activity. This disease, which shows cutaneous manifestations primarily with sensitivity to light, is known as **porphyria cutanea tarda**. The condition is not expressed unless patients either take drugs that cause an increase in porphyrin synthesis or drink large amounts of alcohol. Alcohol-induced cirrhosis leads to the accumulation of iron, which then acts to inhibit further the activity of uroporphyrinogen decarboxylase. The treatment for this condition is phlebotomy.

Coproporphyrinogen Oxidase: Coproporphyrinogen oxidase, a mitochondrial enzyme, is specific for type III coproporphyrinogen. It does not act on the type I isomer. Coproporphyrinogen III enters mitochondria and it is converted to protoporphyrinogen IX. A dominant hereditary disease associated with a deficiency of this enzyme leads to a form of hereditary hepatic porphyria, known as **hereditary coproporphyria**.

Protoporphyrinogen Oxidase: Another mitochondrial enzyme, protoporphyrinogen oxidase, oxidizes the methylene bridges and generates protoporphyrin IX, which, in contrast to the other heme precursors, is very water insoluble. Excess amounts of

protoporphyrin IX that are not converted to heme are excreted by the biliary system into the intestinal tract. An autosomal dominant disease, **variegate porphyria**, is due to a deficiency of protoporphyrinogen oxidase.

Ferrochelatase: The last enzyme of the pathway is ferrochelatase, which inserts ferrous iron into protoporphyrin IX. Ascorbic acid and cysteine are required as reductants for its activity. The protein is sensitive to the effects of heavy metals, especially lead and, of course, to iron deprivation. In these latter instances, zinc instead of iron is incorporated to form a zinc–protoporphyrin IX complex. In contrast to heme, the zinc–protoporphyrin IX complex is brilliantly fluorescent and easily detectable in small amounts. Prokaryotic ferrochelatase does not contain a prosthetic group, whereas the mammalian enzyme contains a Fe_2S_2 group.

ALA Synthase Catalyzes Rate-Limiting Step of Heme Biosynthesis

ALA synthase controls the rate-limiting step of heme synthesis in all tissues. Succinyl CoA and glycine are substrates for a variety of reactions. The modulation of the activity of ALA synthase determines the quantity of the substrates that will be shunted into heme biosynthesis. Heme and hematin, a derivative of oxidized heme, act both as a repressor of the synthesis of ALA synthase and as an inhibitor of its activity. Since heme resembles neither the substrates nor the product of the enzyme's action, it is probable that it acts at an allosteric site. Almost 100 different drugs and metabolites can cause induction of ALA synthase, some as much as 40-fold. The effect of pharmacological agents has led to the important clinical

TABLE 19.2 • Derangements in Porphyrin Metabolism

Enzyme	*Substrate*	*Prevalence*	*Indicators and Symptoms*	*OMIM**	*Porphyria*
ALA synthase	Glycine, Succinyl CoA			125290	Contributes to porphyrias by induction
ALA dehydratase (porphobilinogen synthase)	D-Amino-levulinic acid	Rare	Mild to severe neuropathy; intermittent fever, hypertension	125270	Ala-dehydratase deficiency
PBG deaminase (hydroxymethylbilane synthase)	Porphobilinogen	Among most prevalent	Mild to severe neuropathy; intermittent fever, hypertension and gastric problems	176000	Acute intermittent porphyria
Uroporphyrinogen III synthase	Hydroxymethyl-bilane	Very rare	Very severe; mutilating; evidence in infancy Pink, red, or violet urine staining diapers	606938	Congenital or hereditary erythropoietic porphyria
Uroporphyrinogen III decarboxylase	Uroporphyrinogen III	Among most prevalent	Mild to severe dermapathy; siderosis; liver	176100	Porphyria cutanea tarda
Coproporphyrinogen III oxidase	Coproporphyrinogen III	Among most prevalent	Intermittent fever; hypertension; liver	121300	Coproporphyria
Protoporphyrinogen oxidase	Protoporphyrinogen IX	Among most prevalent	Intermittent fever; hypertension; skin and neurological involvement	176200	Variegate porphyria
Ferrochelatase	Protoporphyrin IX	Quite rare	Mild to severe dermopathy; intermittent fever; hypertension; liver damage; gallstones	177000	Erythropoietic protoporphyria
No particular enzyme		Among most prevalent	Dermatopathy in some cases but not in others; usually neuropathy; variable intermittent fever; hypertension		Intoxication porphyria
Ferrochelatase; ALA dehydratase		Frequent but declining	All tissues		Lead poisoning

*OMIM: Online Mendelian Inheritance in Man. http://www.ncbi.nlm.nih.gov/Omim/Entry#/.

feature where some patients with certain kinds of porphyria have had exacerbations of their condition following the inappropriate administration of certain drugs (e.g., barbiturates). ALA dehydratase is also inhibited by heme; but this is of little physiological consequence, since the activity of ALA dehydratase is about 80-fold greater than that of ALA synthase, and thus heme-inhibitory effects are reflected first in the activity of ALA synthase.

Glucose or one of its proximal metabolites inhibits heme biosynthesis by a mechanism involving inactivation of transcription factors. This is of clinical relevance, since some patients manifest their porphyric state for the first time when placed on a very low caloric (and therefore glucose) intake. Other regulators of porphyrin metabolism include certain steroids. Steroid hormones (e.g., oral contraceptive pills) with a double bond in ring A between C4 and C5 atoms can be reduced by two different reductases. The product of 5α-reduction has little effect on heme biosynthesis; however, the product of 5β-reduction serves as a stimulus for the synthesis of ALA synthase.

Porphyrias

Porphyrias are a family of diseases of great interest because they have revealed that the regulation of heme biosynthesis is complicated. The clinical presentations of the different porphyrias provide a fascinating exposition of biochemical regulatory abnormalities and their relationship to pathophysiological processes. Table 19.2 lists some characteristics of the different porphyrias.

19.8 • HEME CATABOLISM

Catabolism of heme-containing proteins presents two requirements to the mammalian host: (1) a means of processing the hydrophobic products of porphyrin ring cleavage and (2) retention and mobilization of the iron atom so that it may be reutilized. Red blood cells have a life span of approximately 120 days. Senescent cells are recognized by changes in their membranes and engulfed by the reticuloendothelial system at extravascular sites. The globin chains denature, releasing heme into the cytoplasm. The globin is degraded to its constituent amino acids, which are reutilized for general metabolic needs.

Figure 19.86 depicts the events of heme catabolism. Heme is degraded primarily by an endoplasmic reticulum enzyme system in reticuloendothelial cells that requires molecular oxygen and NADPH. **Heme oxygenase** has two isomers; type I is substrate inducible and type II is constitutive. The enzyme catalyzes cleavage of the α-methene bridge, which joins the two pyrrole residues that contain vinyl substituents. The α-methene carbon is converted quantitatively to carbon monoxide. This is the only endogenous source of **carbon monoxide** in humans. Most of the carbon monoxide is released via the respiratory tract, and measurement of CO in respired air is a good measure of heme destruction. The oxygen present in the carbon monoxide and in the newly derivatized lactam rings of biliverdin come directly from molecular oxygen. The stoichiometry of the reaction requires 3 mol of oxygen for each ring cleavage. Heme oxygenase will only use heme as a substrate, with the iron possibly participating in the cleavage mechanism. Thus free protoporphyrin IX is not a substrate. The linear tetrapyrrole **biliverdin IX** is formed by heme oxygenase. Biliverdin IX is reduced by **biliverdin reductase** to bilirubin IX. The products of heme oxygenase action are found to be cytoprotective (Clin. Corr. 19.24).

Bilirubin Is Conjugated to Form Bilirubin Diglucuronide in Liver

Bilirubin is derived from senescent red cells but also from turnover of other heme-containing proteins, such as the cytochromes. Studies with labeled glycine as a precursor have revealed that an early-labeled bilirubin, with a peak within 1–3 h, appears very quickly after a pulsed administration of the labeled precursor. A larger amount of bilirubin appears much later at about 120 days, reflecting the turnover of heme in red blood cells. Early-labeled bilirubin can be divided into two parts: an early-early part, which reflects turnover of heme proteins, such as the cytochromes, in the liver, and a late-early part, which is a result

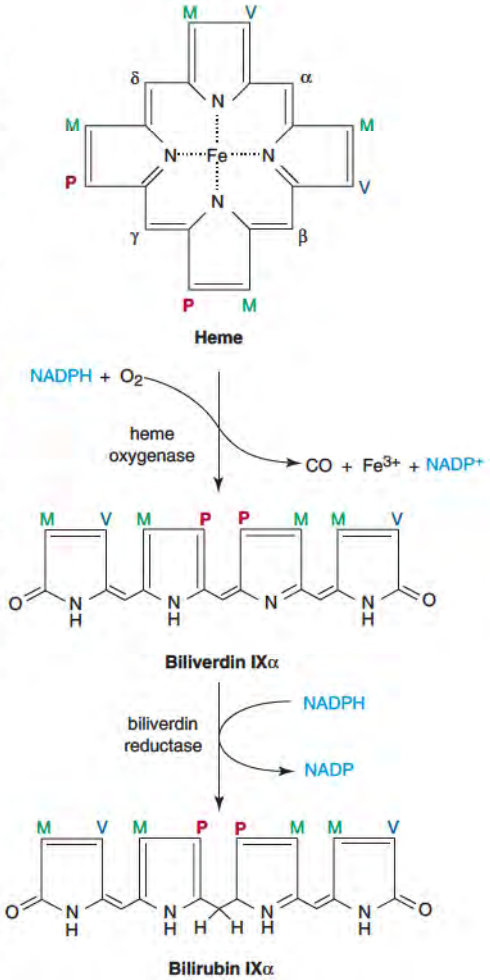

Figure 19.86 Formation of bilirubin from heme Greek letters indicate labeling of methene carbon atoms in heme.

CLINICAL CORRELATION 19.24

Cytoprotective Role of Heme Oxygenase

Carbon monoxide (CO) and biliverdin are not merely passive products of heme oxygenase action. Biliverdin is an antioxidant and as such performs a significant role when heme oxygenase is induced by stress. CO, like nitric oxide (NO) which it structurally resembles, acts on smooth muscle, and thus as a vasodilator has been shown to have a protective effect, for instance in stroke victims. Like NO, CO acts apparently through cyclic GMP. The interaction with NO is complex; at times CO is complementary to and at other settings antagonistic to NO. Simplistically, CO appears generally to function protectively whereas NO, depending on the circumstance, can either be protective or cause cell damage. Bilirubin has been shown to inhibit the expression of inducible NO-synthase.

CLINICAL CORRELATION 19.25

Neonatal Isoimmune Hemolysis (OMIM 111689)

Rh-negative women pregnant with Rh-positive fetuses develop antibodies to Rh factors. These antibodies cross the placenta to hemolyze fetal red blood cells. Usually this is not of clinical relevance until about the third Rh-positive pregnancy, in which the mother has had antigenic challenges from earlier babies. Antenatal studies reveal rising maternal levels of IgG antibodies against Rh-positive red blood cells, indicating that the fetus is Rh-positive. DNA testing can be used to determine RhD (Rhesus blood group, D antigen) type in chorionic villus samples or amniotic cells. A safer method for diagnosis of RhD status has recently been developed. PCR technology can be used to amplify DNA from fetal cells in the mother's bloodstream, obviating the need for more invasive procedures. Damage from Rhesus is initiated at birth. Placental transfer of fetal bilirubin occurs with excretion through the maternal liver. Because hepatic enzymes of bilirubin metabolism are poorly expressed in the newborn, infants may not be able to excrete the large amounts of bilirubin that can be generated from red cell breakdown. At birth these infants usually appear normal; however, the unconjugated bilirubin in the umbilical cord blood is elevated up to 4 mg/dL, due to the hemolysis initiated by maternal antibodies. During the next 2 days the serum bilirubin rises, reflecting continuing isoimmune hemolysis, leading to jaundice, hepatosplenomegaly, ascites, and edema. If untreated, signs of central nervous system damage can occur, with the appearance of lethargy, hypotonia, spasticity, and respiratory difficulty, constituting the syndrome of kernicterus.

Treatment involves exchange transfusion with whole blood, which is serologically compatible with both the infant's blood and the maternal serum. This is necessary to prevent hemolysis of the transfused cells. Additional treatment includes external phototherapy, which facilitates the breakdown of bilirubin. The problem can be prevented by treating Rh-negative mothers with anti-Rh globulin. These antibodies recognize the fetal red cells, block the Rh antigens, and cause them to be destroyed without stimulating an immune response in the mothers.

M., Fidler, C., Sargent, I. L., et al. Prenatal diagnosis of fetal RhD status by molecular analysis of maternal plasma. *N. Engl. J. Med.* 339:1734, 1998.

of incomplete erythropoesis. The latter is a measurement of ineffective erythropoiesis and can be very pronounced in disease states such as pernicious anemia and the thalassemias. Bilirubin is produced in cells of the reticulo–endothelial system, including phagocytes, the Kupffer cells of the liver, and cells in the spleen and bone marrow (Clin. Corr. 19.25). Bilirubin is poorly soluble in aqueous solutions at physiological pH values. When transported in plasma, it is bound to serum albumin with an association constant greater than 10^6. Albumin contains one high-affinity site and another with a lesser affinity. However, bilirubin toxicity **(kernicterus)**, which is manifested by the transfer of bilirubin to membrane lipids, suggests that the weak affinity of the second site does not allow it to serve effectively in the transport of bilirubin. Bilirubin is released from albumin and taken up by liver cells using a transporter mechanism. Once in the cell, bilirubin is bound to two major proteins, cytosolic Y protein (glutathione S-transferase B, also called ligandin) and cytosolic Z protein (also known as fatty-acid-binding protein [FABP]). The binding of bilirubin to these proteins prevents the return flow out of the cell. Ligandin has been purified and

CLINICAL CORRELATION 19.26

Bilirubin UDP-Glucuronosyltransferase Deficiency

Three forms of mutations can lead to bilirubin UDP-glucuronosyltransferase deficiency (OMIM 191740). All three are in the UGT1A1 gene (UDP-glucuronosyltransferase 1A1), and all three have different outcomes. The mutation that leads to Crigler–Najjar type I deficiency produces a situation where very low levels of bilirubin diglucuronides are found in blood, and, unlike the other types, type I does not respond to phenobarbital therapy. Crigler–Najjar syndrome type II that results in high levels of free bilirubin and the third type of transferase deficiency, Gilbert syndrome (intermediate amounts of bilirubin), are both responsive to phenobarbital therapy. Over 40 separate mutations have been described, and the levels of bilirubin in blood vary from patient to patient. In some cases very little free bilirubin is found, and this is due to a low rate of bilirubin production. The effectiveness of phenobarbital treatment is based on the ability of this drug to induce synthesis of UDP-glucuronosyltransferase.

Chowdhury, J. R., Bakker, C., et al. The genetic basis of the reduced expression of bilirubin UDP-glucuronosyltransferase 1 in Gilbert syndrome. *N. Engl. J. Med.* 333:1171, 1995; Burchell, B, and Hume, R. Molecular genetic basis of Gilbert syndrome. *J. Gastroenterol. Hepatol.*14:960, 1999; Gantla, S., Bakker, C. T. M., Deocharan, B., Thummala, N. R., et al. Splice-site mutations: A novel genetic mechanism of Crigler–Najjar syndrome type 1. *Am. J. Hum. Genet.* 62:585, 1998; and Gong, Q.-H., Cho, J. W., Huang, T., Potter, C., et al. Thirteen UDP-glucuronosyltransferase genes are encoded at the human UGT1 gene complex locus. *Pharmacogenetics* 11:357, 2001.

characterized as having two subunits (22 kDa and 27 kDa). The stoichiometry of binding is one bilirubin molecule per complete ligandin molecule.

Once in the hepatocyte the propionyl side chains of bilirubin are conjugated to form a diglucuronide (Clin. Corr. 19.26 and Figure 19.87). The reaction utilizes uridine diphosphoglucuronate derived from the oxidation of uridine diphosphoglucose. In normal bile the diglucuronide is the major form of excreted bilirubin, with only small amounts of the monoglucuronide or other glycosidic adducts. **Bilirubin diglucuronide** is much more water soluble than free bilirubin, and thus the action of the transferase facilitates the excretion of the bilirubin into bile. Bilirubin diglucuronide is poorly absorbed by the intestinal mucosa. The glucuronide residues are released in the terminal ileum and large intestine by bacterial hydrolases; the released bilirubin is reduced to the colorless linear tetrapyrroles

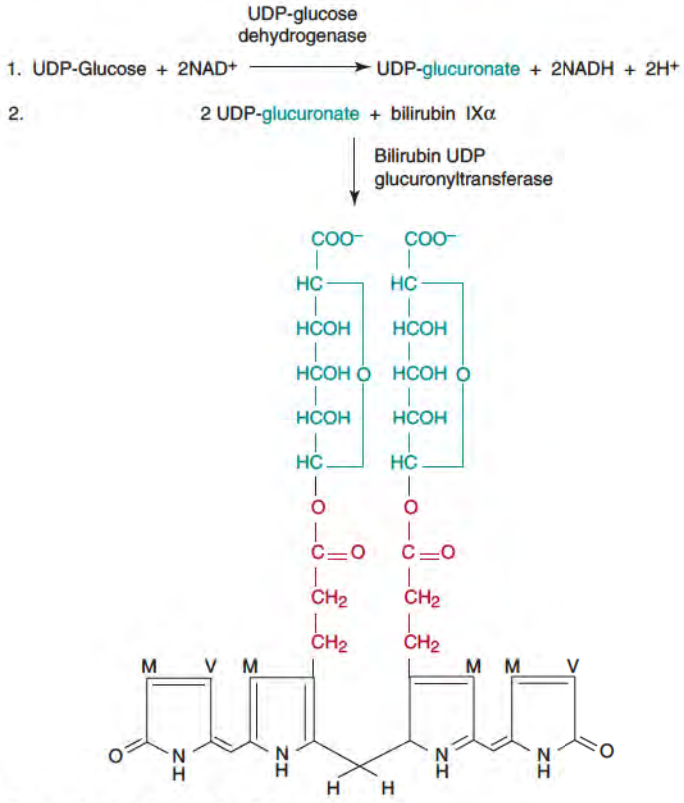

Figure 19.87 **Biosynthesis of bilirubin diglucuronide.**

A CLOSER LOOK 19.7

Urochrome

Urochrome was the original name given to the pigment thought to give urine its color. It is now known that several related pigments are responsible, so the original name has been dropped. Urine is yellow because of **urobilins**, specifically D-urobilin, L-urobilin, L-stercobilin, and possibly others. Urobilins are composed of four modified pyrrole rings connected by methylene bridges.

known as **urobilinogens**, which become oxidized to colored products known as **urobilins**, which are excreted in the feces. A small fraction of urobilinogen is reabsorbed by the terminal ileum and large intestine to be removed by hepatic cells and resecreted in bile. When urobilinogen is reabsorbed in large amounts in certain disease states, the kidney serves as a major excretory site (A Closer Look 19.7).

Plasma bilirubin concentrations are 0.3–1 mg/dL in the normal state, and this is almost all in the unconjugated state (Clin. Corr. 19.27). Conjugated bilirubin is expressed as **direct bilirubin** because it can be coupled readily with diazonium salts to yield azo dyes in the direct **van den Bergh reaction**. Unconjugated bilirubin is bound noncovalently to albumin, and it does not react until released by the addition of an organic solvent such as ethanol. This is the indirect van den Bergh reaction, and this measures the **indirect bilirubin** or the unconjugated bilirubin. Unconjugated bilirubin binds so tightly to serum albumin and lipid that it does not diffuse freely in plasma and therefore does not appear in urine. It has a high affinity for membrane lipids, which leads to the impairment of cell membrane function, especially in the nervous system. In contrast, conjugated bilirubin is relatively water soluble, and elevations of conjugated bilirubin lead to high urinary concentrations with the characteristic deep yellow-brown color. The deposition of conjugated and unconjugated bilirubin in skin and the sclera gives the yellow to yellow-green color seen in patients with jaundice.

A third form of plasma bilirubin occurs only with hepatocellular disease in which a fraction of the bilirubin binds so tightly that it is not released from serum albumin by the usual techniques and is thought to be linked covalently to the protein. In some cases, up to 90% of total bilirubin can be in this covalently bound form.

The normal liver has a very large capacity to conjugate and excrete the bilirubin that is delivered. Therefore, hyperbilirubinemia due to excess heme destruction (see Clin. Corr. 19.25), as in hemolytic diseases, rarely leads to bilirubin levels that exceed 5 mg/dL, except in situations in which functional derangement of the liver is present (see Clin. Corr.19.26). Thus, marked elevation of unconjugated bilirubin reflects primarily a variety of hepatic diseases, including those inherited and those acquired.

Increase in conjugated bilirubin in plasma is attributable to liver and/or biliary tract disease. In simple uncomplicated biliary tract obstruction, the major component is the

CLINICAL CORRELATION 19.27

Elevation of Serum-Conjugated Bilirubin

Elevations of serum conjugated bilirubin are attributable to liver and/or biliary tract disease. In simple uncomplicated biliary tract obstruction, the major component of the elevated serum bilirubin is the diglucuronide form, which is released by the liver into the vascular compartment. Biliary tract disease may be extrahepatic or intrahepatic, the latter involving the canaliculi and biliary ductules.

Hydrophobic compounds have an affinity for membranes and thus enter cells. To remove these compounds, ATP-dependent membrane channels pump them into the circulation where they can be bound by serum albumin and transferred to the liver. These pumps were initially described in the setting of cancer chemotherapy where the agents are commonly hydrophobic and used in high concentrations. One kind of resistance to therapy was found to be due to the increased activity of the pumps in tumor cells, reducing intracellular drug concentrations. Accordingly, these pumps have been called MRPs (multidrug resistance proteins) (OMIM 601107). At least six kinds are known. The property of hydrophobicity reduces the need of a specific pump for each compound since capture from a dilute aqueous medium is a minor issue, in contrast to hydrophilic compounds where channels have to be very specific. The MRPs serve also to transfer physiological hydrophobic compounds such as steroids from the adrenal gland and bilirubin from hepatocytes into bile. Dubin–Johnson syndrome is an autosomal recessive disease involving a defect in the biliary secretory mechanism of the liver. Excretion from the hepatocyte to the canaliculi relies upon MRP 2. In Dubin–Johnson syndrome mutations occur in this protein (known also as cMOAT, **c**analicular **m**ultispecific **o**rganic **a**nion **t**ransporter). Excretion through the biliary tract of a variety (but not all) of organic anions is affected. Retention of melanin-like pigment in the liver in this disorder leads to a characteristic gray-black color of this organ. A second heritable disorder associated with elevated levels of serum-conjugated bilirubin is Rotor syndrome. In this poorly defined disease no hepatic pigmentation occurs.

Iyanagi, E. Y., and Accoucheur, S. Biochemical and molecular disorders of bilirubin metabolism. *Biochim. Biophys. Acta* 1407:173, 1998; and Tsugi, H., Konig, J., Rost, D., et al. Exon–intron organization of the human multidrug-resistance protein 2 (MRP 2) gene mutated in Dubin–Johnson syndrome. *Gastroenterology* 117:653, 1999.

diglucuronide form, which is released by the liver into the vascular compartment. Biliary tract disease may be extrahepatic or intrahepatic, the latter involving the canaliculi and biliary ductules (see Clin. Corr. 19.27).

Intravascular Hemolysis Requires Scavenging of Iron

In certain diseases, destruction of red blood cells occurs in the intravascular compartment rather than in the extravascular reticuloendothelial cells. In the former case, the appearance of free hemoglobin and heme in plasma could lead potentially to their excretion through the kidney with substantial loss of iron. To prevent this, specific plasma proteins are involved in scavenging mechanisms. Transferrin binds free iron and thus permits its reutilization. Free hemoglobin, after oxygenation in the pulmonary capillaries, dissociates into α,β-dimers, which are bound to a family of circulating plasma proteins, the **haptoglobins**, which have a high affinity for the oxyhemoglobin dimer. Since deoxyhemoglobin does not dissociate into dimers in physiological settings, it is not bound by haptoglobin. Two α,β-oxyhemoglobin dimers are bound by a haptoglobin molecule.

Haptoglobins are α_2-globulins, synthesized in the liver. They consist of two pairs of polypeptide chains (α being the lighter and β the heavier). The α- and β-chains are derived from a single polypeptide that is cleaved to form the two different chains. The β-chains are glycopeptides of 39 kDa and are invariant in structure; α-chains are of several kinds. The haptoglobin chains are joined by disulfide bonds between the α- and β-chains and between the two α-chains.

The haptoglobin–hemoglobin complex is too large to be filtered through the renal glomerulus. Free hemoglobin (appearing in renal tubules and in urine) will occur during intravascular hemolysis only when the binding capacity of circulating haptoglobin has been exceeded. Haptoglobin delivers hemoglobin to the reticuloendothelial cells. The heme in free hemoglobin is relatively resistant to the action of heme oxygenase, whereas the heme residues in an α,β-dimer of hemoglobin bound to haptoglobin are very susceptible.

Measurement of serum haptoglobin is used clinically as an indication of the degree of intravascular hemolysis. Patients who have significant intravascular hemolysis have little or no plasma haptoglobin because of the removal of haptoglobin–hemoglobin complexes by the reticuloendothelial system. Haptoglobin levels can also be low in severe extravascular hemolysis, in which the large load of hemoglobin in the reticuloendothelial system leads to the transfer of free hemoglobin into plasma.

Free heme and hematin (with iron in the ferric state) appearing in plasma are bound by a β-globulin, **hemopexin** that binds one heme residue per molecule. Hemopexin transfers heme to liver, where further metabolism by heme oxygenase occurs. Normal plasma hemopexin contains very little bound heme, whereas in intravascular hemolysis, it is almost completely saturated by heme and is cleared with a half-life of about 7 h. In the latter excess heme binds to albumin, with newly synthesized hemopexin serving as a mediator for the transfer of the heme from albumin to the liver. Hemopexin also binds free protoporphyrin.

Key Terms

nitrogen balance
aminotransferases
glutamate alanine aminotransferase
glutamate aspartate aminotransferase
glutamate dehydrogenase
pyridoxal phosphate
amino acid oxidase
asparaginase
glutaminase
glutamine synthetase
urea cycle
arginase
citrulline
N-acetylglutamate
ornithine transcarbamoylase
carbamoyl phosphate synthetase I
glutamic semialdehyde
serine dehydratase
phenylalanine hydroxylase
tetrahydrobiopterin
homocysteine
S-adenosylmethionine
propionyl-CoA carboxylase
tryptophan dioxygenase
dihydroxyphenylalanine
dopamine
epinephrine
melanin
tyrosine hydroxylase
3′-phosphoadenosine-5′-phosphosulfate
carnitine
serotonin
histamine
polyamines
spermine
glutathione
heme
porphyrinogens
porphyrin
protoporphyrin
δ-aminolevulinic acid synthase
aminolevulinic acid dehydratase
porphobilinogen deaminase
uroporphyrinogen III synthase
ferrochelatase
biliverdin reductase
heme oxygenase
bilirubin diglucuronide
urobilins

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. Aminotransferases
- **A.** usually require α-ketoglutarate or glutamine as one of the reacting pair.
- **B.** catalyze reactions that result in a net use or production of amino acids.
- **C.** catalyze irreversible reactions.
- **D.** require pyridoxal phosphate as an essential cofactor for the reaction.
- **E.** are not able to catalyze transamination reactions with essential amino acids.

2. The production of ammonia in the reaction catalyzed by glutamate dehydrogenase
- **A.** requires the participation of NADH or NADPH.
- **B.** proceeds through a Schiff base intermediate.
- **C.** may be reversed to consume ammonia if it is present in excess.
- **D.** is favored by high levels of ATP or GTP.
- **E.** would be inhibited when gluconeogenesis is active.

3. *S*-Adenosylmethionine
- **A.** contains a charged sulfur that carries the methyl group to be transferred.
- **B.** yields α-ketobutyrate in the reaction in which the methyl is transferred.
- **C.** donates a methyl group in a freely reversible reaction.
- **D.** generates H_2S by transsulfuration.
- **E.** provides the carbons for the formation of cysteine.

4. Glutathione does all of the following except
- **A.** participate in the transport of amino acids across some cell membranes.
- **B.** scavenge peroxides.
- **C.** form conjugates with some drugs to increase water solubility.
- **D.** decreases the stability of erythrocyte membranes.
- **E.** acts as a cofactor for some enzymes.

5. Heme oxygenase
- **A.** can oxidize the methene bridge between any two pyrrole rings of heme.
- **B.** requires molecular oxygen.
- **C.** produces bilirubin.
- **D.** produces carbon dioxide.
- **E.** can use either heme or protoporphyrin IX as substrate.

6. Conjugated bilirubin is
- **A.** transported in blood bound to serum albumin.
- **B.** deficient in Crigler–Najjar syndrome, a deficiency of a UDP-glucuronosyltransferase.
- **C.** reduced in serum in biliary tract obstruction.
- **D.** the form of bilirubin most elevated in hepatic (liver) disease.
- **E.** less soluble in aqueous solution than the unconjugated form.

Questions 7 and 8: Defects in the metabolism of the branched-chain amino acids are rare but serious. The most common one is called maple syrup urine disease (named from the smell of the urine), which is a deficiency of branched-chain keto acid dehydrogenase complex. The disease is characterized by mental retardation and a short life span.

7. All of the following are true about the branched-chain amino acids except they
- **A.** are essential in the diet.
- **B.** differ in that one is glucogenic, one is ketogenic and one is classified as both.
- **C.** are catabolized in a manner that bears a resemblance to β-oxidation of fatty acids.
- **D.** are oxidized by a dehydrogenase complex to branched-chain acyl CoAs one carbon shorter than the parent compound.
- **E.** are metabolized initially in the liver.

8. Valine and isoleucine give rise to propionyl CoA, a precursor of succinyl CoA. A disease related to a defect in this conversion is methylmalonic aciduria. Some patients respond to megadoses of vitamin B_{12}. Which of the following statements about the conversion of propionyl CoA to succinyl CoA is/are correct?
- **A.** The first step in the conversion is a biotin-dependent carboxylation.
- **B.** Some methylmalonic aciduria patients respond to B_{12} because the defect in the mutase converting malonyl CoA to succinyl CoA is poor binding of the cofactor.
- **C.** The same pathway of propionyl CoA to succinyl CoA is part of the metabolism of odd-chain fatty acids.
- **D.** All of the above.
- **E.** None of the above.

Questions 9 and 10: Hyperammonemia caused by deficiencies of the enzymes involved in carbamoyl phosphate synthesis or any of the enzymes of the urea cycle is a very serious condition. Untreated, the result is early death or mental retardation and other developmental abnormalities. Ornithine transcarbamoylase deficiency is the most common error in the cycle. Treatment aims to relieve the hyperammonemia and sometimes there is supplementation with arginine.

9. In the formation of urea from ammonia, all of the following are correct except
- **A.** aspartate supplies one of the nitrogens found in urea.
- **B.** this is an energy-expensive process, utilizing several ATPs.
- **C.** the rate of the cycle fluctuates with the diet.
- **D.** fumarate is produced.
- **E.** ornithine transcarbamoylase catalyzes the rate-limiting step.

10. Carbamoyl phosphate synthetase I
- **A.** is a flavoprotein.
- **B.** is controlled primarily by feedback inhibition.
- **C.** is unresponsive to changes in arginine.
- **D.** requires *N*-acetyl glutamate as an allosteric effector.
- **E.** requires ATP as an allosteric effector.

Questions 11 and 12: A woman appears in an emergency room in an agitated state with severe abdominal pain and marked weakness in all her limbs. Usual laboratory tests are normal and no specific abnormality can be found. She is sedated with phenobarbital (a barbiturate) and observed over the next few hours. Her condition rapidly deteriorates and further study finds an elevated level of porphobilinogen in her urine. A diagnosis of acute intermittent porphyria is made. Enzyme abnormalities in this disease are a marked increase in ALA synthase and a 50% reduction in porphobilinogen deaminase.

11. Aminolevulinic acid synthase
- **A.** requires NAD for activity.
- **B.** is allosterically activated by heme.
- **C.** synthesis is inhibited by steroids.
- **D.** is synthesized in mitochondria.
- **E.** synthesis can be induced by a variety of drugs.

12. Normally, porphobilinogen is an intermediate in the pathway to heme biosynthesis. There are many other intermediates. Uroporphyrinogen III
- **A.** is synthesized rapidly from porphobilinogen in the presence of a cosynthase.
- **B.** does not contain a tetrapyrrole ring.
- **C.** is formed from coproporphyrinogen III by decarboxylation.
- **D.** is converted directly to protoporphyrinogen IX.
- **E.** formation is the primary control step in heme synthesis.

Problems

13. An inability to generate tetrahydrobiopterin would have what specific effects on the metabolism of phenylalanine, tyrosine, and tryptophan?

14. Ornithine, an intermediate of the urea cycle, and proline, found in proteins, are both synthesized from glutamate. How does this occur?

Answers

1. D The mechanism of action begins with the formation of a Schiff base with pyridoxal phosphate. A: Most mammalian aminotransferases use glutamate or α-ketoglutarate. B: One amino acid is converted into another amino acid; there is neither net gain nor net loss. C: The reactions are freely reversible. E: Only lysine and threonine do not have aminotransferases.

2. C This is an important mechanism for reducing toxic ammonia concentrations. A: This would favor ammonia consumption. B: The cofactor is a pyridine nucleotide, not pyridoxal phosphate. D: These are inhibitory. E: Since part of the role is to provide amino acid carbon chains for gluconeogenesis, this would be active.

3. A The reactive, positively charged sulfur reverts to a neutral thioether when the methyl group is transferred to an acceptor. B: The product, *S*-adenosylhomocysteine, is hydrolyzed to homocysteine. C: Transmethylations from AdoMet are irreversible. D: Transsulfuration refers to the combined action of cystathionine synthase and cystathionase transferring methionine's sulfur to serine to yield cysteine. E: Methionine provides only the sulfur; carbons are from serine.

4. D Most of the functions of glutathione listed are dependent on the sulfhydryl group (-SH). It increases membrane stability. Glutathione reductase helps to maintain the ratio of GSH to GSSG at about 100:1.

5. **B** Oxygenases usually use O_2. A: The enzyme is specific for the methene between the two rings containing the vinyl groups (α-methene bridge). C and D: The products are biliverdin and CO; the measurement of CO in the breath is an index of heme degradation. E: Iron is necessary for activity.
6. **B** Conjugated bilirubin is bilirubin diglucuronide. A: Unconjugated bilirubin is transported bound to albumin. C: Liver conjugates bilirubin, but if the bile duct is obstructed, it won't be excreted. D: Liver is responsible for the conjugation, which would be impaired in hepatic damage. E: The purpose of conjugation is to increase water solubility.
7. **E** A: Aminotransferase, the first enzyme, is much higher in muscle than in liver. B, C, and D: Their catabolism is similar but the end products are different because of the differences in the branching. The similarity to β-oxidation comes in steps like oxidation to an α,β-unsaturated CoA, hydration of the double bond, and oxidation of an hydroxyl to a carbonyl.
8. **D** A: This is a typical carboxylation reaction like pyruvate carboxylase. B: Megadoses of a cofactor if the defect is in binding has been used in a number of diseases. C: The final cleavage of odd-chain fatty acids produces propionyl CoA.
9. **E** Carbamoyl phosphate synthetase I catalyzes the rate-limiting step. A, B, and D: One of the nitrogen atoms is supplied as aspartate, with its carbon atoms being released as fumarate. C: The level of CPSI and the synthesis of *N*-acetylglutamate increase as protein in the diet increases.
10. **D** The primary control is by the allosteric effector, *N*-acetylglutamate. B: This is an activation, not an inhibition. C: Synthesis of the effector, and therefore activity of CPSI, is increased in the presence of arginine. E: ATP is a substrate.
11. **E** The enzyme is induced in response to need as well as by drugs and metabolites. Giving the porphyria patient phenobarbital increased her already high ALA synthase. A: The mechanism involves a Schiff base with glycine; therefore the coenzyme is pyridoxal phosphate. B: Heme both allosterically inhibits and suppresses synthesis of the enzyme. C: One reduction product of catabolic steroids stimulates the synthesis. D: The gene for this enzyme is on nuclear DNA.
12. **A** In the absence of cosynthase, uroporphyrinogen I is synthesized slowly. B: The tetrahydropyrrole ring has formed by this point. C and D: The decarboxylation goes from uroporphyrinogen to coproporphyrinogen, which is then converted to protoporphyrinogen. E: The synthesis of aminolevulinic acid is the rate-limiting step.
13. Tetrahydrobiopterin is a necessary component of phenylalanine, tyrosine and tryptophan hydroxylases. Its deficiency would inhibit normal degradation of both phenylalanine and tyrosine because their degradative pathways begin with the respective hydroxylases. Catecholamine formation (norepinephrine and epinephrine) begins with the formation of DOPA from tyrosine via tyrosine hydroxylase so catecholamine synthesis would be inhibited. The initial step in the conversion of tryptophan to serotonin is catalyzed by tryptophan hydroxylase.
14. Glutamate, using ATP and NADH, can be reduced to glutamic semialdehyde. The semialdehyde spontaneously cyclizes to form a Schiff base between the aldehyde and amino groups which is then reduced by NADPH to proline. If, instead, the semialdehyde undergoes transamination, ornithine is produced.

Key Concepts

- Purine and pyrimidine nucleotides are required for many normal cellular functions including DNA and RNA synthesis. Nucleotides in the cell are supplied by *de novo* synthesis and by salvage of preformed nucleobases or nucleosides.
- Synthesis of both purine and pyrimidine nucleotides requires specific amino acids, tetrahydrofolate, and 5-phosphoribosyl-1-pyrophosphate (PRPP). IMP is a precursor for both AMP and GMP synthesis. Synthesis is tightly regulated by allosteric control of the committed steps in the individual pathways.
- Deoxyribonucleotides are formed by reduction of ribonucleoside 5′-diphosphates. Deoxythymidylate synthesis requires N^5, N^{10}-methylene H_4folate

- PRPP is required for the salvage pathway. Uric acid is the end product of purine degradation in man, and β-aminoisobutyric acid of thymidine nucleotide.
- Nucleotide kinases convert nucleoside 5′-monophosphates to nucleoside 5′-diphosphates and nucleoside 5′-diphosphates to nucleoside 5′-triphosphates.
- Defects or alterations in nucleotide metabolism lead to defined clinical problems, such as gout, Lesch–Nyhan, and immunodeficiency. Inhibitors of specific steps in the synthesis of the nucleotides are effective anti-tumor drugs.
- NAD, FAD, and coenzyme A, critical coenzymes in metabolism, are synthesized by mammalian cells.

20.1 • INTRODUCTION

There are major differences between nucleotide metabolism in bacteria and mammalian cells, and even differences between humans and animals. The following discussion is limited to nucleotide metabolism in mammalian cells and where appropriate to nucleotide metabolism in humans.

Purine and pyrimidine nucleotides participate in many critical cellular functions. The cellular levels of the purine and pyrimidine nucleotides are maintained by *de novo* synthetic pathways and "salvage" reactions. Amino acids, CO_2, "Carbon-1"-tetrahydrofolate, and ribose-5-phosphate serve as sources for carbon, nitrogen, and oxygen atoms.

Intracellular concentrations of nucleotides are finely controlled by allosterically regulated enzymes in the pathways. Nucleotide end products of the pathways serve as effectors and regulate key steps in the pathways. 2′-Deoxyribonucleotides required for DNA replication are generated directly from ribonucleotides, and their production is also carefully regulated by nucleoside 5′-triphosphate nucleotides acting as positive and negative effectors. In addition to the regulation of nucleotide metabolism via allosteric regulation, concentrations of key enzymes in their metabolic pathways are altered during the cell cycle with many of the increases in enzyme activity occurring especially during late G_1/early S phase just preceding DNA replication.

The importance of both the *de novo* synthesis and the salvage pathways is shown by the fact there are clinical diseases or syndromes due to defects in either pathway. These conditions include gout (defect in *de novo* purine nucleotide synthesis), **Lesch–Nyhan syndrome** (defect in purine nucleobase salvage), orotic aciduria (defect in *de novo* pyrimidine nucleotide synthesis), and immunodeficiency diseases (defects in purine nucleoside degradation). Because nucleotide synthesis is required for DNA replication and RNA synthesis in dividing cells, drugs that block *de novo* pathways of nucleotide synthesis have been successfully used as antitumor and antiviral agents.

The structures, chemistry, and properties of nucleobases, nucleosides, and nucleotides are presented on pages 1132–1133 and in the Appendix.

20.2 • METABOLIC FUNCTIONS OF NUCLEOTIDES

Nucleotides and their derivatives play critical and diverse roles in cellular metabolism. Many different nucleotides are present in mammalian cells. Some, such as ATP and NAD are present in millimolar concentrations while others such as dATP and cyclic AMP are orders of magnitude lower in concentration. The functions of nucleotides are summarized in Table 20.1 with some examples given.

Distribution of Nucleotides Varies with Cell Type

The principal purine and pyrimidine compounds found in cells are the 5′-nucleotide derivatives with ATP being present in the highest concentration. The distribution of the various nucleotides in cells varies with cell type. In red blood cells, adenine nucleotides far exceed the concentrations of guanine, cytosine, and uracil nucleotides; in

TABLE 20.1 • Functions of Nucleotides

Function	*Selected Examples*
1. Energy metabolism	ATP (muscle contraction; active transport; ion gradients; phosphate donor)
2. Monomeric units of nucleic acids	NTPs and dNTPs (substrates for RNA and DNA)
3. Physiological mediators	Adenosine (coronary blood flow); ADP (platelet aggregation); cAMP and cGMP (second messengers); signal transduction via GTP-binding proteins
4. Precursor function	GTP (mRNA capping); tetrahydrobiopterin, (hydroxylation of aromatic amino acids)
5. Components of coenzymes	NAD, FAD, FMN, and coenzyme A
6. Activated intermediates	UDP-glucose (glycogen); CDP-choline (phospholipids); SAM (methylation); PAPS (sulfation)
7. Allosteric effectors	ATP (negative effector of PFK-I); AMP (positive effector of phosphorylase b); dATP (negative effector of ribonucleotide reductase)

other tissues, such as liver, there is a complete spectrum of nucleotides, which also include NAD^+, NADH, UDP-glucose, and UDP-glucuronic acid. In normally functioning cells, nucleoside 5′-triphosphates predominate, whereas in hypoxic cells the concentrations of nucleoside 5′-monophosphates and nucleoside 5′-diphosphates are greatly increased. Free nucleobases, nucleosides, nucleoside 2′- and 3′-monophosphates, and modified bases are found in the cytosol represent degradation products of endogenous or exogenous nucleotides or nucleic acids.

The concentrations of ribonucleotides in cells are in great excess over the concentrations of 2′-deoxyribonucleotides. For example, the concentration of ATP in Ehrlich tumor cells is 3600 pmol per 10^6 cells compared to dATP concentrations of 4 pmol per 10^6 cells. However, at the time of DNA replication the concentrations of dATP and other deoxyribonucleoside 5′-triphosphates are markedly increased to meet the substrate requirements for DNA replication. In normal cells, the total concentration of nucleotides is essentially constant. Thus, the total concentration of AMP plus ADP plus ATP remains constant, but there can be major changes in the individual concentration of each such that the ratio of ATP/(ATP + ADP + AMP) is altered depending on the energy state of the cell. The same is true for NAD^+ and NADH. The total concentration of NAD^+ plus NADH is normally fixed within rather narrow concentration limits. Consequently, when it is stated that the NADH level is increased, it follows that the concentration of NAD^+ is correspondingly decreased in that cell. The basis for this fixed concentration of nucleotides is that *de novo* synthesis and salvage pathways for nucleotides, nucleosides, and nucleobases are very rigidly controlled under normal conditions.

20.3 • 5′-PHOSPHORIBOSYL-1-PYROPHOSPHATE AND GLUTAMINE IN *DE NOVO* SYNTHESIS OF NUCLEOTIDES

5′-Phosphoribosyl-1-pyrophosphate

Ribose 5-phosphate generated from the pentose phosphate pathway or from the phosphorylysis of nucleosides supplies the **5′-phosphoribosyl-1-pyrophosphate (PRPP)** required for the *de novo* and salvage pathways of nucleotides. The reaction catalyzed by PRPP synthetase is shown in Figure 20.1. This reaction is normally under tight regulation. The properties of PRPP synthetase are listed in Table 20.2. There is a rare but severe clinical

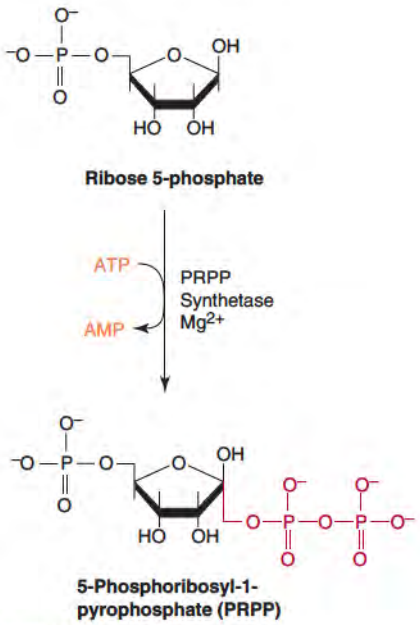

Figure 20.1 Synthesis of PRPP.

CLINICAL CORRELATION 20.1

Loss-of-Function Mutations in Phosphoribosylpyrophosphate Synthetase1 (PRPS1): Arts Syndrome (OMIM 301835)

Arts syndrome is a very rare genetic disorder that is caused by mutations in phosphoribosyl pyrophosphate synthetase (PRPS1) that results in loss of PPRS1 activity. It is X linked, and the child suffers from mental retardation, delayed motor development, and optic atrophy. In the patients studied, at least two different missense mutations have been identified. The clinical problems are likely the result of the lack of purine nucleotide synthesis. Hypoxanthine is undetectable in the urine and there is reduced uric acid in serum. Arts syndrome represents the completely opposite case in which PPRS1 activity is elevated leading to over production of purine nucleotides and the clinical condition of gout.

condition that has been documented in a Dutch family in which there is a loss of function of 5-phosphoribosylpyrophosphate synthetase (PRS1) (Clin. Corr. 20.1). On the other hand there is the involvement of excess PRPP levels contributing to gout (Clin. Corr. 20.2). PRPP levels are critical not only for the *de novo* syntheses of nucleotides but also for the salvage of nucleobases and synthesis of NAD. Table 20.3 lists the reactions and pathways requiring PRPP.

Glutamine

The amino acid, glutamine, while not considered as an essential amino acid, is a critical substrate in five specific reactions involved in the *de novo* synthesis of nucleotides. These reactions are summarized in Table 20.4. A limiting supply of glutamine in serum or cells could greatly influence the rate of nucleotide synthesis if the concentrations of glutamine were less than saturating. This in turn, could have severe consequences on the ability of a cell to synthesize RNA and DNA at the time of cell replication.

The overall *de novo* syntheses of purine and pyrimidine nucleotides are highly regulated at **PRPP amidotransferase** and **carbamoyl phosphate synthetase (CPS II)**, respectively. The regulation of CTP synthetase is critical for maintaining the appropriate cellular ratio of UTP to CTP in cells.

20.4 • SYNTHESIS OF PURINE NUCLEOTIDES

The *de novo* synthesis pathways for purine and pyrimidine nucleotides in mammalian cells utilize amino acids as carbon and nitrogen donors. Although all of the enzymes of the purine nucleotide pathway are cytosolic, the enzymes of pyrimidine nucleotide synthesis pathway are located in the cytosol and mitochondria. Both types of nucleotides derive the ribose 5-phosphate from PRPP and both pathways are very finely regulated. The energy from the hydrolysis of ATP is used to drive several reactions. Overall, the *de novo* pathways are expensive in terms of moles of ATP utilized per mole of nucleotide synthesized.

All enzymes involved in synthesis of purine nucleotides are present in the cytosol. However, not all cells (e.g., red cells) are capable of *de novo* purine nucleotide synthesis. In the *de*

CLINICAL CORRELATION 20.2

Gout

Gout is characterized by elevated uric acid concentrations in blood and urine due to a variety of metabolic abnormalities that include the overproduction of purine nucleotides or the decreased excretion of uric acid. It appears to be a growing health problem, related to lifestyle and the aging population. Many of the clinical symptoms associated with elevated concentrations of uric acid arise because of the very poor solubility of uric acid in the aqueous environment. Sodium urate crystals deposit in joints of the extremities and in renal interstitial tissue. These events tend to trigger the sequelae. Hyperuricemia from overproduction of uric acid via the *de novo* pathway can be distinguished from hyperuricemia that results from kidney disease or excessive cell death (e.g., increased degradation of nucleic acids from radiation therapy or cancer chemotherapy). Feeding of ^{15}N-glycine to a patient who is an overproducer results in uric acid excreted in urine that is enriched in ^{15}N at the N7 of uric acid. In contrast, a patient who is not an overproducer will not have enrichment of ^{15}N in the excreted uric acid.

Studies of patients with gout have shown that multiple and heterogenous metabolic defects can cause overproduction of uric acid. In some cases, biochemical defects have not been unequivocally defined. Examples of biochemical defects that result in increased purine nucleotide synthesis include the following: (1) Increased PRPP synthetase (OMIM 300661) activity leads to increased intracellular concentrations of PRPP, which serve as a positive effector of glutamine-PRPP amidotransferase leading to increased flux through the *de novo* pathway since activity of the rate-limiting step is markedly increased. (2) Partial decrease in HGPRTase activity (OMIM 308000) has two effects that lead to increased *de novo* pathway for purine nucleotide synthesis. Since there is decreased salvage of hypoxanthine and guanine, PRPP is not consumed by the HGPRtase. PRPP not consumed by the HGPRTase reaction can serve to activate glutamine-PRPP amidotransferase activity. With decreased salvage of hypoxanthine and guanine, IMP and GMP are not formed via this pathway so that regulation of the PRPP amidotransferase step by IMP and GMP as negative effectors is compromised. (3) Glucose 6-phosphatase deficiency (von Gierke disease, Type I glycogen storage disease, (OMIM 232200)) is frequently associated with hyperuricemia and gout as well since loss of glucose 6-phosphatase activity results in more glucose 6-phosphate being shunted to the pentose phosphate pathway. As a result, more ribose 5-phosphate is generated and the intracellular levels of PRPP are increased stimulating PRPP amidotransferase activity. Increased levels of cellular PRPP in each of these cases appears to be sufficient to attenuate the regulation of purine nucleotide synthesis by IMP, AMP, and GMP at the PRPP amidotransferase step.

These examples demonstrate that factors that increase the rate-limiting step in *de novo* synthesis of purine nucleotide synthesis lead to increased generation of uric acid. Under normal conditions, increased purine nucleotide synthesis occurs only to meet the cellular needs for purine nucleotides for RNA and DNA synthesis.

There are different approaches for the treatment of gout. These include colchicine (antimitotic agent), uricosuric drugs (to enhance renal excretion of uric acid), and allopurinol. Allopurinol and its metabolite, alloxanthine, are effective inhibitors of xanthine oxidoreductase and will cause a decrease in uric acid levels. In overproducers who have only a partial deficiency of HGPRTase activity, allopurinol treatment inhibits xanthine oxidoreductase, causing increases in the concentrations of hypoxanthine and xanthine which can be salvaged via HGPRTase to form IMP and XMP. These reactions consume PRPP and generate purine nucleotides that inhibit PRPP amidotransferase. The overall effect is that allopurinol treatment decreases both uric acid formation and *de novo* synthesis of purine nucleotides in these individuals with partial HGPRTase activity. However, there is a population of patients who do not respond to conventional allopurinol treatment and are considered treatment resistant. Studies are in progress to treat these patients with the use of recombinant polyethylene glycol-uricase (PEG-uricase), which enzymatically converts uric acid to allantoin, a product that is more water soluble than uric acid and readily excreted.

Becker, M.A. Hyperuricemia and gout. In Scriver, C. R., Beaudet, A. L. Sly, W. S., and Valle, D. (Eds.), *The Metabolic and Molecular Bases of Inherited Disease,* 8th ed. L., et al. Pharmokinetics and pharmacodynamics of intravenous PEGylated recombinant mammalian urate oxidase. *Arthritis and Rheumatism* 56:1021, 2007.

novo pathway, a series of reactions leads to synthesis of IMP, which serves as the common precursor for both adenosine 5′-monophosphate (AMP) and guanosine 5′-monophosphate (GMP). This pathway is highly regulated by AMP, GMP, and IMP; although IMP is the end product, it is not normally found to any extent under aerobic conditions.

Formation of IMP

Formation of IMP is shown in Figure 20.2. Several points should be emphasized about this pathway: 5′-phosphoribosyl-1-pyrophosphate (PRPP) is synthesized from ribose 5-phosphate that is generated primarily by the pentose phosphate pathway; the equivalent of 6 mol of ATP are utilized per mole of IMP synthesized; formation of 5-phosphoribosylamine (the first step) is the committed and regulated step. In formation of 5-phosphoribosylamine, the N–C bond is formed that will ultimately be the *N*-glycosidic bond of the purine nucleotide; there are no known regulated

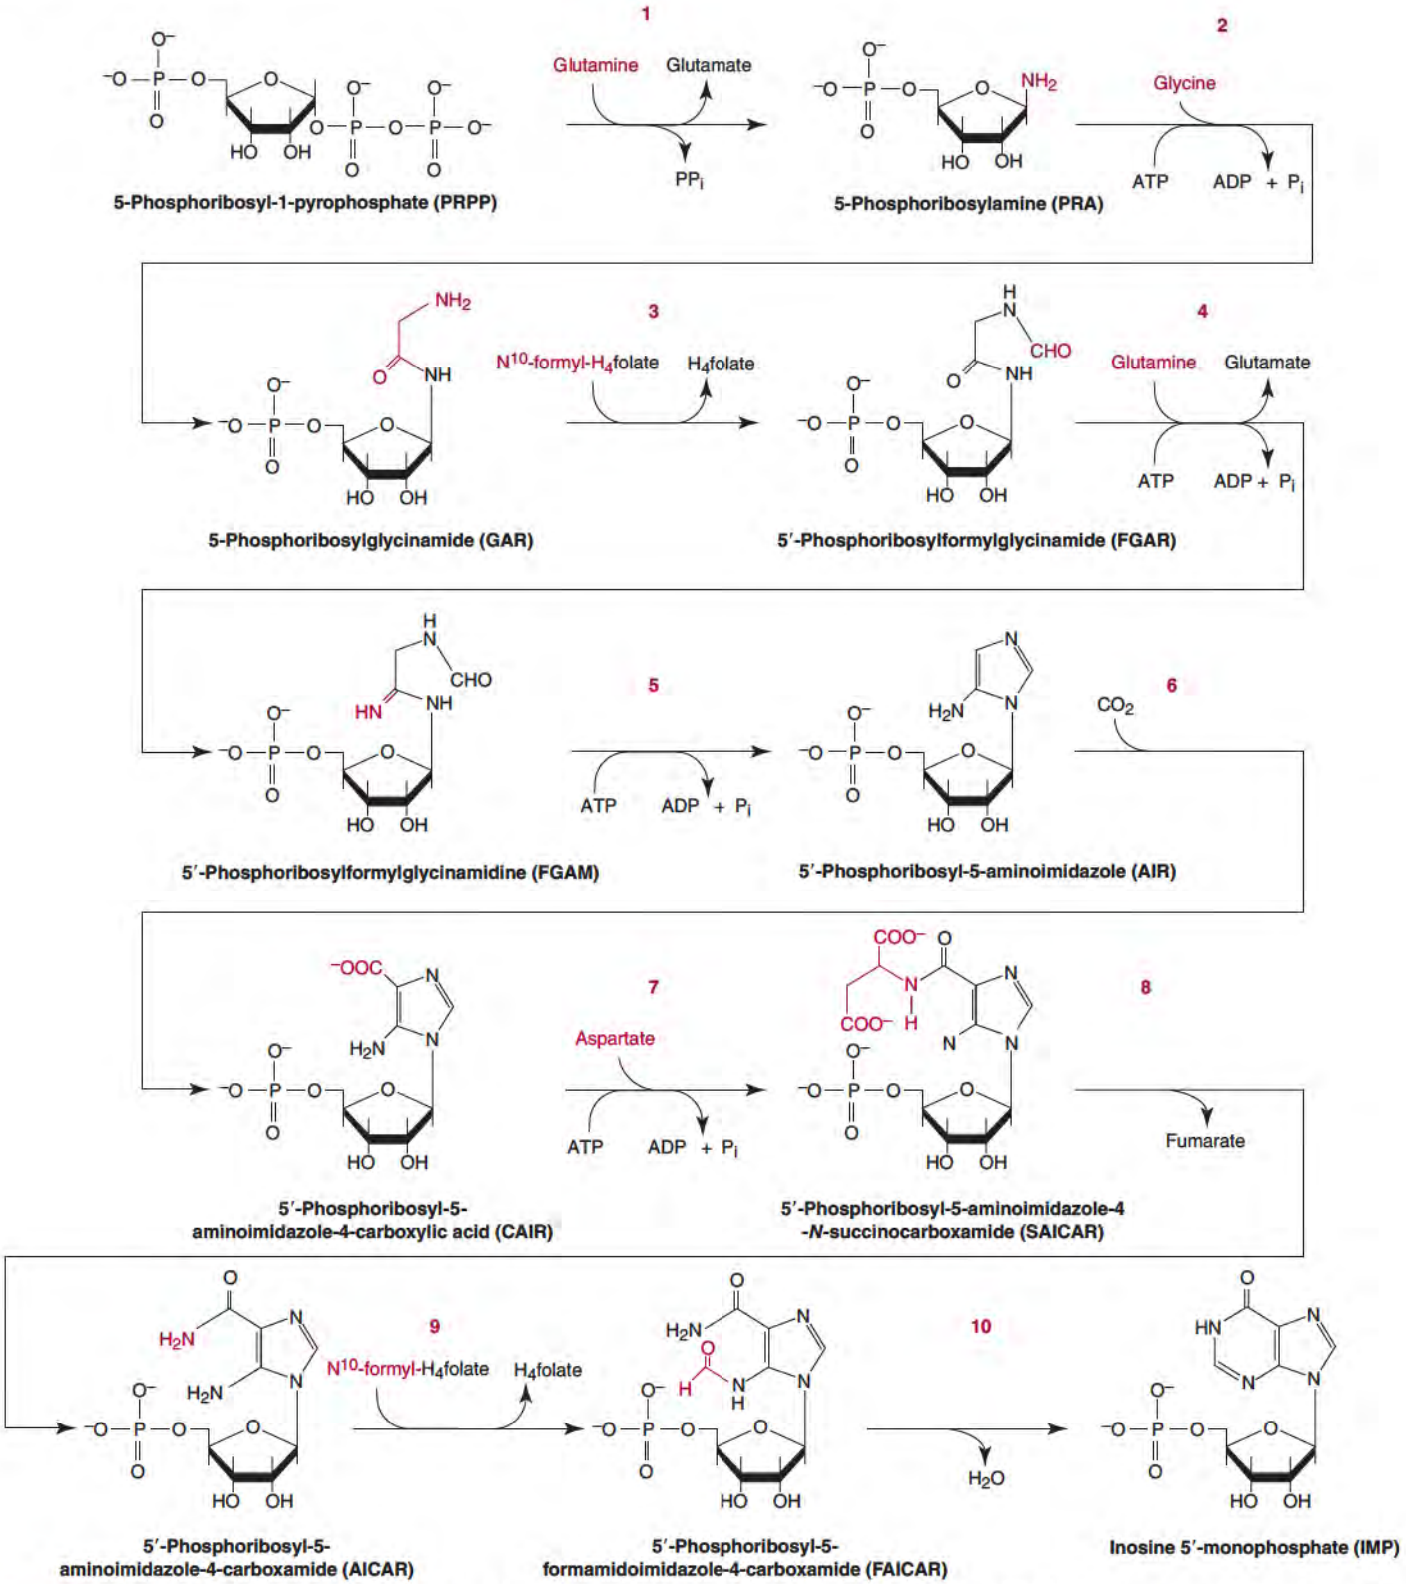

Figure 20.2 ***De novo*** **synthesis of purine ribonucleotides.** The enzymes catalyzing the reactions are (1) glutamine PRPP amidotransferase, (2) GAR synthetase, (3) GAR transformylase, (4) FGAM synthetase, (5) AIR synthetase, (6) AIR carboxylase, (7) SAICAR synthetase, (8) adenylosuccinate lyase, (9) AICAR transformylase, and (10) IMP cyclohydrolase.

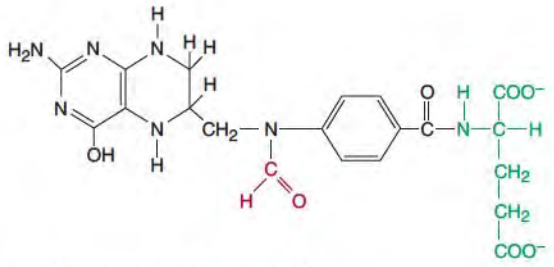

Figure 20.3 **Structure of N^{10}-formyl H_4folate.**

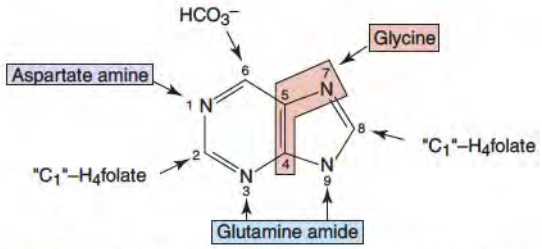

Figure 20.4 **Sources of carbon and nitrogen atoms in the purine ring.** C4, C5, and N7 from glycine; N3 and N9 from glutamine; C2 and C8 from C_1-H_4folate; N1 from aspartate; and C6 from CO_2.

steps between the formation of 5-phosphoribosylamine and IMP; and tetrahydrofolate serves as a C_1-carrier (N^{10}-formyl H_4folate, Figure 20.3) in this pathway. It is important to point out that in Reactions 3 and 9, tetrahydrofolate is only a one-carbon carrier and is regenerated. Phosphoribosyl-5-aminoimidazole carboxylase, which catalyzes the reaction in which CO_2 is used to introduce carbon-6 of the ring, is not a biotin-dependent carboxylase.

The enzyme activities catalyzing several steps the pathway reside on separate domains of **multifunctional proteins**. (1) Activities of 5′-phosphoribosylglycinamide synthetase (step 2), 5′-phosphoribosylglycinamide transformylase (step 3), and 5′-phosphoribosylaminoimidazole synthetase (step 5), form part of a trifunctional protein. (2) 5′-Phosphoribosylaminoimidazole carboxylase (step 6) and 5′-phosphoribosyl-4-(*N*-succinocarboxamide)-5-aminoimidazole synthetase (step 7) activities are on the same bifunctional protein. (3) 5′-Phosphoribosyl-4-carboxamide-5-aminoimidazole transformylase (step 9) and IMP cyclohydrolase (step 10) activities are present on a bifunctional protein.

To summarize, *de novo* synthesis of purine nucleotides requires amino acids as carbon and nitrogen donors, CO_2 as a carbon source, and C_1-units transferred via H_4-folate. The contributions of these sources to the purine ring are shown in Figure 20.4. Several amino acids including serine, glycine, tryptophan and histidine can provide C_1-units to H_4folate (p. 1079), and therefore they may contribute to carbon-2 and carbon-8 of the purine ring.

IMP Is Common Precursor for AMP and GMP

IMP, the first ribonucleotide formed in the *de novo* pathway, is the common precursor for AMP and GMP synthesis (Figure 20.5). AMP and GMP are converted to ATP and GTP respectively, by nucleoside 5′-monophosphate kinases and nucleoside 5′-diphosphate kinases, which are not rate limiting. Conversion of IMP to AMP and GMP is regulated such that the appropriate cellular ratios of adenine and guanine nucleotides are maintained. Formation of GMP from IMP requires ATP as an energy source whereas formation of AMP from IMP requires GTP as the energy source. This reciprocal relationship ensures that when there is sufficient ATP in the cell, GMP will be synthesized from IMP and, when there is sufficient GTP, AMP will be synthesized from IMP.

Purine Nucleotide Synthesis Is Highly Regulated

The committed step of a metabolic pathway is generally the site of major regulation. In *de novo* purine nucleotide synthesis, formation of 5-phosphoribosylamine from glutamine and 5-phosphoribosyl-1-pyrophosphate (PRPP) is the committed step in IMP formation. The enzyme catalyzing this reaction, glutamine PRPP-amidotransferase, is rate limiting and is regulated allosterically by the end products of the pathway. IMP, GMP, and AMP serve as negative effectors of PRPP amido tranferase, while PRPP is a positive effector. Glutamine PRPP amidotransferase is a monomer of 135 kDa. In the presence of IMP, AMP, or GMP the enzyme forms a dimer that is much less active while

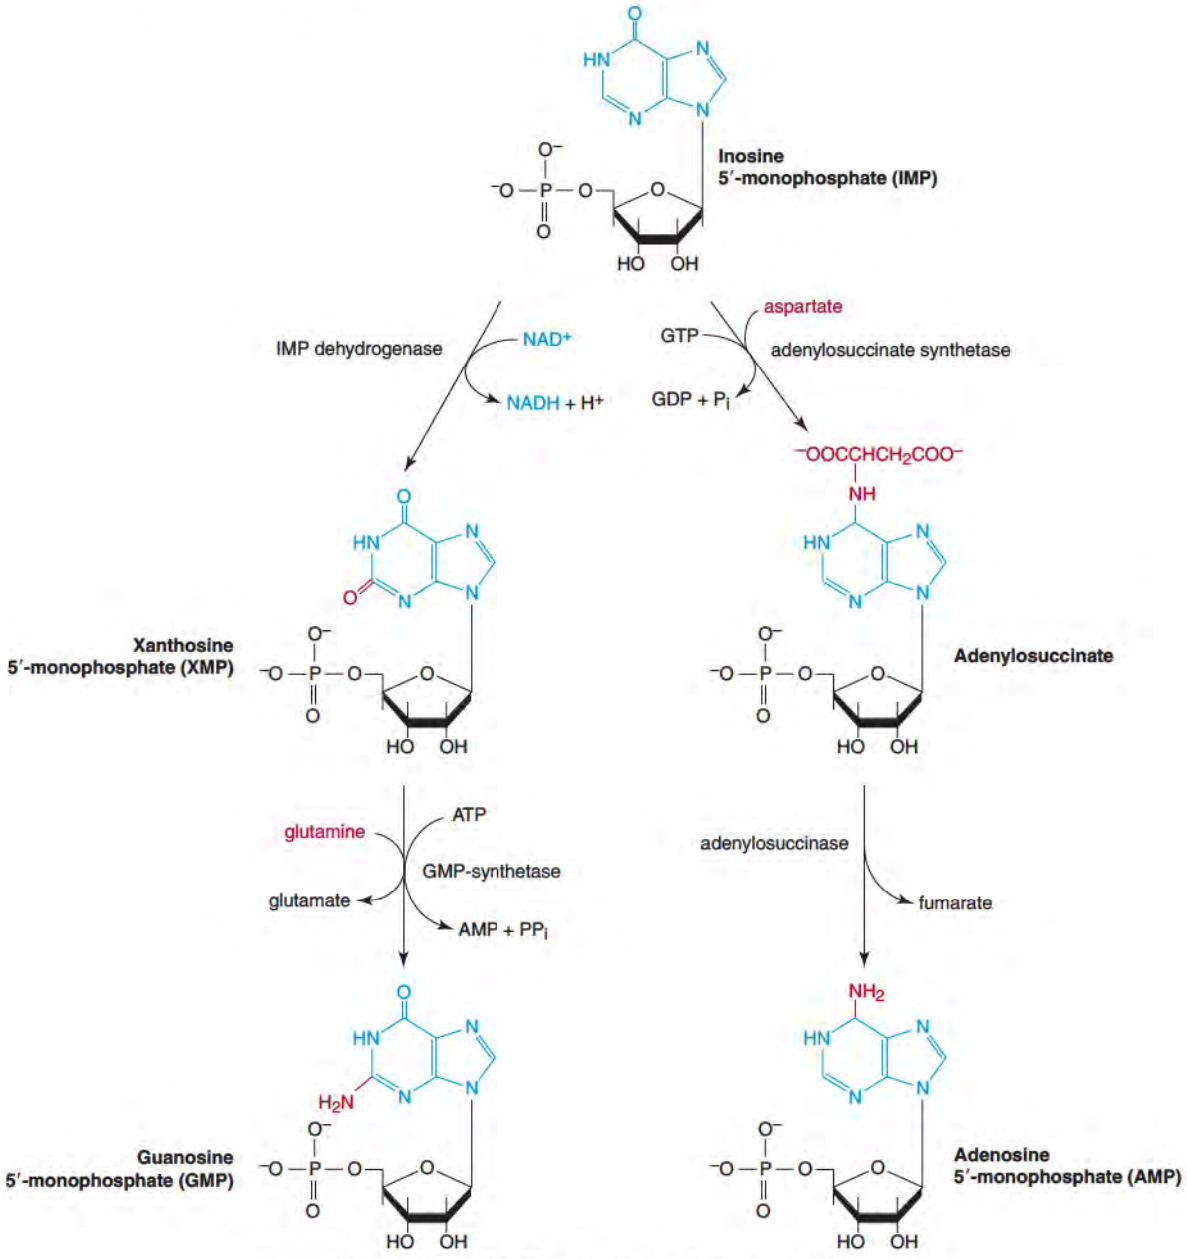

Figure 20.5 **Formation of AMP and GMP from IMP branch point.**

the presence of PRPP shifts the equilibrium in favor of the active monomeric form of the enzyme (Figure 20.6).

The enzyme from human tissues has distinct nucleotide binding sites. One site specifically binds oxypurine nucleotides (IMP, XMP, and GMP) whereas the other site specifically binds aminopurine nucleotides (AMP). When AMP and GMP (or IMP) are present simultaneously, the enzyme activity is inhibited synergistically by the combination of an oxy and amino purine nucleotide. Glutamine PRPP amidotransferase displays hyperbolic kinetics with respect to glutamine as the substrate and sigmoidal kinetics with respect to PRPP (Figure 20.7). Since the intracellular concentration of glutamine normally varies relatively little and is close to the K_m of the enzyme, the glutamine concentration is thought to have little effect in regulating IMP synthesis. However, in cancer patients who are treated with asparaginase (which also possesses glutaminase activity), the decreased concentration of glutamine as a result of asparaginase treatment may have an effect on the *de novo* pathway by limiting the availability of glutamine. The intracellular concentration of PRPP varies widely and can be 10 to 100 times less than the K_m for PRPP. Therefore, the

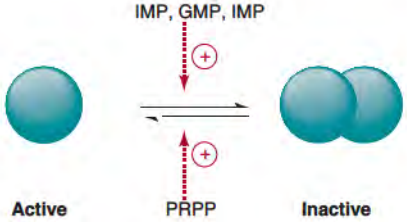

Figure 20.6 **Effects of allosteric modulators on molecular forms of glutamine PRPP amidotransferase.**

concentration of PRPP plays an important role in regulating synthesis of purine nucleotides under normal conditions.

Between formation of 5-phosphoribosylamine and IMP, there are no known regulated steps although alterations in the tetrahydrofolate levels will have an effect on the *de novo* synthesis of purine nucleotides. Methotrexate, a drug used extensively in the treatment of cancer, is cytotoxic because it markedly alters the folate pools. There is regulation at the branch point of IMP to AMP and IMP to GMP. From IMP to GMP, IMP dehydrogenase (IMPDH) is the rate-limiting enzyme and it is regulated by GMP acting as a competitive inhibitor with respect to IMP of IMPDH. There are two distinct genes for IMPDH with IMPDH-I serving as the constitutive form of the enzyme while IMPDH-II is related to cell growth and proliferation. Adenylosuccinate synthetase is rate limiting in conversion of IMP to AMP with AMP acting as a competitive inhibitor.

Since the ATP to GTP ratio in various cell types is relatively constant, it would suggest that additional control mechanisms function at the IMP *branch point.* Total cellular concentration of adenine nucleotides (ATP + ADP + AMP) in most cells is four to six times that of guanine nucleotides (GTP + GDP + GMP). The overall regulation of purine nucleotide synthesis is summarized in Figure 20.8. Defects in the metabolic pathway that lead to loss of regulation of purine nucleotide synthesis result in overproduction of purine nucleotides and the end product, uric acid. This results in a relatively common clinical condition known as gout (see Clin. Corr. 20.2, p. 811).

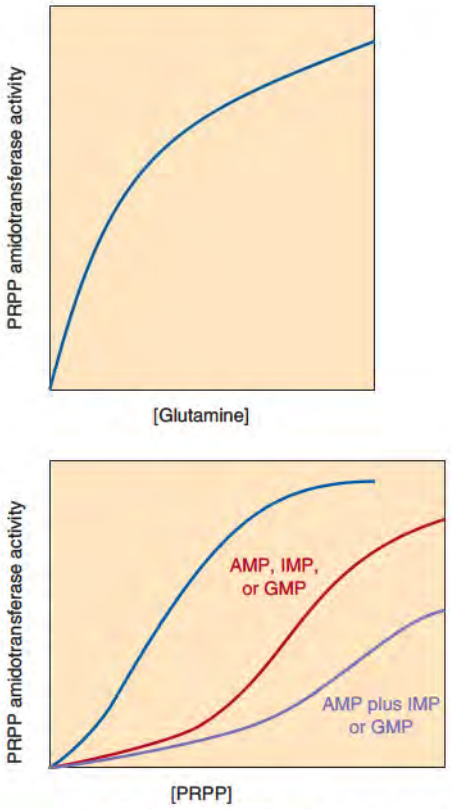

Figure 20.7 Glutamine PRPP amidotransferase activity as a function of glutamine or PRPP concentrations.

Purine Bases and Nucleosides Are Salvaged to Reform Nucleotides

The efficiency of normal metabolism is shown by the presence of two distinct "salvage pathways". One pathway utilizes the nucleobases, hypoxanthine, guanine, and adenine as substrates whereas the other pathway utilizes preformed nucleosides as the substrates. Each pathway is specific with respect to the nucleobase or nucleoside that is salvaged. The salvage of nucleobases requires the activity of phosphoribosyl transferases that utilize PRPP as the ribose phosphate donor. There are two distinct phosphoribosyl transferases. **Hypoxanthine-guanine phosphoribosyl transferase (HGPRTase)** catalyzes the reactions.

$$\text{Hypoxanthine} + \text{PRPP} \rightleftharpoons \text{IMP} + \text{PPi}$$

and

$$\text{Guanine} + \text{PRPP} \rightleftharpoons \text{GMP} + \text{PPi}$$

and **adenine phosphoribosyl transferase (APRTase)** catalyzes

$$\text{Adenine} + \text{PRPP} \rightleftharpoons \text{AMP} + \text{PPi}.$$

These two enzymes do not overlap in substrate utilization. The reactions are regulated by their end products. IMP and GMP are competitive inhibitors of HGPRTase with respect to PRPP; AMP is a competitive inhibitor with respect to PRPP of APRTase. In this way, salvage of purine bases is regulated; this has the overall effect of regulating the *de novo* pathway.

Hypoxanthine and guanine for salvage arise from degradation of endogenous or exogenous purine nucleotides. Adenine utilized in the APRTase reaction is generated mainly from synthesis of polyamines (p. 787). For each molecule of spermine synthesized, two molecules of 5′-methylthioadenosine are released that are then degraded to 5-methylthioribose-1-phosphate and adenine by the 5′-methylthioadenosine phosphorylase-catalyzed reaction. Adenine is salvaged through the APRTase reaction to form AMP.

Generation of AMP and GMP through these phosphoribosyltransferase reactions is very effective in decreasing the *de novo* pathway at the PRPP amidotransferase step. First, PRPP (a positive effector) is consumed in the reaction, decreasing the rate of formation of 5-phosphoribosylamine, and second, the products, AMP, IMP and GMP serve as negative effectors of PRPP amidotransferase (Figure 20.9).

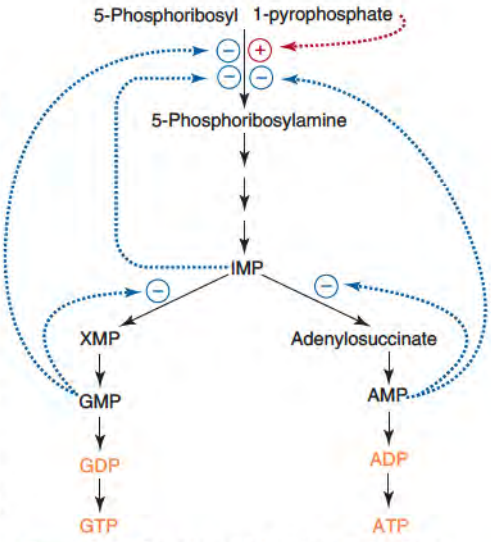

Figure 20.8 Regulation of purine nucleotide synthesis.

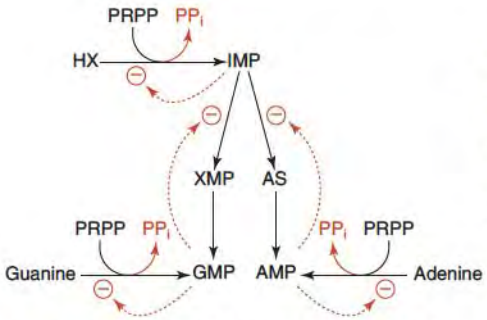

Figure 20.9 Salvage of purine nucleobases via phosphoribosyl transferases. Effects of products on AMP and GMP synthesis from IMP. The dashed lines represent sites of regulation.

HGPRTase activity is markedly depressed in the Lesch–Nyhan syndrome (Clin. Corr. 20.3), which is characterized clinically by hyperuricemia, mental retardation, and self-mutilation. In contrast to HGPRTase deficiency, there are no neurological problems such as mental retardation or self-mutilation associated with APRTase deficiency. APRTase-deficient individuals show increased excretion of adenine, 8-hydroxyadenine (8-HA) and 2,8-dihydroxyadenine (2,8-DHA). 8-HA and 2,8-DHA are generated from adenine by the action of xanthine oxidoreductase (xanthine dehydrogenase). The accumulation of 2,8-DHA can lead to the formation of calculi consisting of 2,8-DHA (which are sometimes misinterpreted as sodium urate calculi). Allopurinol treatment can be used to decrease the amount of 2,8-DHA formed and the associated nephrotoxicity.

Nucleosides such as adenosine are salvaged by adenosine kinase, a 5′-phosphotransferase that utilizes ATP as the phosphate donor. The substrate specificity of the 5′-phosphotransferases varies with the particular nucleoside kinase.

CLINICAL CORRELATION 20.3

Lesch–Nyhan Syndrome

The Lesch–Nyhan syndrome (OMIM 300322) is characterized by hyperuricemia, excessive uric acid synthesis, and neurological problems, which may include spasticity, mental retardation, and self-mutilation. This disorder is associated with a very severe or complete deficiency of HGPRTase (hypoxanthine-guanine phosphoribosylsyltranferase). HGPRTase is on the X chromosome; hence, the deficiency is virtually limited to males. Exceptions have been reported. In a detailed study of the available patients, it was observed that if HGPRTase activity were less than 2% of normal, mental retardation was present, but if the activity were less than 0.2% of normal, the unique self-mutilation phenomenon was present. The defect also leads to excretion of elevated levels of hypoxanthine and xanthine.

There are more than 200 mutations in the HGPRTase gene from patients with the Lesch–Nyhan syndrome. These mutations have led to the loss of HGPRTase protein, loss of HGPRTase activity, K_m mutants, and HGPRTase protein with a short half-life. HGPRTase catalyzes the reactions in which hypoxanthine, xanthine, and guanine are converted to IMP, GMP, and XMP with PRPP as the ribose 5-phosphate donor. The hyperuricemia and excessive uric acid production that occur in patients with the Lesch–Nyhan syndrome are easily explained by the lack of HGPRTase activity. As a consequence, hypoxanthine and guanine are not salvaged, leading to increased intracellular pools of PRPP and decreased levels of IMP or GMP. Both of these factors promote *de novo* synthesis of purine nucleotides without regard for appropriate regulation of this pathway at PRPP amidotransferase, the rate-limiting step. It is not understood why a severe defect in this salvage pathway leads to neurological problems. Adenine phosphoribosyltransferase (APRTase) activity in these patients is normal or slightly elevated. With APTRase present, the cellular needs for purine nucleotides could be met by conversion of AMP to IMP followed by the conversion of IMP to GMP if the cell's *de novo* pathway were not functioning. The normal tissue distribution of HGPRTase activity perhaps could explain the neurological symptoms. The brain (frontal lobe, basal ganglia, and cerebellum) has from 10 to 20 times the level of enzyme activity found in liver, spleen, or kidney and from 4 to 8 times that of erythrocytes. Individuals who have primary gout with excessive uric acid formation and hyperuricemia do not display neurological problems so that it is argued that products of purine degradation (hypoxanthine, guanine, xanthine, and uric acid) should not be toxic to the central nervous system (CNS). However, it is possible that these metabolites are toxic to the developing CNS or that lack of enzyme leads to an imbalance in the concentrations of adenine and guanine nucleotides at critical times during development. If IMP dehydrogenase activity in brain were extremely low, lack of HGPRTase could lead to decreased amounts of intracellular GTP due to decreased salvage of guanine. Since GTP is a precursor of tetrahydrobiopterin, a required cofactor in the biosynthesis of neurotransmitters and nitric oxide, and is required in other functions such as signal transduction via G proteins and protein synthesis, low concentrations of GTP during development could be the triggering factor in the observed neurological manifestations.

Some data indicate that patients with Lesch–Nyhan disease have impairment with dopamine function. This could be related to the role of tetrahydrobiopterin in the hydroxylation of tyrosine leading to dopamine synthesis. However, at this time there is no unequivocal explanation for why the loss of HGPRTase activity leads to the unusual neurological symptoms seen in the patients.

Because of the lack of a curative treatment for Lesch–Nyhan, there have been various treatments tried to reduce the self-injury aspect of the disease. These treatments have included therapy with levodopa, *S*-adenosylmethionine, and even injections with botulinum toxin A. There is no cure. Treatment with allopurinol serves only to decrease the amount of uric acid formed; this relieves some of the problems caused by sodium urate deposits. However, since the Lesch–Nyhan patient has a marked reduction in HGPRTase activity, hypoxanthine and guanine are not salvaged, PRPP is not consumed, and consequently *de novo* synthesis of purine nucleotides is not regulated. This is in contrast to patients with gout who will have decreased uric acid levels and decreased *de novo* synthesis in response to allopurinol treatment. There is no successful treatment for the neurological problems. These patients usually die from kidney failure.

Iiassa, T. Increased activity of PRPP synthetase. *Nippon Rinsho* 66:694, 2008; and Nyhan, W. L. Lesch–Nyhan disease. *Nucleosides, Nucleotides Nucleic Acids* 6: 559, 2008.

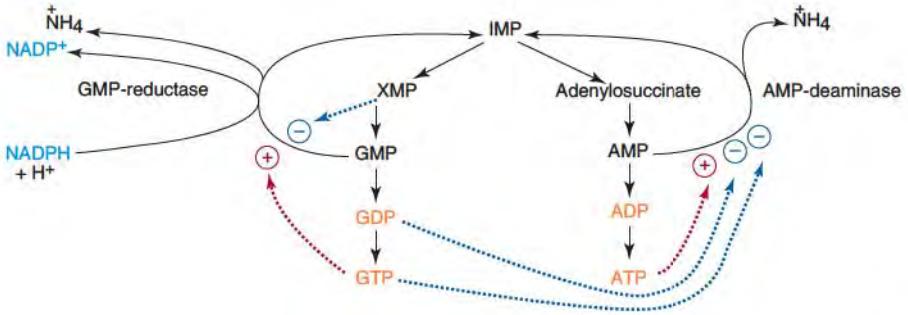

Figure 20.10 Interconversions of purine nucleotides.

Overall, these salvage reactions conserve energy and permit cells to form nucleotides from the free nucleobases or nucleosides. Erythrocytes, for example, do not have glutamine PRPP amidotransferase and hence cannot synthesize 5-phosphoribosylamine, the first unique metabolite in the pathway of purine nucleotide synthesis. Therefore, they must depend on purine phosphoribosyl transferases and 5′-phosphotransferase (adenosine kinase) to replenish their nucleotide pools.

Purine Nucleotides Are Interconverted to Balance Cellular Levels of Adenine and Guanine Nucleotides

De novo synthesis of purine nucleotides is under very fine control by the regulation at glutamine PRPP amidotransferase and at the branch points, IMP to AMP (adenylosuccinate synthetase) and IMP to GMP (IMP dehydrogenase). Additional enzymes present in mammalian cells allow for interconversions of adenine and guanine nucleotides to maintain the appropriate balance of cellular concentrations of these purine nucleotides. These interconversions occur by indirect steps since there is no direct one-step pathway for conversion of GMP to AMP or AMP to GMP. In each case, AMP or GMP is converted to IMP (Figure 20.10). These reactions are catalyzed by separate enzymes, each of which is under separate regulation. Reductive deamination of GMP to IMP is catalyzed by GMP reductase. GTP activates this step whereas xanthosine 5′-monophosphate (XMP) is a strong competitive inhibitor of the reaction. GTP, although not required by the enzyme, increases enzyme activity by lowering the K_m with respect to GMP and by increasing V_{max}.

AMP deaminase (5′-AMP aminohydrolase) catalyzes deamination of AMP to IMP and is activated by K^+ and ATP and inhibited by P_i, GDP, and GTP. In the absence of K^+, the velocity-versus-AMP concentration curve is sigmoidal. The presence of K^+ is not required for maximum activity but serves as a positive allosteric effector reducing the apparent K_m for AMP.

The net effect of these reactions is that cells can interconvert adenine and guanine nucleotides to meet cellular needs, while maintaining control over these reactions.

20.5 • GTP IS THE PRECURSOR OF TETRAHYDROBIOPTERIN

GTP is the direct precursor for **tetrahydrobiopterin** synthesis (Figure 20.11). Reactions from GTP to tetrahydrobiopterin are catalyzed by GTP cyclohydrolase I, 6-pyruvoyltetrahydropterin synthase, and sepiapterin reductase. GTP cyclohydrolase I catalyzes the rate-limiting step. Many cell types synthesize tetrahydrobiopterin, which is a required cofactor in hydroxylation reactions involving phenylalanine, tyrosine, and tryptophan (p. 767). In addition, tetrahydrobiopterin is involved in the generation of nitric oxide by nitric oxide synthases. Inhibitors of IMP dehydrogenase cause a marked reduction in cellular levels of tetrahydrobiopterin, demonstrating the importance of GTP as the precursor of tetrahydrobiopterin and of IMP dehydrogenase as the rate-limiting enzyme in GTP formation.

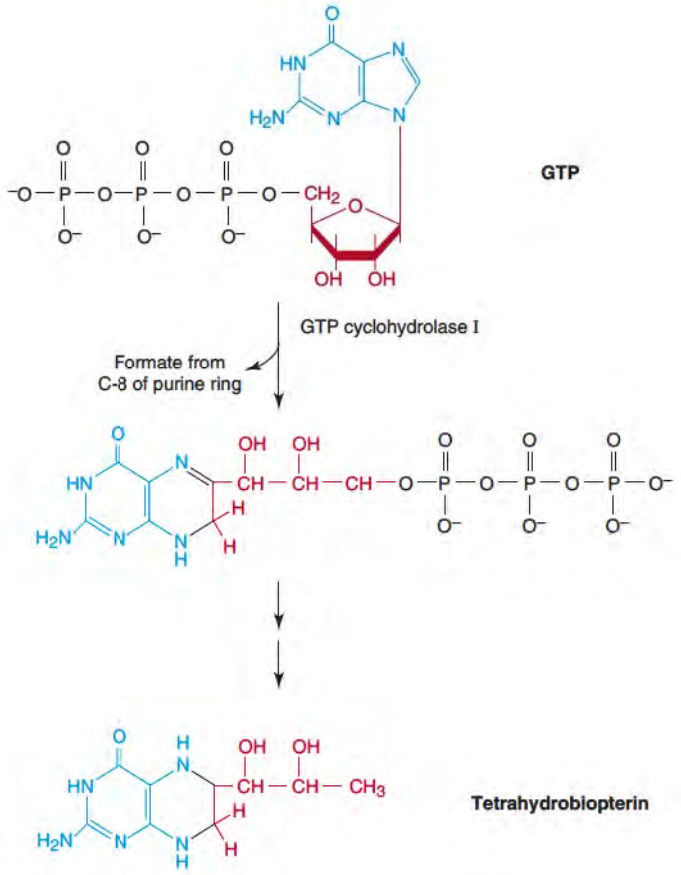

Figure 20.11 Synthesis of tetrahydrobiopterin from GTP.

The degradation of purine nucleotides, nucleosides, and nucleobases follow a common pathway that leads to formation of **uric acid** (Figure 20.12). The enzymes involved in degradation of nucleic acids, nucleotides and nucleosides vary in specificity. **Nucleases** are specific toward either RNA or DNA and also toward the bases and position of cleavage site at the 3′, 5′-phosphodiester bonds. Nucleotidases range from those with relatively high specificity, such as 5′-AMP nucleotidase to those with broad specificity, such as the acid and alkaline phosphatases, which will hydrolyze any of the 3′- or 5′-nucleotides (Clin. Corr. 20.4). AMP deaminase is specific for AMP. Adenosine deaminase is less specific, since adenosine, 2′-deoxyadenosine, and many other 6-aminopurine nucleosides are deaminated by this enzyme.

Purine nucleoside phosphorylase catalyzes the reversible reactions.

$$\text{Inosine} + \text{Pi} \rightleftharpoons \text{hypoxanthine} + \text{ribose 1-P}$$

or

$$\text{Guanosine} + \text{Pi} \rightleftharpoons \text{guanine} + \text{ribose 1-P}$$

with 2′-deoxyinosine and 2′-deoxyguanosine also being natural substrates for purine nucleoside phosphorylase. This is important since removal of deoxyguanosine prevents uncontrolled accumulation of dGTP, which is toxic to cells at high concentrations. Although the equilibrium constants for reactions catalyzed by purine nucleoside phosphorylase favor the direction of nucleoside synthesis, cellular concentrations of free purine base and ribose-1-phosphate are too low to support nucleoside synthesis under normal conditions. Therefore, the main function of the enzyme under cellular conditions is the degradative rather than synthetic pathway. Adenosine deaminase deficiency is associated with severe combined immunodeficiency whereas purine nucleoside phosphorylase deficiency leads to a defective T-cell immunity but normal B-cell immunity (Clin. Corr. 20.5).

CLINICAL CORRELATION 20.4

Increased Cytosolic 5′-Nucleotidase Activity

Four patients were identified in whom 5′-nucleotidase activity in fibroblast lysates as measured using 5′-AMP or 5′-UMP as substrate was increased to 6- to 10- fold in these patients compared to the controls. These four unrelated children had problems associated with developmental delay, seizures, ataxia, infections, severe language deficit, and an unusual behavioral phenotype characterized by hyperactivity, short attention span, and poor social interaction. Since it was possible that the increased cellular 5′-nucleotidase activity decreased nucleotide pools and these patients were anemic, they were treated with oral uridine. Remarkably, all four patients treated with uridine improved dramatically in all aspects of the physical and clinical behaviors. The concentration of uridine needed to treat these children was much higher than the concentration needed to treat the children with orotic aciduria. How the increased 5′-nucleotidase activity leads to the clinical symptoms is not known. It is possible that the increased cellular adenosine level that results from the increased enzyme activity is involved in the problems as adenosine has metabolic interactions even at low concentrations (adenosine receptors, potassium ion channels, etc.).

These findings again point to the fact that either overproduction or blockage of nucleotide synthesis or decreased or increased degradation of nucleotides or nucleosides can have major consequences on the well-being of the individual.

CLINICAL CORRELATION 20.5

Immunodeficiency Diseases Associated with Defects in Purine Nucleoside Degradation

Distinct immunodeficiency diseases are associated with defects in adenosine deaminase (ADA) and purine nucleoside phosphorylase (PNP), respectively. These enzymes are involved in the degradative pathways leading to formation of uric acid as the end product. Natural substrates for adenosine deaminase are adenosine and deoxyadenosine whereas natural substrates for purine nucleoside phosphorylase are inosine, guanosine, deoxyinosine and deoxyguanosine. A deficiency in ADA is associated with a severe combined immunodeficiency involving both T-cell and B-cell functions. PNP deficiency is associated with an immunodeficiency involving T-cell functions with little or no effect on B-cell function. In neither case is the specific mechanism(s) by which the lack of these enzymes leads to immune dysfunction known. The deficiency in ADA activity arises from mutations in various exons that cause either missense or nonsense effects. In ADA-deficient patients, intracellular concentrations of dATP and *S*-adenosylhomocysteine are greatly increased. Several hypotheses have been put forth to explain the biochemical consequences of a lack of ADA. (1) High concentrations of dATP inhibit ribonucleotide reductase activity and as a consequence inhibit DNA synthesis. (2) deoxyadenosine inactivates *S*-adenosyl homocysteine hydrolase leading to decreased *S*-adenosylmethionine that is required for methylation of bases in RNA and DNA. (3) Increased concentrations of adenosine result in increased cAMP levels. It is possible that each of these mechanisms contributes to the overall effect of immune dysfunction. There is not, however, a suitable explanation for the specificity of the effects on only T-cells and B-cells.

Treatments of children with ADA deficiency have included (1) blood transfusions, (2) bone marrow transplantation, (3) enzyme replacement therapy with ADA-polyethylene glycol conjugate (ADA-PEG), and most recently (4) gene therapy. Each of these treatments has disadvantages. Blood transfusions produce problems of iron overload and safety of the blood source. Bone marrow transplantation, while curative, requires a suitably matched donor. Enzyme replacement therapy with adenosine deaminase covalently attached to polyethylene glycol (ADA-PEG) has been the most successful to date, but the treatment requires constant monitoring of ADA levels, frequent injections of ADA-PEG and there is considerable cost involved for the ADA-PEG. Studies using erythrocytes from SCID patients treated with ADA-PEG have shown that as the serum level of ADA increased, there was a corresponding increase in adenosylhomocysteine hydrolase activity and a decrease in dATP levels to essentially zero. Concurrently, there were the reappearances of circulating T and B lymphocytes. Gene therapy presents the hope for the future. There are indications in gene therapy trials that the ADA gene has been successfully transfected into stem cells of ADA-deficient children. There is a second type of SCID not related to adenosine deaminase deficiency. This type of SCID is caused by a mutant form of the gamma C interleukin receptor that blocks the development of T lymphocytes and natural killer cells. Gene therapy to correct this defect was essentially successful in treating the immune dysfunction. However, two of the nine children who had received the gene therapy for this defect, developed a rare form of leukemia. It is believed that the genetic disruptions caused by the retroviral vector used in the gene transfer process led to the leukemia. Gene therapy trials have proceeded with extreme caution following this unexpected problem.

20.6 • URIC ACID IS THE END PRODUCT OF PURINE DEGRADATION IN HUMANS

As shown in Figure 20.12, adenine nucleotides are degraded to hypoxanthine whereas guanine nucleotides are metabolized to xanthine. Hypoxanthine and xanthine are oxidized by xanthine oxidoreductase which has both dehydrogenase and oxidase activities. Xanthine dehydrogenase activity requires NAD as the electron acceptor whereas the oxidase activity utilizes molecular oxygen with the generation of hydrogen peroxide as product. Xanthine oxidoreductase, which contains FAD, Fe, and Mo, can exist in either the dehydrogenase or oxidase form. Uric acid is the unique end product of purine nucleotide degradation in man. The reactions are shown in Figure 20.13.

Since uric acid is not very soluble in aqueous medium, in gout (see Clin. Corr. 20.2, p. 811) there are elevated levels of uric acid that can result in deposition of sodium urate crystals primarily in joints. Hyperuricemia is a clinical condition characterized by excess levels of uric acid in the blood and accompanied by increased levels of uric acid in urine (hyperuricuria). Since uric acid is the unique end product of purine degradation in

CLINICAL CORRELATION 20.6

Tumor Lysis Syndrome (TLS)

Cancer patients with large tumor burdens who undergo radiation therapy or chemotherapy treatments also show increased serum and urine concentrations of uric acid. The source of this increased uric acid is not due to increased purine nucleotide synthesis but rather from the destruction of the tumor cells by radiation or cytoxic drugs that in turn release degraded nucleic acids and cellular nucleotides that are further metabolized to uric acid by the normal pathway. Many of the cancer treatment protocols include allopurinol as one of the drugs for the sole purpose of limiting the buildup of uric acid in the patients.

Tumor lysis syndrome (TLS) represents a group of metabolic consequences that can result in response to the cancer treatment. Concurrent with the increase in uric acid formation as a result of xanthine oxidase activity, the patients can suffer from hypercalcemia, hyperkalemia, hyperphosphatemia, and acute renal failure. Rasburicase, a recombinant urate oxidase, has been used successfully, especially in children, to treat the hyperuricemia that is associated with TLS. Rasburicase functions to catalyze the degradation of uric acid, to allantoin, which is a more water-soluble product than uric acid and much more readily excreted. Rasburicase, although useful in the treatment of TLS, is contraindicated in patients who have a deficiency in glucose 6-phosphate dehydrogenase (G6PDH). The urate oxidase reaction generates hydrogen peroxide as a product which in the absence G6PDH activity, leads to red cell lysis due to the lack of reduced glutathione in cells. Although the use of uricase has certain pharmacological advantages over allopurinol, it has the disadvantage that it is very expensive and probably not readily available to all.

Recombinant urate oxidase (Rasburicase) for prevention and treatment of tumor lysis syndrome in patients with hematologic malignancies. *Acta Haematol.* 115:35, 2006; and Ribeiro, R. C., and Pui, C. H. Recombinant urate oxidase for prevention of hyperuricemia and tumor lysis syndrome in lymphoid malignancies. *Clin. Lymphoma* 3: 252, 2003.

humans, excess levels of uric acid indicate some metabolic situation which may or may not be serious. There are several instances in which the cause of the hyperuricemia/hyperuricuria can be defined as a metabolic defect related to the overproduction of purine nucleotides and other situations in which there are not defined metabolic alterations (see Clin. Corr. 20.1, p. 810). Cancer patients undergoing chemotherapy or radiation treatment become hyperuricemic due to cellular destruction and the release of uric acid (Clin. Corr. 20.6).

20.7 • METABOLISM OF PYRIMIDINE NUCLEOTIDES

The *de novo* synthesis of the pyrimidine ring in mammalian cells utilizes amino acids as carbon and nitrogen donors in addition to CO_2. **Uridine 5′-monophosphate** (UMP) is synthesized in a metabolic pathway. Energy from ATP hydrolysis (or equivalent) is required to drive several steps in the pathway.

Synthesis of Pyrimidine Nucleotides

In contrast to *de novo* purine nucleotide synthesis, not all enzymes for *de novo* synthesis of pyrimidine nucleotides are cytosolic. Reactions leading to formation of UMP are shown in Figure 20.14. Important aspects of the pathway should be noted. The pyrimidine ring is formed first and then ribose 5-phosphate is added with PRPP as the ribose 5-phosphate donor. The enzyme-catalyzing formation of cytosolic carbamoyl phosphate, carbamoyl phosphate synthetase II (CPS II), is cytosolic and is distinctly different from mitochondrial carbamoyl phosphate synthetase I (CPS I) in mitochondria and which functions as part of the urea cycle. Formation of *N*-carbamoylaspartate is the committed step in pyrimidine nucleotide synthesis but formation of cytosolic carbamoyl phosphate (CPS II) is the regulated step. Formation of orotate from dihydroorotate is catalyzed by mitochondrial **dihydroorotate dehydrogenase (DHODH)**. DHODH is located on the outer surface of the inner mitochondrial membrane. This location is the functional connection between the respiratory electron transport chain

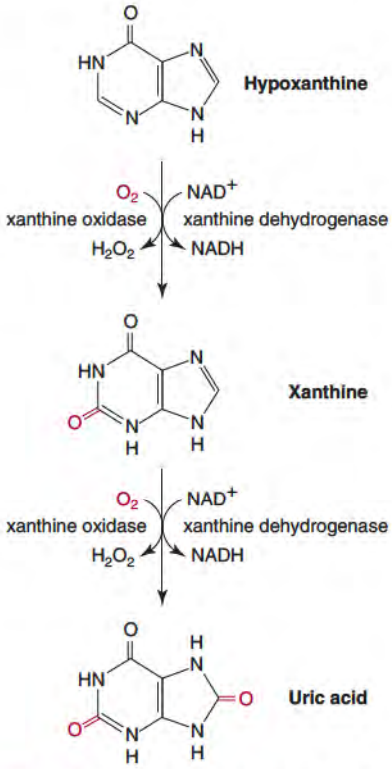

Figure 20.13 Reactions catalyzed by xanthine oxidoreductase (XOR). XOR contains both xanthine dehydrogenase and oxidase activities. The dehydrogenase and oxidase forms of the enzyme are interconvertible.

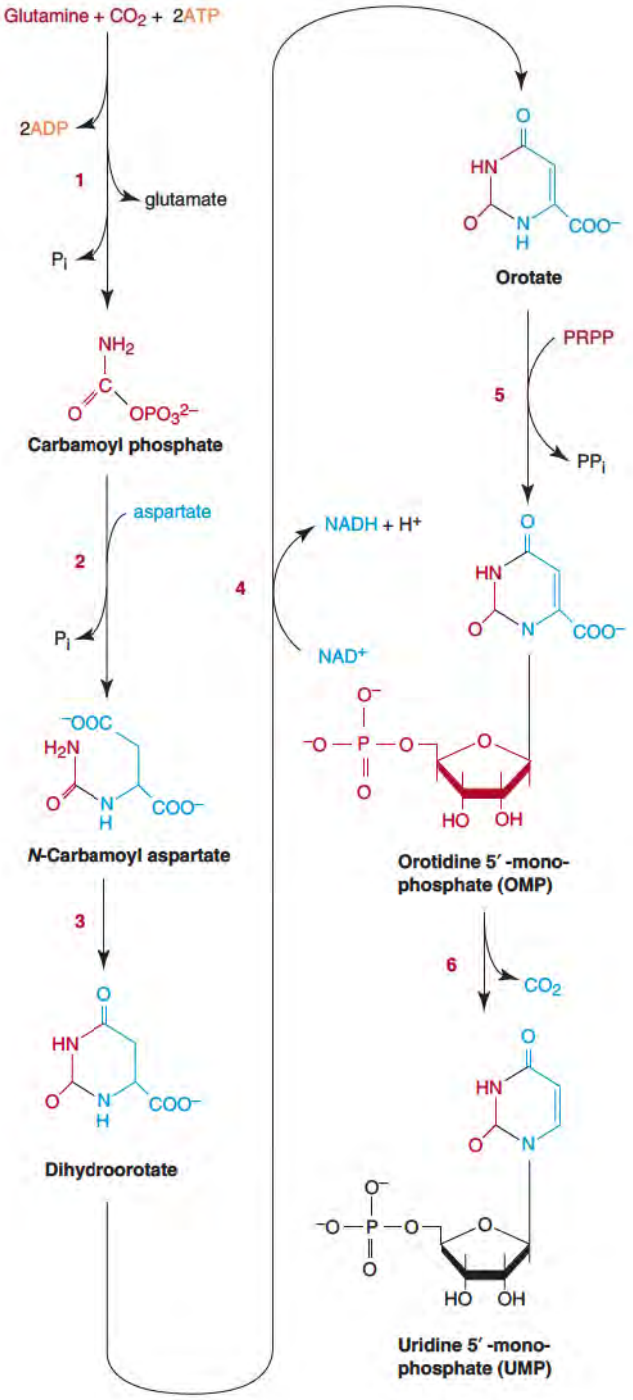

Figure 20.14 *De novo* synthesis of pyrimidine nucleotides. Enzyme activities catalyzing the reactions are (1) carbamoyl phosphate synthetase II, (2) aspartate carbamoyltransferase, (3) dihydroorotase, (4) dihydroorotate dehydrogenase, (5) orotate phosphoribosyltransferase, and (6) OMP decarboxylase. The activities of 1, 2, and 3 are on a trifunctional protein (CAD); the activities of 5 and 6 are on a bifunctional protein (UMP synthase).

through ubiquinone and dihydroorotate metabolism. The relationship of this connection is borne out by the fact that pyrimidine nucleotide synthesis is inhibited under conditions in which mitochondrial respiration is reduced. The other activities of the pathway are found in the cytosol on multifunctional proteins. The activities of CPS II, aspartate carbamoyl transferase and dihydroorotase are found on a trifunctional protein (CAD), whereas orotate phosphoribosyltransferase and OMP decarboxylase activities are found on a bifunctional protein (UMP synthase). A defect in this bifunctional protein that affects either phosphoribosyl transferase activity or decarboxylase activity leads to a rare clinical condition known as hereditary orotic aciduria (Clin. Corr. 20.7). The immunosuppressive drug, leflunomide, which is used in the treatment of rheumatoid arthritis, inhibits *de novo* synthesis of pyrimidine nucleotides specifically at dihydroorotate dehydrogenase.

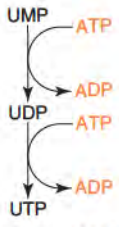

Figure 20.15 Formation of UTP from UMP.

Nucleotide kinases convert UMP to UTP (Figure 20.15). UTP is the direct substrate for CTP synthetase. CTP synthetase catalyzes formation of CTP from UTP with glutamine

CLINICAL CORRELATION 20.7

Hereditary Orotic Aciduria

Hereditary orotic aciduria (OMIM 258900) results from a defect in *de novo* synthesis of pyrimidine nucleotides. This genetic disease is characterized by severe anemia, growth retardation, and high levels of orotic acid excretion. The biochemical basis for orotic aciduria is a defect in one or both of the activities (orotate phosphoribosyl transferase or orotidine decarboxylase) associated with UMP synthase, the bifunctional protein. It is a very rare disease, but the understanding of the metabolic basis for this disease has led to successful treatment of the disorder. Patients are fed uridine, which leads not only to reversal of the anemia but also to decreased formation of orotic acid. Uridine taken up by cells is salvaged by uridine phosphotransferase to UMP that is sequentially converted to UDP and then to UTP. UTP formed from exogenous uridine in turn inhibits carbamoyl phosphate synthetase II, the major regulated step in the *de novo* pathway. As a result, orotic acid synthesis via the *de novo* pathway is markedly decreased to essentially normal levels. Since UTP is also the substrate for CTP synthesis, uridine treatment serves to replenish both the UTP and CTP cellular pools. In effect, then, exogenous uridine bypasses the defective UMP synthase and supplies cells with UTP and CTP required for nucleic acid synthesis and other cellular functions. The success of treatment of hereditary orotic aciduria with uridine provides *in vivo* data that show the importance of the step catalyzed by carbamoyl phosphate synthase II as the site of regulation of pyrimidine nucleotide synthesis in humans.

Suchi, M., Mizuno, H., Kawai, Y., Tonboi, T., et al. Molecular cloning of the human UMP synthase gene and characterization of a point mutation in two hereditary orotic aciduria families. *Am. J. Hum. Genet.* 60: 525, 1997; Webster, D. R., Becroft, D. M. O., van Gennip, A. H., and Van Kuilenburg, A. B. P. Hereditary orotic aciduria and other disorders of pyrimidine metabolism. In Scriver, C. R., Beaudet, A. L., Sly, W. S. and Valle, D.(Eds.), *The Metabolic and Molecular Bases of Inherited Disease*, 8th ed. New York: McGraw Hill, 2001, vol. 2, Chap. 113, 2663.

as the amino group donor (Figure 20.16). CTP synthetase displays homotropic sigmoidal kinetics with respect to UTP whereas CTP, the product, is a negative effector of the reaction as shown in Figure 20.17. The regulation of CTP synthetase in this way is critical as it allows cells to maintain an appropriate ratio of UTP and CTP for cellular functions and RNA synthesis.

To summarize, *de novo* synthesis of pyrimidine nucleotides requires aspartate as a carbon and nitrogen donor, glutamine as a nitrogen donor, and CO_2 as a carbon donor (Figure 20.18). Five of the six reactions in the pathway take place in the cytosol of the cell, whereas the other reaction occurs in mitochondria. The cytosolic enzyme activities reside on multifunctional proteins. UTP is the direct precursor of CTP.

Genetic disorders of pyrimidine nucleotide metabolism as a result of defects in either the synthetic or degradative pathways that lead to clinical disorders indicate that the substrate or product is critical for normal cellular function. Interestingly, these defects present in a variety of clinical situations, ranging from anemia to neurological conditions.

Pyrimidine Nucleotide Synthesis Is Regulated at the Level of Carbamoyl Phosphate Synthetase II

Regulation of pyrimidine nucleotide synthesis in mammalian cells occurs at the carbamoyl phosphate synthetase II step. CPS II is a cytosolic enzyme and is distinct from mitochondrial CPS I, which utilizes ammonia as the amino donor instead of glutamine and which requires activation by *N*-acetyl glutamate. CPS II is inhibited by UTP, an end product of the pathway and is activated by PRPP. The K_i for UTP (at CPSII) and the K_a for PRPP (at CPSII) are in the range of values that would allow intracellular levels of UTP and PRPP to have an effect on the control of pyrimidine nucleotide synthesis. CPS II is the only source of carbamoyl phosphate in extrahepatic tissues. However, in liver, under stressed conditions in which there is excess ammonia, CPS I generates carbamoyl phosphate in mitochondria, which moves into the cytosol and serves as a substrate for orotic acid synthesis. This pathway serves to detoxify excess ammonia. Elevated levels of orotic acid are excreted during ammonia toxicity in humans. This points to carbamoyl phosphate synthetase II as being the major regulated activity of pyrimidine nucleotide metabolism. However, the lack of sufficient PRPP leads to the accumulation of orotic acid rather than to excess pyrimidine nucleotide synthesis.

UMP does not inhibit carbamoyl phosphate synthetase II but competes with OMP to inhibit OMP decarboxylase (Figure 20.19). As discussed earlier, conversion of UTP to CTP is also regulated so that cells maintain a balance between uridine and cytidine nucleotides in the cell.

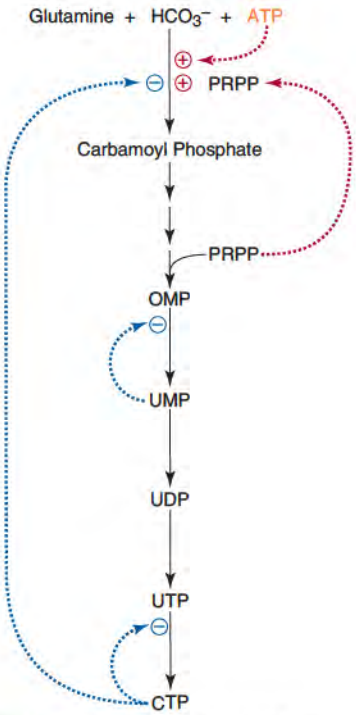

Figure 20.19 Regulation of pyrimidine nucleotide synthesis. Solid arrows represent enzyme catalyzed reactions, and dashed arrows inhibition by products of the reactions.

Pyrimidine Bases Are Salvaged to Reform Nucleotides

Pyrimidines are salvaged by conversion to nucleotides by pyrimidine phosphoribosyltransferase. The general reaction is

$$\text{Pyrimidine} + \text{PRPP} \rightleftharpoons \text{pyrimidine nucleoside 5′-monophosphate} + PP_i$$

The enzyme from human erythrocytes utilizes orotate, uracil, and thymine as substrates but not cytosine. These reactions divert the pyrimidine bases from the degradative pathway to nucleotide formation. As a pyrimidine base becomes available to cells, there are competing reactions that will either result in degradation and excretion of the products or reutilization of the bases for nucleotide synthesis. For example, when normal liver is presented with uracil, it is rapidly degraded to β-alanine, whereas in proliferating tumor cells uracil would be converted to UMP. This is the result of the availability of PRPP, enzyme levels and metabolic state of the cells.

20.8 • DEOXYRIBONUCLEOTIDE FORMATION

The concentrations of the 2′-deoxyribonucleoside 5-triphosphates (dNTPs) are extremely low in nonproliferating cells. However, the cellular levels of dNTPs rapidly expand during DNA replication (S phase of the cell cycle) and repair (following DNA damage) due to increased ribonucleotide reductase activity. The relative and absolute concentrations of dNTPs during these times are critical for determining the fidelity of DNA replication and repair. Unbalanced levels of the individual dNTPs can lead to a wide range of genetic disturbances or ultimately cell death.

Deoxyribonucleotides Are Formed by Reduction of Ribonucleoside 5′-Diphosphates

Nucleoside 5′-diphosphate reductase (ribonucleotide reductase) catalyzes the reaction in which ribonucleoside 5′-diphosphates are converted to the corresponding 2′-deoxyribonucleoside 5′-diphosphates. The reaction is controlled by the amount of enzyme present in cells and by a very finely regulated allosteric control mechanism. The reaction is summarized in Figure 20.20.

Mammalian ribonucleotide reductase consists of two nonidentical protein subunits (R1 and R2). The larger subunit (R1) has at least two different effector-binding sites and the smaller subunit (R2) contains a nonheme iron and a stable tyrosyl free radical. The two subunits are encoded by genes on separate chromosomes. The ratios of the mRNAs for these subunits, and consequently the proteins, do not remain constant as cells transit the cell cycle. Recently, a homolog of R2 (referred to as p53R2) was identified. The p53R2 contains a tyrosyl free radical and complements R1 to generate ribonucleotide reductase activity. The exact role of p53R2 has yet to been defined, but there are developing data that indicate that p53R2 is involved in repair of DNA damage and mitochondrial DNA replication. To complete the catalytic cycle, small molecular weight proteins, **thioredoxin** or glutaredoxin, along with NADPH are required to regenerate the free sulfhydryl groups on thioredoxin or glutaredoxin.

The activity of ribonucleotide reductase is under very strict allosteric control. Although reduction of each substrate requires a specific positive effector (nucleoside 5′-triphosphate),

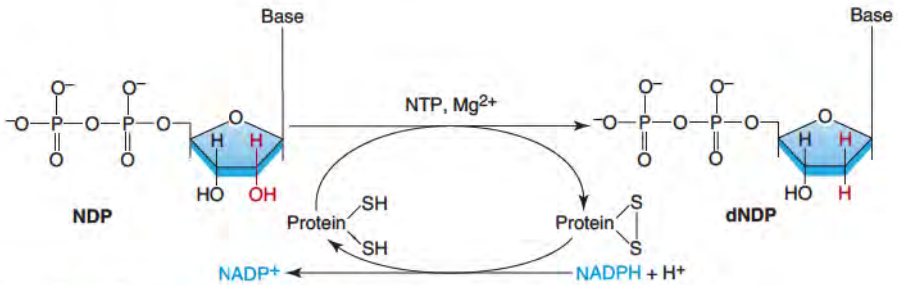

Figure 20.20 *De novo* synthesis of 2′-deoxyribonucleotides from ribonucleotides.

TABLE 20.5 • Nucleoside 5′-Triphosphates as Regulators of Ribonucleotide Reductase Activity

Substrate	*Major Positive Effector*	*Major Negative Effector*
CDP	ATP	dATP, dGTP, dTTP[a]
UDP	ATP	dATP, dGTP, dTTP[a]
ADP	dGTP	dATP
GDP	dTTP	dATP

[a]In decreasing order of effectiveness.

the dNTP products can serve as potent negative effectors of the enzyme. The effects of nucleoside 5′-triphosphates as regulators of ribonucleotide reductase activity are summarized in Table 20.5. 2′-DeoxyATP is a potent inhibitor of the reduction of all four substrates, CDP, UDP, GDP, and ADP; dGTP inhibits reduction of CDP, UDP, and GDP, and dTTP inhibits reduction of CDP, UDP, and ADP. Thus, dGTP and dTTP serve as either positive or negative effectors of ribonucleotide reductase activity depending on the substrate. This means that while dGTP is the required positive activator for ADP reduction, it also serves as an effective inhibitor of CDP and UDP reductions; dTTP is the positive effector of GDP reduction and serves as an inhibitor of CDP and UDP reductions. Effective inhibition of ribonucleotide reductase by dATP, dGTP, or dTTP explains why high concentrations of exogenous 2′-deoxyadenosine, 2′-deoxyguanosine, and thymidine are toxic to a variety of mammalian cells due to the intracellular accumulation of dATP, dGTP, and dTTP.

Ribonucleotide reductase is uniquely responsible for catalyzing the rate-limiting reactions in which 2′-deoxyribonucleoside 5′-triphosphates are synthesized *de novo* from ribonucleoside 5′-diphosphates for DNA replication and repair as summarized in Figure 20.21. Inhibitors of ribonucleotide reductase are potent inhibitors of DNA synthesis and hence, of cell replication.

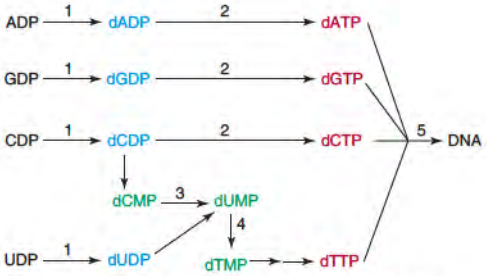

Figure 20.21 Role of ribonucleotide reductase in DNA synthesis. The enzymes catalyzing the reactions are (1) ribonucleotide reductase, (2) nucleoside 5′-diphosphate kinase, (3) deoxycytidylate deaminase, (4) thymidylate synthase, and (5) DNA polymerase.

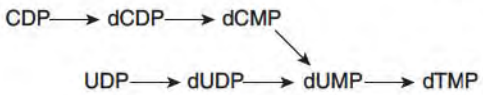
Deoxythymidylate Synthesis Requires N^5, N^{10}-Methylene H_4Folate

2′-Deoxythymidine 5′-monophosphate (dTMP) is formed directly from 2′-deoxyuridine 5′-monophosphate (dUMP) in a unique reaction. **Thymidylate synthase** catalyzes the transfer of a one-carbon unit from N^5, N^{10}-methylene H_4folate (Figure 20.22) to dUMP, which is simultaneously reduced to a methyl group. The reaction is presented in Figure 20.23. In this reaction, N^5, N^{10}-methylene H_4folate serves as a one-carbon donor and as a reducing agent. This is the only reaction in which H_4folate, acting as a one-carbon carrier, is oxidized to H_2folate. There are no known regulatory mechanisms for this reaction.

The substrate for this reaction can come from two different pathways.



In both pathways, dCDP or dUDP, are generated in the reactions catalyzed by ribonucleotide reductase. In one pathway, dUMP is generated from dUDP whereas in the other pathway, dCMP is deaminated to dUMP. Labeling studies indicate that the major pathway for formation of dUMP involves deamination of dCMP by dCMP deaminase, an enzyme that is subject to allosteric regulation by dCTP acting as a positive effector and dTTP acting as a negative effector (Figure 20.24). This regulation of dCMP deaminase by dCTP and dTTP allows cells to maintain the correct ratio of dCTP and dTTP for DNA synthesis.

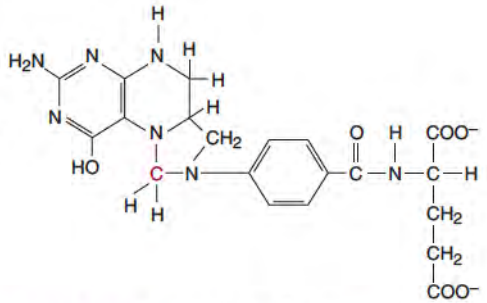


Figure 20.22 Structure of N^5,N^{10}-methylene H_4folate.

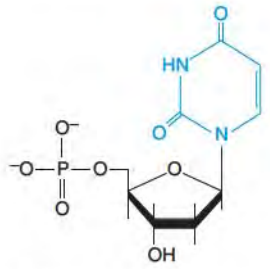
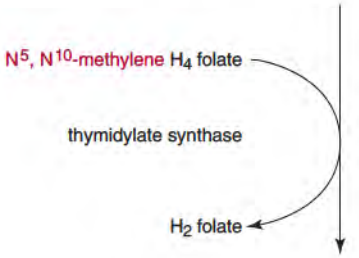
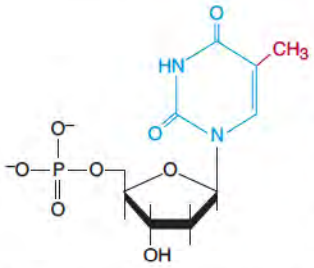
Pyrimidine Interconversions: Deoxyribopyrimidine Nucleosides and Nucleotides

Metabolic pathways for interconversions of AMP and GMP (see Figure 20.10, p. 817) are regulated to maintain appropriate intracellular levels of adenine and guanine nucleotides.



Deoxyuridine 5′-monophosphate (dUMP)





Deoxythymidine 5′-monophosphate (dTMP)

Figure 20.23 **Synthesis of 2′-deoxythymidine monophosphate.**

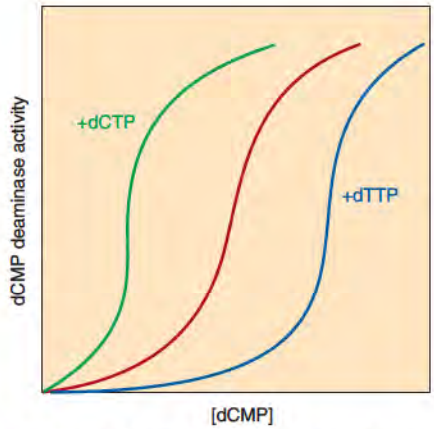


Figure 20.24 **Regulation of dCMP deaminase.**

Pathways also exist for interconversions of pyrimidine nucleotides and are of particular importance for pyrimidine deoxyribonucleosides and deoxyribonucleotides as summarized in Figure 20.25. Note that dCTP and dTTP are major positive and negative effectors of the interconversions and salvage of deoxyribonucleosides. There are specific deoxyribonucleoside kinases in mammalian cells that catalyze the committed step in the formation of 2′-deoxyribonucleoside 5′-monophosphates. These include the kinases for thymidine, deoxyguanosine, and deoxycytidine. The monophosphates are converted to the triphosphates by relatively nonspecific nucleotide kinases. Of clinical importance is the fact that these kinases play an important role in converting exogenous analogs to chemotherapeutic dNTPs as antitumor or antiviral agents.

20.9 • DEGRADATION OF PYRIMIDINE NUCLEOTIDES

Turnover of nucleic acids results in release of pyrimidine and purine nucleotides. Degradation of pyrimidine nucleotides follows the pathways shown in Figure 20.26. Pyrimidine nucleotides are converted to nucleosides by nonspecific phosphatases. Cytidine and 2′-deoxycytidine are deaminated to uridine and 2′-deoxyuridine, respectively, by pyrimidine nucleoside deaminase. Uridine phosphorylase catalyzes phosphorolysis of uridine, deoxyuridine, and deoxythymidine to uracil and thymine.

Uracil and thymine are degraded further by analogous reactions, although the final products are distinctly different as shown in Figure 20.27. Uracil is degraded to β-alanine, NH_4^+, and CO_2. None of these products is unique to uracil degradation, and consequently the turnover of cytosine or uracil nucleotides from RNA or DNA cannot be estimated from the end products of this pathway. Thymine degradation on the other hand, yields **β-aminoisobutyric acid**, NH_4^+, and CO_2. β-Aminoisobutyric acid is excreted in urine of humans, and it originates exclusively from degradation of thymine from DNA. Thus, its excretion can be used to estimate the turnover of DNA or deoxythymidine nucleotides by measurement of β-aminoisobutyric acid in urine. Increased levels of β-aminoisobutyric acid are excreted in cancer patients undergoing chemotherapy or radiation therapy in which large numbers of cells are killed and DNA is degraded.

Enzymes catalyzing the degradation of uracil and thymine (dihydropyrimidine dehydrogenase, dihydropyrimidinase, and uriedopropionase) do not show a preference for either uracil or thymine as substrates or their reaction products.

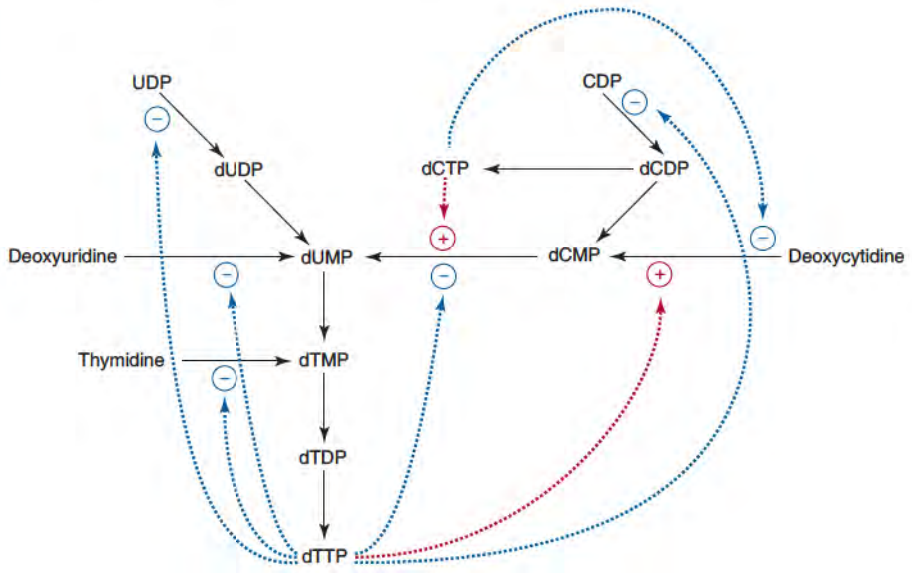

Figure 20.25 **Interconversions of pyrimidine nucleotides with emphasis on deoxyribonucleotide metabolism.** The solid arrows indicate enzyme-catalyzed reactions; the dashed lines represent positions of negative control points.

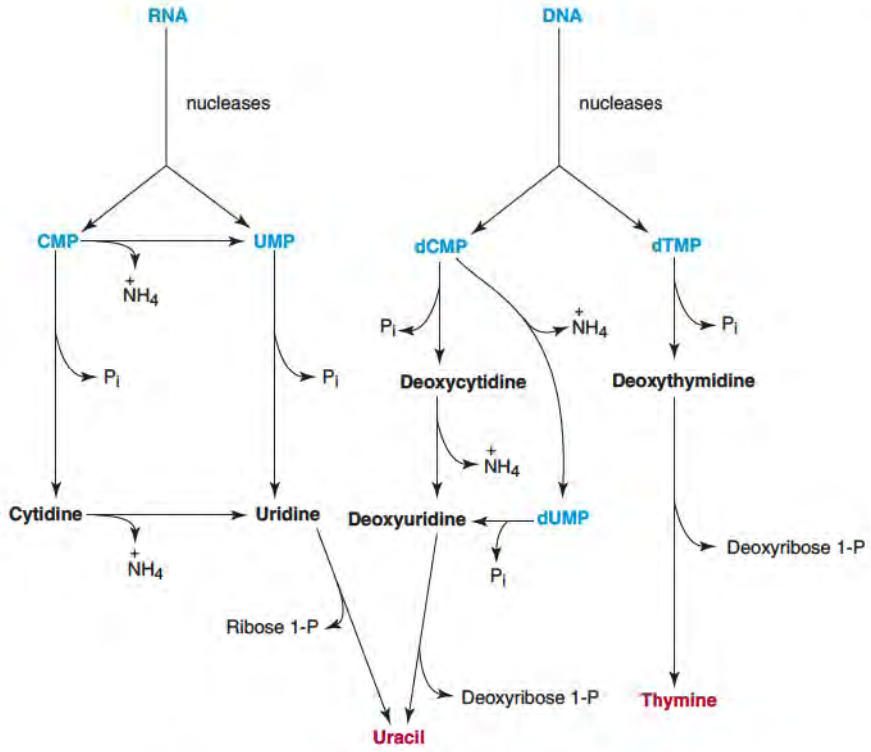

Figure 20.26 **Pathways for degradation of pyrimidine nucleotides.**

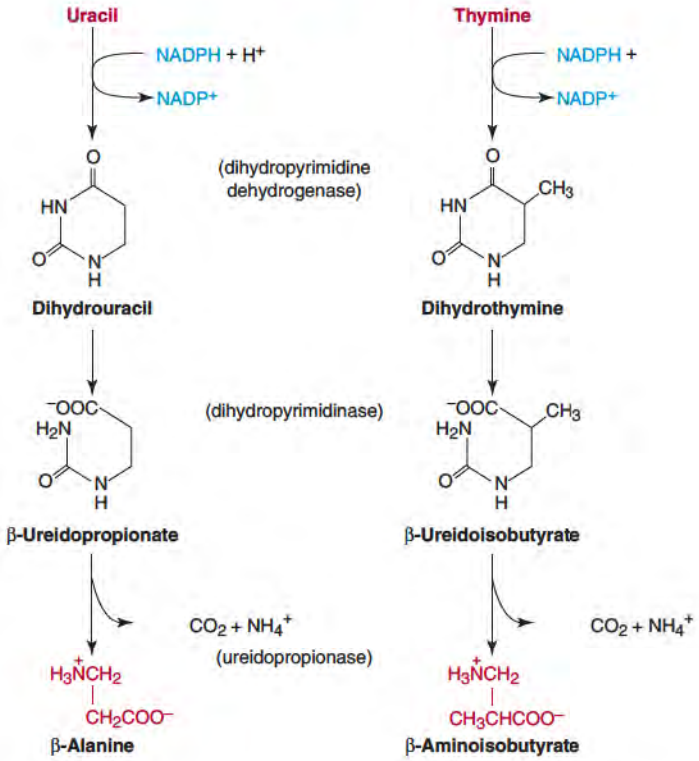

Figure 20.27 **Degradation of uracil and thymine to end products.**

20.10 • NUCLEOSIDE AND NUCLEOTIDE KINASES

De novo synthesis of both purines and pyrimidine nucleotides yields nucleoside monophosphates. Likewise, the salvage of nucleobases by phosphoribosyl transferases or nucleosides by nucleoside kinases also yields nucleoside 5′-monophosphates. This is particularly important in cells such as erythrocytes that cannot form nucleotides *de novo*. Nucleotide kinases convert nucleoside 5′-monophosphates to nucleoside 5′-diphosphates and nucleoside

CLINICAL CORRELATION 20.8

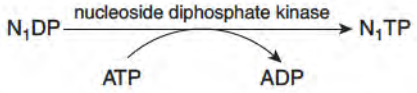
Mitochondrial Neurogastrointestinal Encephalopathy Syndrome (MNGIE)

MNGIE (OMIM 603041) is characterized by external disorders of the eye muscles, gastrointestinal problems, cachexia, and peripheral neuropathy. Multiple mutations have been reported for ECGF1 (platelet-derived Endothelial Growth Factor) gene that has been implicated. It is a progressive disease. Biochemically, the condition arises from a defect in the gene for cytosolic thymidine phosphorylase activity. Thymidine phosphorylase catalyzes the reversible phosphorylsis of dThd or dUrd to thymine or uracil, respectively. Although the reaction is thermodynamically reversible, only the catabolic direction is physiologically relevant because the concentrations of products would not favor the reverse reaction. As a result of decreased thymidine phosphorylase activity, the systemic levels of thymidine and deoxyuridine are greatly increased because they are not further degraded. Consequently, these nucleosides are salvaged and lead to increased dTTP and/or dUTP in mitochondria and are incorporated into mitochondrial DNA during mitochondrial DNA replication. As a result of the abnormal mitochondrial DNA, clinical manifestations are observed but the exact basis for these cannot be explained. This is an interesting case and another example of an effect at the nuclear DNA level that has major consequences on mitochondrial DNA synthesis and cellular function.

Although it is generally accepted that MNGIE is due to the loss of thymidine phosphorylase, it has been questioned whether MNGIE results from the loss of 5′-thymine phosphorylase activity as a result of their studies.

Thymidine and deoxyuridine accumulate in tissues of patients with mitochondrial neurogastrointestinal encephalomyopathy (MNGIE). *FEBS Lett.* 581: 3410, 2007.

5′-diphosphates to nucleoside 5′-triphosphates. These are important reactions since most reactions in which nucleotides function require nucleoside 5′-triphosphates (primarily) or nucleoside 5′-diphosphates. Some of these nucleoside kinases show a high degree of specificity, especially deoxynucleoside kinases (Clin. Corr. 20.8), with respect to the base and sugar moieties while others are much less specific. There is also some substrate specificity with the nucleotide kinases. Mammalian cells contain, in high concentration, nucleoside diphosphate kinase that is relatively nonspecific for either phosphate donor or phosphate acceptor in terms of purine or pyrimidine base or the sugar. This reaction is as follows:



Since ATP is present in the highest concentration in most cells and is most readily regenerated by glycolysis or oxidative phosphorylation, it is probably the major phosphate donor for these reactions.

20.11 • NUCLEOTIDE METABOLIZING ENZYMES AS A FUNCTION OF THE CELL CYCLE

The strict regulation of nucleotide synthesis requires that mechanisms must be available in cells to meet the requirements for ribonucleotide and deoxyribonucleotide precursors at the time of increased RNA synthesis and DNA replication. To meet these needs, cells increase levels of specific enzymes involved with nucleotide formation during very specific periods of the cell cycle (p. 157).

Enzymes involved in purine nucleotide synthesis and interconversions that are elevated during the S phase of the cell include PRPP amidotransferase and IMP dehydrogenase. Enzymes involved in pyrimidine nucleotide synthesis that are elevated during S phase include aspartate carbamoyltransferase, dihydroorotase, dihydroorotate dehydrogenase, orotate phosphoribosyltransferase, and CTP synthetase. Many enzymes involved in synthesis and interconversions of deoxyribonucleotides are also elevated during the S phase. Included in these enzymes are ribonucleotide reductase, thymidine kinase, dCMP deaminase, thymidylate synthase, and dTMP kinase.

The deoxyribonucleotide pool is extremely small (less than 1 μM) in resting cells. As a result of the increase in ribonucleotide reductase activity, concentrations of deoxyribonucleotides reach 10–20 μM during DNA synthesis. However, this concentration would sustain DNA synthesis for only minutes, whereas complete DNA replication requires hours. Consequently, levels of ribonucleotide reductase activity must not only increase but must also be sustained during S-phase order to provide the necessary substrates for DNA synthesis. Pools of dNTPs must also be maintained for DNA repair. There is evidence that ribonucleotide reductase activity also increases in response to DNA damage. Since growing tissues such as regenerating liver, embryonic tissues, and intestinal mucosal cells are geared toward DNA replication and RNA synthesis, these tissues will also show elevated levels of the key enzymes involved with purine and pyrimidine nucleotide synthesis and interconversions with complementary decreases in amount for enzymes that catalyze reactions in which these precursors are degraded. These changes in enzyme levels actually reflect the proportion of the cells that are in S-phase in that tissue.

20.12 • NUCLEOTIDE COENZYME SYNTHESIS

The nucleotide coenzymes NAD and FAD, and coenzyme A have common features in that they each have a vitamin moiety as part of their structure and AMP is part of the structure although not directly involved in the reaction in which each of these functions. The structure and synthesis of NAD and the pathway of its synthesis in mammalian cells is presented in Figure 20.28.

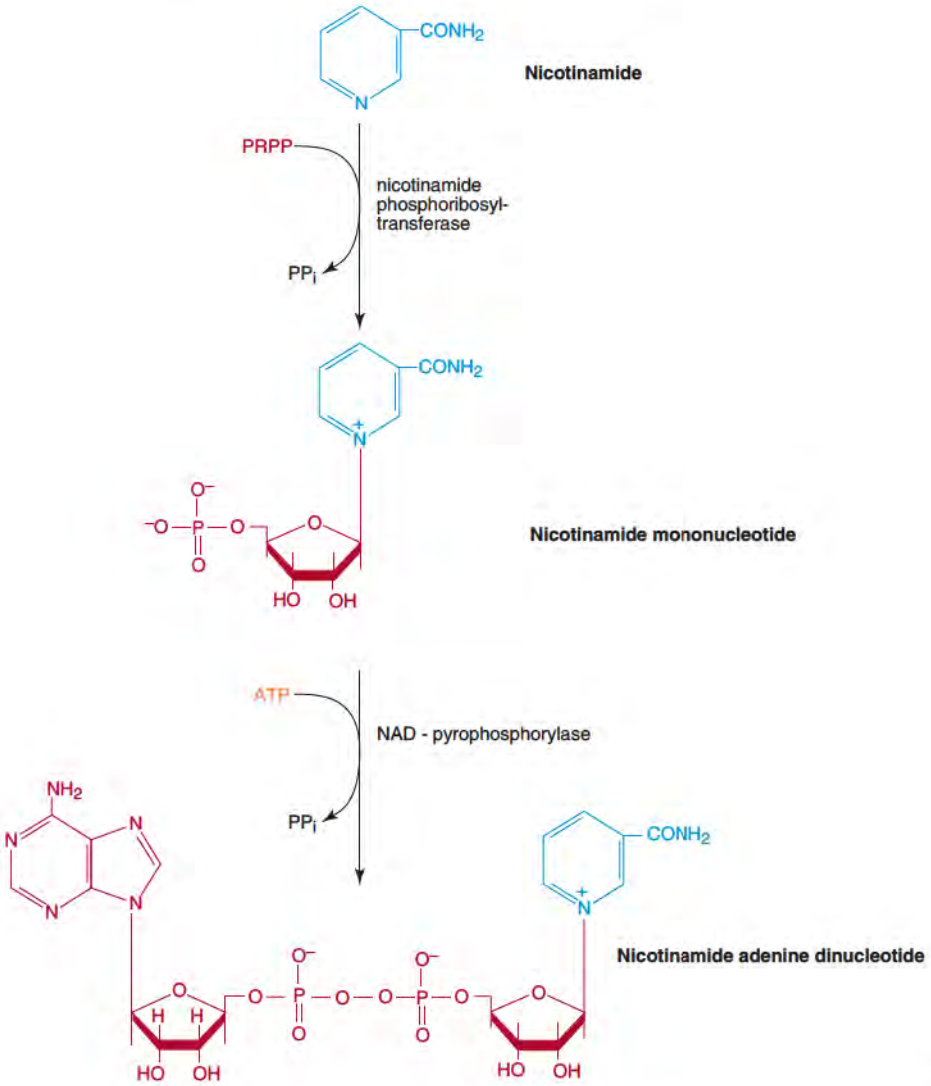


Figure 20.28 **Pathway for nicotinamide adenine nucleotide synthesis.**

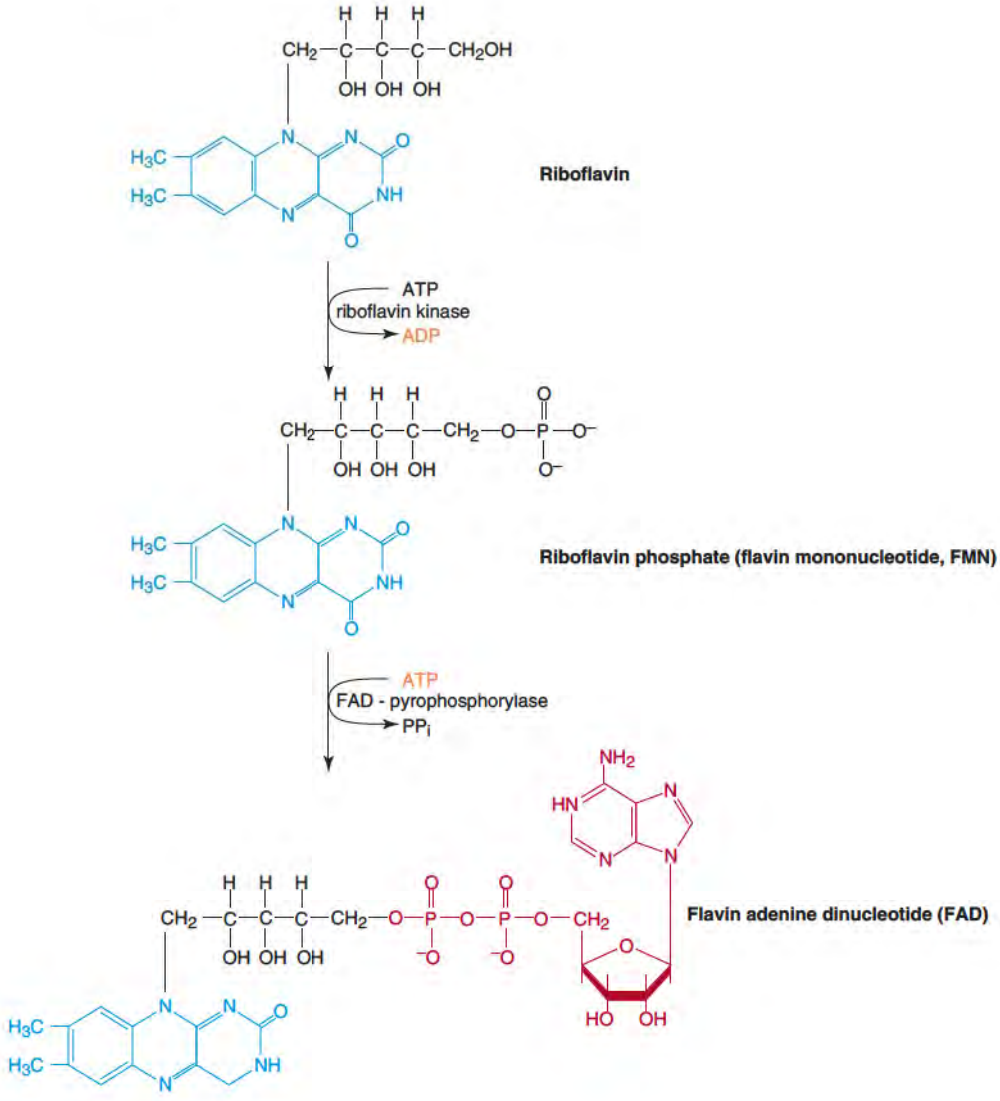

Figure 20.29 **Synthesis of flavin adenine dinucleotide.**

NAD synthesis requires niacin. NAD can be synthesized by three different pathways starting with tryptophan, nicotinamide, or nicotinic acid, respectively. When tryptophan is in excess of the amount required for protein or serotonin synthesis, it can be used for NAD synthesis. This is not a likely situation for most individuals and therefore niacin is required in the diet.

Synthesis of NAD by any of the pathways requires PRPP as the ribose 5-phosphate donor. Nicotinamide adenine dinucleotide (NADP) is synthesized by the phosphorylation of NAD. NAD, NADH, NADP, and NADPH have specific roles in cellular metabolism with respect to energy production. In these roles, they are involved in reversible oxidation–reduction reactions. However, there are important pathways in which NAD serves as a substrate and is consumed in the reaction. These pathways include ADP-ribose transferases (poly ADP polymerases [PARPs]), ADP ribose synthases, and sirtuins (type III protein lysine deacetylases). NAD utilization through these pathways is linked to processes that control gene expression, calcium mobilization, neuroprotection, death, and aging.

The structures of FMN and FAD are presented in Figure 20.29. They have the vitamin riboflavin as part of their structures. FAD and FMN have important roles in reversible oxidation–reduction reactions. Depending on the reaction and/or enzyme in which it participates, the flavin nucleotides can serve as either a coenzyme in enzyme-catalyzed reactions or as prosthetic groups in proteins.

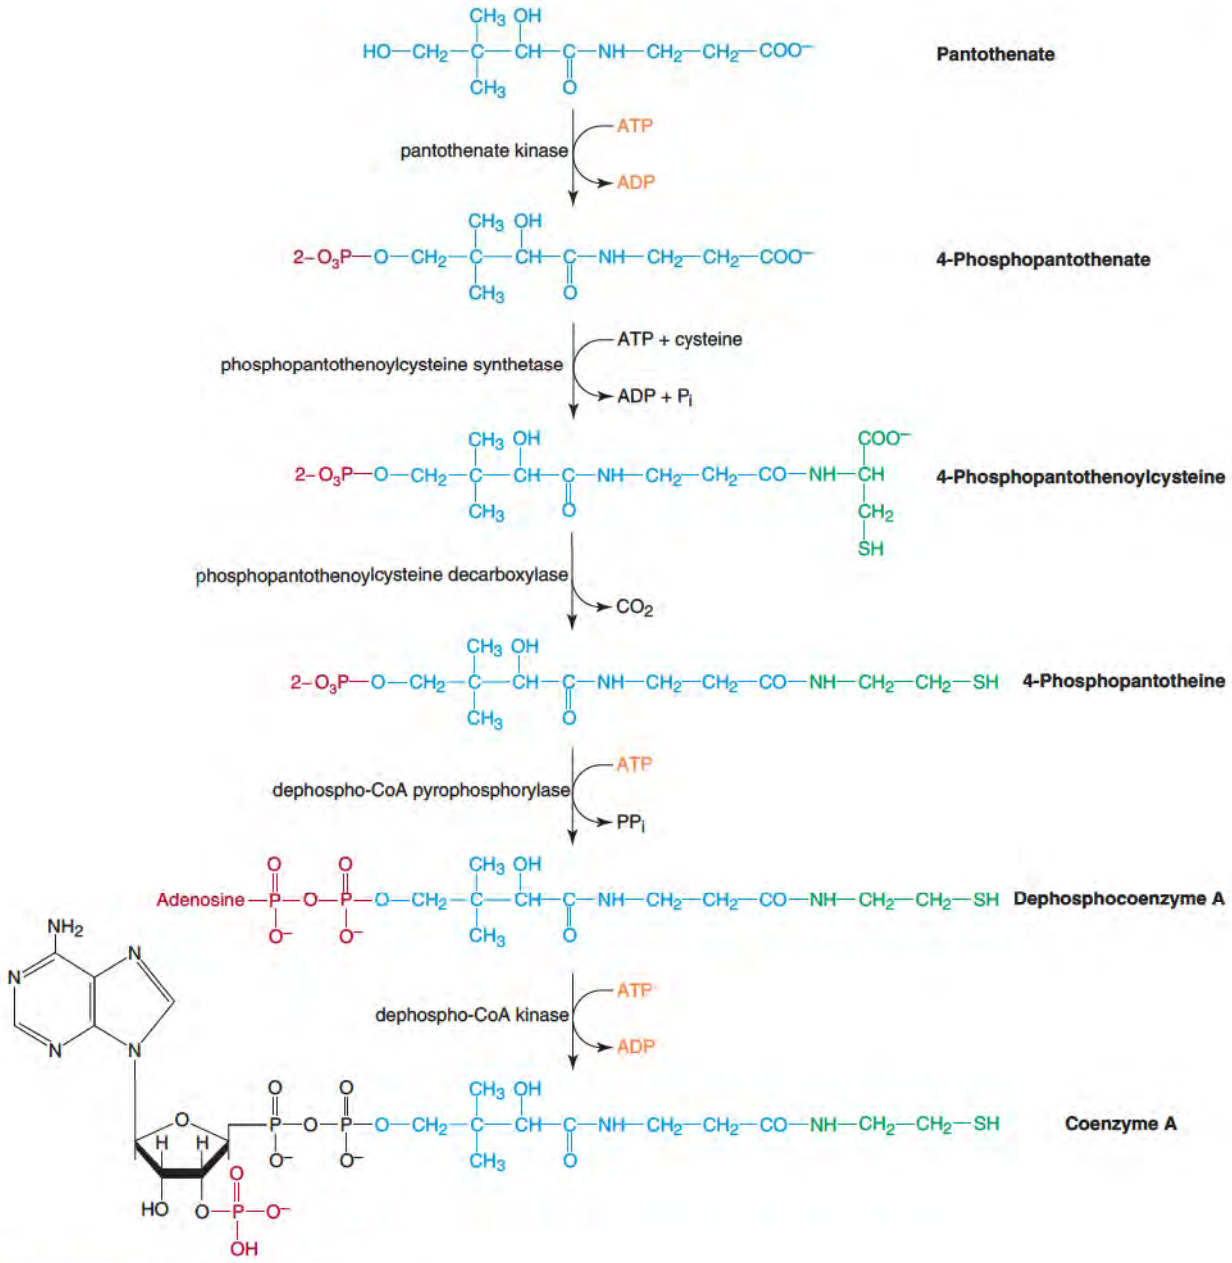

Figure 20.30 **Synthesis of coenzyme A.**

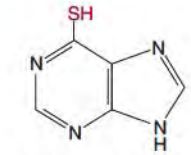
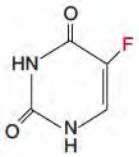
The pathway of synthesis and structure of pantothenic acid are presented in Figure 20.30. This coenzyme is easily recognized for its central and critical role in intermediary metabolism as a component of acetyl CoA. However, acetyl CoA also serves an important function in the acetylation of the amino termini of proteins and the ε amino groups of lysine in proteins. These posttranslational modifications serve to alter the biological properties of these modified proteins and play important roles in cellular function.

20.13 • CHEMOTHERAPEUTIC AGENTS THAT INTERFERE WITH PURINE AND PYRIMIDINE NUCLEOTIDE METABOLISM

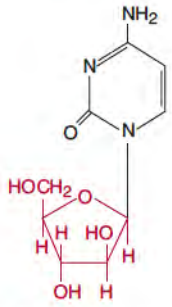
De novo synthesis of purine and pyrimidine nucleotides is critical for normal cell replication, maintenance, and function. Regulation of these pathways is important since disease states have been identified that arise from defects in the regulatory enzymes. Synthetic



6-Mercaptopurine



5-Fluorouracil



Cytosine arabinoside

Figure 20.31 Structures of antimetabolites: 6-mercaptopurine, 5-fluorouracil, and cytosine arabinoside.

compounds and natural products from plants, bacteria, or fungi that are structural analogs of the nucleobases or nucleosides used in metabolic reactions have been shown to be cytotoxic. These compounds are relatively specific inhibitors of enzymes involved in nucleotide synthesis or interconversions and have proven to be useful in therapy of diverse clinical problems. They are generally classified as antimetabolites, antifolates, glutamine antagonists. and other agents.

Inhibitors of Purine and Pyrimidine Nucleotide Metabolism

Antimetabolites Are Structural Analogs of Bases or Nucleosides

Antimetabolites are usually structural analogs of purine and pyrimidine bases or nucleosides that interfere with very specific metabolic reactions. They include 6-mercaptopurine and **6-thioguanine** used in the treatment of acute leukemia, azathioprine for immunosuppression in patients with organ transplants, allopurinol for treatment of hyperuricemia, and acyclovir for treatment of herpesvirus infection. The detailed understanding of purine nucleotide metabolism aided in the development of these compounds as drugs. Conversely, study of the mechanism of action of these drugs has led to a better understanding of normal nucleotide metabolism in humans.

Three antimetabolites will be specifically discussed to show (1) the importance of *de novo* synthetic pathways in normal cell metabolism, (2) that regulation of these pathways occurs *in vivo,* (3) the requirement for metabolic activation of the drugs utilizing the cellular salvage enzymes, and (4) that inactivation of these compounds greatly influences their usefulness.

6-Mercaptopurine (6-MP) (Figure 20.31) is a useful antitumor drug in humans. Its cytotoxic activity depends on the formation of 6-mercaptopurine ribonucleotide by the tumor cells. Utilizing PRPP and HGPRTase, 6-mercaptopurine ribonucleoside 5′-monophosphate is formed in cells and serves as a negative effector of PRPP-amidotransferase, the committed step in the *de novo* pathway. This nucleotide also acts as an inhibitor of the conversion of IMP to GMP at the IMP-dehydrogenase step and of IMP to AMP at the adenylosuccinate synthetase step. Since 6-mercaptopurine is a substrate for xanthine oxidoreductase and is oxidized to 6-thiouric acid, allopurinol is usually administered to inhibit degradation of 6-MP and to potentiate the antitumor properties of 6-MP.

5-Fluorouracil (Fura) (Figure 20.31) is an analog of uracil. 5-Fluorouracil is not the active species as it must be converted by cellular enzymes to the active metabolites, 5-fluorouridine 5′-triphosphate (FUTP) and 5-fluoro-2′-deoxyuridine 5′-monophosphate (FdUMP). FUTP is efficiently incorporated into RNA and, once incorporated, inhibits maturation of 45 S precursor rRNA into the 28S and 18S RNA species and alters splicing of pre-mRNA into functional mRNA. FdUMP is a potent and specific inhibitor of thymidylate synthase. In the presence of H_4folate, FdUMP and thymidylate synthase, a ternary complex is formed with the covalent binding of FdUMP to thymidylate synthase, which results in irreversible inhibition of thymidylate synthase. This inhibits dTMP synthesis and leads to "thymineless death" for cells.

Cytosine arabinoside (AraC) (Figure 20.31) is used in treatment of several forms of human cancer. It must be metabolized by cellular enzymes to cytosine arabinoside 5′-triphosphate (araCTP) to exert its cytotoxic effects. AraCTP competes with dCTP in the DNA polymerase reaction, and araCMP is incorporated into DNA. This inhibits synthesis of the growing DNA strand. Clinically, the efficacy of araC as an antileukemic drug correlates with the concentration of araCTP that is achieved in the leukemic cells; this in turn determines the amount of araCMP incorporated into DNA. Formation of araCMP by deoxycytidine kinase appears to be the rate-limiting step in the activation to araCTP. Ara-C is inactivated by deamination to araU.

Antifolates Inhibit Reactions Involving Tetrahydrofolate

Folate analogs, depending on their specific structure, interfere with metabolic steps in which tetrahydrofolate is involved either as a substrate or product. **Methotrexate (MTX)**, a synthetic structural analog of folic acid, interferes with formation of H_2folate and H_4folate

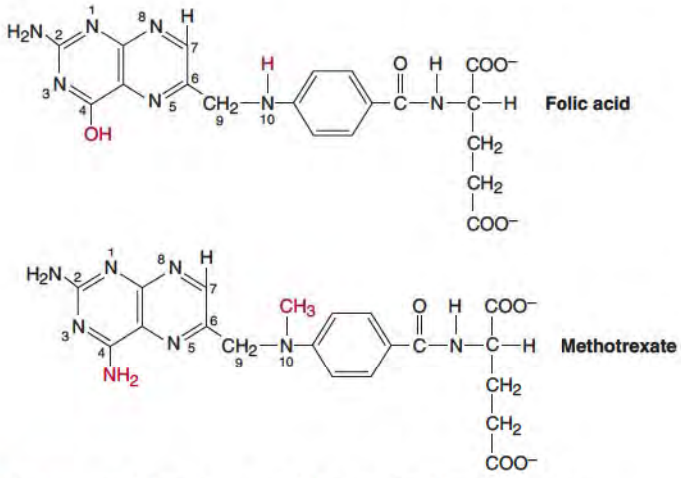


Figure 20.32 Comparison of the structures of folic acid and methotrexate.

from folate by specifically inhibiting H_2folate reductase (DHFR). MTX is used as an antitumor agent in the treatment of human cancers. The structures of folic acid and MTX are compared in Figure 20.32. MTX and folate differ only at C-4 where an amino group replaces a hydroxyl group and at N-10 where a methyl group replaces a hydrogen atom. MTX specifically inhibits H_2folate reductase with a K_i in the range of 0.1 nM. The reactions inhibited by MTX are shown in Figure 20.33.

MTX at very low concentrations is cytotoxic to mammalian cells in culture. The inhibition of dihydrofolate reductase by MTX results in lowering the intracellular pools of both ribonucleoside 5′-triphosphates and 2′-deoxyribonucleoside 5′-triphosphates. The effects can be prevented, at least partially, by addition of deoxythymidine and hypoxanthine to the culture medium. Reversal of the MTX effects by thymidine and hypoxanthine indicates that MTX causes depletion of both deoxythymidine and purine nucleotides in cells. Figure 20.34 shows the relationship between H_4-folate, *de novo* purine nucleotide synthesis, and dTMP formation. Note that in the thymidylate synthase reaction, H_2-folate is generated. Unless it were readily reduced back to H_4folate via dihydrofolate reductase, cells would not be capable of *de novo* synthesis of purine nucleotides or thymidylate synthesis due to depletion of H_4 folate pools.

In treatment of human leukemias, normal cells can be rescued from the toxic effects of high-dose MTX by N^5-formyl-H_4 folate (leucovorin). This increases the clinical efficacy of MTX in the treatment of cancer. MTX is also being successfully used at very low doses in the treatment of rheumatoid arthritis (RA) although the molecular basis by which MTX acts in this disorder is not known. It is not clear that the effects of MTX treatment in RA are related to its effects on nucleotide metabolism. However, it is interesting to note that leflunomide, another drug being used to treat RA, has as one of its defined sites of action the inhibition of mitochondrial dihydroorotate dehydrogenase.

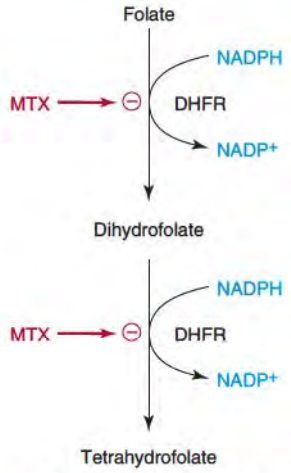

Figure 20.33 Sites of inhibition by methotrexate.

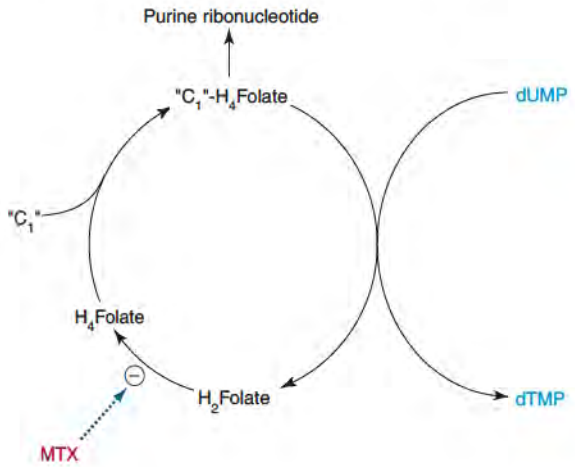

Figure 20.34 Relationship between H_4folate, *de novo* purine nucleotide synthesis, and dTMP synthesis.

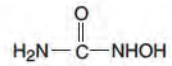
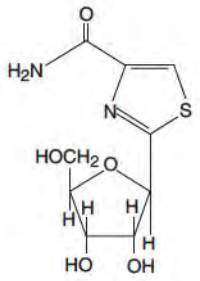


Hydroxyurea



Tiazofurin

Figure 20.35 **Structures of hydroxyurea and tiazofurin.**

Newer antifolates have been synthesized that are relatively specific inhibitors of either thymidylate synthase or *de novo* purine nucleotide synthesis, but not both. These compounds are in clinical trials for the treatment of cancer.

Glutamine Antagonists Inhibit Enzymes That Utilize Glutamine as Nitrogen Donor

Many reactions in mammalian cells require glutamine as the amino group donor. In contrast, bacteria primarily utilize ammonia as the amino donor in a similar reaction. These amidation reactions are critical in *de novo* synthesis of purine nucleotide (N-3 and N-9), synthesis of GMP from IMP, formation of cytosolic carbamoyl phosphate, synthesis of CTP from UTP (see Table 20.3, p. 810), and synthesis of NAD^+.

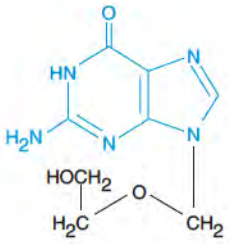
Compounds that inhibit these reactions are referred to as glutamine antagonists. **Azaserine** and **DON** (diazo-5-oxo-L-norleucine), which were first isolated from cultures of *Streptomyces,* are very effective inhibitors of enzymes that utilize glutamine as the amino donor. Since azaserine and DON inactivate many of the glutamine-dependent enzymes involved in nucleotide metabolism, these compounds proved to be too toxic for use clinically as antitumor agents.

Other Agents That Inhibit Cell Growth by Interfering with Nucleotide Metabolism

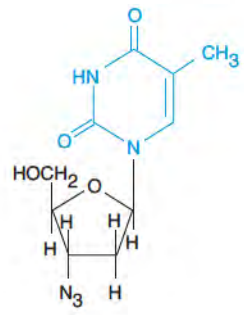
Tumor cells treated with hydroxyurea (Figure 20.35) show specific inhibition of DNA synthesis with little or no inhibition of RNA or protein synthesis. Hydroxyurea inhibits ribonucleotide reductase activity by destroying the tyrosyl free radical on the small subunit of ribonucleotide reductase (R2). This results in the inhibition of the reductions of CDP, UDP, GDP, and ADP to the corresponding 2′-deoxyribonucleoside 5′-diphosphates. Toxiciy to cells results from depletion of 2′-deoxyribonucleoside 5′-triphosphates that are required for DNA replication. Clinical use of hydroxyurea as an antitumor agent is limited because of its rapid rate of clearance and the high drug concentration required for effective inhibition. However, hydroxyurea has recently been utilized in the treatment of sickle-cell anemia in both adults and children. By a mechanism not completely understood, hydroxyurea treatment of sickle cell patients results in the re-expression of the fetal (γ) hemoglobin gene resulting in the increased fetal hemoglobin in the red cells. The increased concentration of fetal hemoglobin in the red cells decreases HbS precipitation and, as a result, decreases the frequency of sickle cell crises in the patients during hypoxia. It does not appear that the effect of hydroxyurea on sickle-cell erythrocytes is directly related to inhibition of ribonucleotide reductase.

Tiazofurin (Figure 20.35) is not an active drug, but must be converted by cellular enzymes to the NAD^+ analog, tiazofurin adenine dinucleotide (TAD), which is the active agent. TAD inhibits IMP dehydrogenase, the rate-limiting enzyme in GTP synthesis, with a K_I of 0.1 μM. As a result of IMP dehydrogenase inhibition, the concentration of GTP is markedly depressed with a corresponding decrease in dGTP. Although there are many dehydrogenases that utilize NAD^+ as a substrate, IMP dehydrogenase is most affected, possibly because it catalyzes a rate-limiting step in a critical pathway and is quantitatively limiting in concentration.

These clinically useful drugs serve as examples in which the knowledge of basic biochemical pathways and mechanisms lead to generation of effective drugs.



Acycloguanosine



AZT

Figure 20.36 **Structures of the antiviral agents, acyclovir and AZT.**

Purine and Pyrimidine Analogs as Antiviral Agents

Infections caused by herpes virus (HSV) and the human immunodefciency virus (HIV) infections, present major clinical problems. Two antimetabolites used in the control or treatment (but not cure) of HSV and HIV infections are Acyclovir (acycloguanosine), a purine analog, and 3′-azido-3′-deoxythymidine (AZT), a pyrimidine analog (Figure 20.36). Both drugs must be phosphorylated to yield the active drug. Acycloguanosine is converted to the monophosphate by a specific HSV-thymidine kinase (encoded by the HSV genome), which is present only in the virally infected cells. The host cellular thymidine kinases cannot utilize acyclovir as a substrate. Acycloguanosine monophosphate is then phosphorylated by the cellular enzymes to the di- and triphosphate forms. Acycloguanosine triphosphate serves as a substrate for the HSV-specific DNA polymerase and is incorporated into the growing

viral DNA chain. This causes chain termination. The specificity of acycloguanosine and its high therapeutic index result from the fact that only HSV-infected cells can form the acycloguanosine monophosphate. Unfortunately, resistant strains of HSV have evolved.

AZT is phosphorylated by cellular kinases to AZT-triphosphate, which blocks HIV replication by inhibiting HIV-DNA polymerase (an RNA-dependent polymerase). The selectivity of AZT for HIV-infected versus normal cells occurs because DNA polymerase from HIV is at least 100-fold more sensitive to AZT-triphosphate than is host cell DNA-dependent DNA polymerase. Resistance to AZT has been observed.

These two antiviral agents demonstrate the diversity of responses required for selectivity. In one case, enzyme activity encoded specifically by the viral genome is mandatory for activation of the drug (acycloguanosine); in the second example, although cellular enzymes activate AZT, the viral gene product (HIV-DNA polymerase) is the selective target.

Biochemical Basis for Responses to Chemotherapeutic Agents

There are two aspects to consider with respect to a patient's response to cancer chemotherapy. In the first case there is the development of, or selection of, drug-resistant populations as a result of the drug treatment. In the second case preexisting genetic polymorphisms cause altered drug metabolism such that at the standard dose, the patient shows increased or even severe toxicity to the chemotherapeutic drug or even a reduced response to the drug.

Failure of chemotherapy in treatment of human cancer is often related to development of, or selection of, tumor cell populations that are resistant to the cytotoxic effects of the particular drug. Tumors contain very heterogenous populations of cells and in many instances drug-resistant cells are already present. On therapy, drug-sensitive cells are killed off and resistant cell populations become enriched. In some cases, drug treatments produce genetic alterations that result in the drug-resistant phenotype. Resistance to drugs can be categorized as *specific drug resistance* or *multidrug resistance.*

Biochemical and molecular mechanisms that account for drug resistance have been determined for many drugs. For example, resistance to methotrexate can develop because of several different alterations. These include (1) a defect in or loss of the transporter for N^5-formyl-H_4folate and N^5-methyl-H_4folate that results in decreased cellular uptake of MTX; (2) amplification of the dihydrofolate reductase gene that results in large increases in the amount of dihydrofolate reductase, the target enzyme; (3) alterations in the dihydrofolate reductase gene that result in a mutant dihydrofolate reductase that is less sensitive to inhibition by MTX; and (4) decreased levels of folylpolyglutamate synthetase, which results in lower levels of polyglutamylated MTX, the trapped form of MTX. MTX-resistant populations could have any one or a combination of these alterations. The net result of any of these resistance mechanisms is to decrease the ability of MTX to inhibit dihydrofolate reductase at clinically achievable MTX concentrations. Other specific drug resistance mechanisms could be described for compounds such as cytosine arabinoside, 5-fluorouracil, hydroxyurea, and other drugs.

In multiple drug resistance (MDR), drug-resistant cells are cross-resistant to a variety of seemingly unrelated antitumor agents, such as the vinca alkaloids, adriamycin, actinomycin D, and etoposide. All of these are natural products or are derived from natural products and they are not chemically related in structure. They have different mechanisms of action as antitumor agents but appear to act on some nuclear event.

Multidrug-resistant tumor cells express high levels (compared to the drug-sensitive tumor cells) of membrane transport proteins (P-glycoproteins and multidrug resistance-associated proteins [MRPs], p. 494) that transport drugs out of the cell. These are ATP-dependent pumps and effectively reduce the cellular concentration of drug to below its cytotoxic concentration.

Development of drug-resistant tumor cells presents major clinical problems. However, study of the mechanisms of drug resistance has greatly aided in our understanding of cancer cells and how best to design chemotherapeutic protocols to treat the various forms of cancer.

Many different examples can be given in which genetic polymorphisms play a large role in the metabolism or disposition of various classes of drugs involving distinct gene products. As a result, there will be variability in the responses of patients to a specific drug regimen. As

one example, patients who inherit nonfunctional alleles for thiopurine *S*-methyltransferase (TPMT), an enzyme involved in the metabolism of 6-mercaptopurine (see Figure 20.31, p. 832) have very adverse effects to the standard dose of 6-mercaptopurine. These patients can be successfully treated by reducing the conventional dose of 6-MP and still achieve the necessary clinical response with decreased morbidity. Pharmacogenomics, a relatively new field that is rapidly developing, will allow the identification of many additional candidate genes such as MDR1 with the use of molecular techniques that will allow the physician to move toward personalized medicine so that drug doses for patients can be optimized before therapy has begun rather than later in the course of treatment. The use of pharmcogenomics will apply not only for the defined treatment of cancer but also for many other diseases as well.

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. The two purine nucleotides found in RNA
   - **A.** are formed in a branched pathway from a common intermediate.
   - **B.** are formed in a sequential pathway.
   - **C.** must come from exogenous sources.
   - **D.** are formed by oxidation of the deoxy forms.
   - **E.** are synthesized from nonpurine precursors by totally separate pathways.

2. The type of enzyme known as a phosphoribosyltransferase is involved in all of the following except
   - **A.** salvage of pyrimidine bases.
   - **B.** the *de novo* synthesis of pyrimidine nucleotides.
   - **C.** the *de novo* synthesis of purine nucleotides.
   - **D.** salvage of purine bases.

3. Deoxyribonucleotides
- **A.** cannot be synthesized so they must be supplied preformed in the diet.
- **B.** are synthesized *de novo* using PRPP.
- **C.** are synthesized from ribonucleotides by an enzyme system involving thioredoxin.
- **D.** are synthesized from ribonucleotides by nucleotide kinases.
- **E.** can be formed only by salvaging free bases.

4. The conversion of nucleoside 5′-monophosphates to nucleoside 5'-triphosphates
- **A.** is catalyzed by nucleoside kinases.
- **B.** is a direct equilibrium reaction.
- **C.** utilizes a relatively specific nucleotide kinase and a relatively nonspecific nucleoside diphosphate kinase.
- **D.** generally uses GTP as a phosphate donor.
- **E.** occurs only during the S phase of the cell cycle.

5. The synthesis of the coenzymes NAD, FAD, and coenzyme A have in common
- **A.** the same vitamin.
- **B.** PRPP.
- **C.** AMP.
- **D.** ATP.
- **E.** a nucleotidase.

6. Tetrahydrobiopterin
- **A.** is synthesized from GTP.
- **B.** is an inhibitor of IMP dehydrogenase.
- **C.** is synthesized from ATP.
- **D.** is a degradation product of guanine.
- **E.** requires the addition of glutamine to a purine nucleotide.

Questions 7 and 8: Hereditary orotic aciduria is characterized by severe anemia, growth retardation, and high levels of orotic acid excretion. The defect may be in orotate phosphoribosyl transferase, orotidine decarboxylase, or both. The preferred treatment for this disease is dietary uridine, which reverses the anemia and decreases the formation of orotic acid.

7. Elements involved in the effectiveness of the dietary treatment include
- **A.** conversion of exogenous uridine to UMP by uridine phosphotransferase.
- **B.** UTP from exogenous uridine providing substrate for synthesis of CTP.
- **C.** inhibition of carbamoyl phosphate synthetase II by UTP.
- **D.** all of the above.
- **E.** none of the above.

8. In the *de novo* synthesis of pyrimidine nucleotides
- **A.** reactions take place exclusively in the cytosol.
- **B.** a free base is formed as an intermediate.
- **C.** PRPP is required in the rate-limiting step.
- **D.** UMP and CMP are formed from a common intermediate.
- **E.** UMP inhibition of OMP-decarboxylase is the major control of the process.

Questions 9 and 10: Gout is a disease characterized by hyperuricemia from an overproduction of purine nucleotides via the *de novo* pathway. The specific cause of Lesch–Nyhan syndrome is a severe deficiency of HGPRTase. Allopurinol is used in the treatment of gout to reduce the production of uric acid. In Lesch–Nyhan syndrome, the decrease in uric acid is balanced by an increase in xanthine plus hypoxanthine in blood. In the other forms of gout, the decrease in uric acid is greater than the increase in xanthine plus hypoxanthine.

9. The explanation for this difference in the two forms of gout is
- **A.** it is an experimental artifact and the decrease in uric acid and increase in xanthine plus hypoxanthine in non-Lesch–Nyhan gout is the same.
- **B.** allopurinol is less effective in non-Lesch–Nyhan gout.
- **C.** there is an increased excretion of xanthine and hypoxanthine in non-Lesch–Nyhan gout.
- **D.** PRPP levels are reduced in Lesch–Nyhan.
- **E.** in non-Lesch–Nyhan gout hypoxanthine and xanthine are salvaged to IMP and XMP and inhibit PRPP amidotransferase.

10. Which of the following is/are aspects of the overall regulation of *de novo* purine nucleotide synthesis?
- **A.** AMP, GMP, and IMP shift PRPP amido transferase from a small form to a large form.
- **B.** PRPP amidotransferase shows hyperbolic kinetics with PRPP.
- **C.** AMP inhibits the conversion of IMP to GMP.
- **D.** Change in glutamine concentration is a major regulator.
- **E.** Direct interconversion of AMP to GMP maintains balance of the two.

Question 11 and 12: There are two distinct immunodeficiency diseases that lead to the formation of uric acid as the end product. Mutation in genes for adenosine deaminase (ADA) leads to severe combined immunodeficiency (SCID) in which both T-cells and B-cells are affected. Defects in purine nucleoside phosphorylase (PNP) affect only T-cells. These two enzymes are in the pathways for degradation of nucleic acids. Gene therapy has had some success in treating ADA deficiency.

11. In nucleic acid degradation, all of the following are correct except
- **A.** there are nucleases that are specific for either DNA or RNA.
- **B.** nucleotidases convert nucleotides to nucleosides.
- **C.** the conversion of a nucleoside to a free base is an example of a hydrolysis.
- **D.** because of the presence of deaminases, hypoxanthine rather than adenine is formed.
- **E.** both DNA and RNA degradation lead to uric acid.

12. The best estimate of the turnover of DNA comes from a measurement in urine of
- **A.** uric acid.
- **B.** NH_4^+ and CO_2
- **C.** β-alanine.
- **D.** β-aminoisobutyrate.
- **E.** cytidine.

Problems

13. If a cell capable of *de novo* synthesis of purine nucleotides has adequate AMP but is deficient in GMP, how would the cell regulate synthesis to increase [GMP]? If both AMP and GMP were present in appropriate concentrations, what would happen?

14. Inhibitors of purine and pyrimidine nucleotide metabolism take many forms. 5-Fluorouracil is an antimetabolite, methotrexate is an antifolate, and azaserine is an antagonist. How do these three types differ in their action?

Answers

1. **A** GMP and AMP are both formed from the first purine nucleotide, IMP, in a branched pathway. B: The pyrimidine nucleotides UMP and CTP are formed in a sequential pathway from orotic acid. C: Humans are capable of synthesizing purine nucleotides. D: Deoxy forms are formed by reduction of the ribose forms. E: IMP is the common precursor.
2. **C** In purine nucleotide synthesis, the purine ring is built up stepwise on ribose-5-phosphate and not transferred to it. A, B, and D: Phosphoribosyl transferases are important salvage enzymes for both purines and pyrimidines and are also part of the synthesis of pyrimidines since OPRT catalyzes the conversion of orotate to OMP.
3. **C** Deoxyribonucleotides are synthesized from the ribonucleoside diphosphates by nucleoside diphosphate reductase that uses thioredoxin as the direct hydrogen-electron donor. A, B, and E: There is a synthetic mechanism as just described but it is not a *de novo* pathway. D: Nucleotide kinases are enzymes that add phosphate to a base or nucleotide.
4. **C** These two enzymes are important in interconverting the nucleotide forms. A: These convert nucleosides to nucleoside monophosphates. B: Two steps are required. D: ATP is present in highest concentration and the phosphate donor. E: Occurs during the S phase, but this is a general reaction for the cell.
5. **D** ATP is used both as a source of energy and part of it is incorporated into the product. A: They are different vitamins. B: This is necessary for the formation of NAD but not the other two. C: AMP is part of the final structure but must be incorporated as ATP. E: The removal of the phosphate is associated with the use of ATP as energy, not a simple hydrolysis.
6. **A** This begins with a cyclohydrolase acting on GTP. B: Such an inhibitor would reduce the level of tetrahydrobiopterin by inhibiting production of GTP. C: It is not a derivative of ATP. D: GTP is not converted to guanine. E: Glutamine is not an adduct.
7. **D** It is common for an exogenous agent to require conversion to an active form; in this case the uridine is salvaged to the monophosphate and ultimately to the triphosphate. The cell is deficient in UTP and CTP because the conversion of orotic acid is blocked so the exogenous uridine provides a bypass around the block. Orotic acid formation is decreased since UTP inhibits carbamoyl phosphate synthetase II, the control enzyme.
8. **B** This is in contrast to purine *de novo* synthesis. A: One enzyme is mitochondrial. C: PRPP is required to convert orotate to OMP but this is not rate limiting. D: OMP to UMP to CTP is a sequential process. E: This does occur, but the rate-limiting step is that catalyzed by CPS II.
9. **E** Not only is uric acid production directly inhibited, *de novo* synthesis is as well, thus reducing production of xanthine and hypoxanthine. In Lesch–Nyhan, the only effect is the direct inhibition of xanthine oxidase. A: It is a real effect. B: Actually, it is more effective because of the dual roles. C: This does not happen. D: PRPP levels are very high because of the lack of the salvage of bases, leading to improper or lack of regulation of pathways.
10. **A** This is a mechanism of inhibition since the large form of the enzyme is inactive. B: PRPP amidotransferase shows sigmoidal kinetics with respect to PRPP so large shifts in concentration of PRPP have the potential for altering velocity. C: AMP inhibits the conversion of IMP to itself. D: Glutamine concentration is relatively constant. E: This does not happen.
11. **C** The product is ribose-1-phosphate rather than the free sugar catalyzed by PNP. A: They can also show specificity toward the bases and positions of cleavage. B: A straight hydrolysis. D: AMP deaminase and adenosine deaminase remove the 6-NH_2 as NH_3. The IMP or inosine formed is eventually converted to hypoxanthine. E: This is called severe combined immunodeficiency.
12. **D** This is generated exclusively from the degradation of thymine from DNA. A: Uric acid is formed from purine nucleotides from any source. B: These are generated from many things. C: This comes from more than pyrimidines. E: Cytidine is converted to uridine which is metabolized to β-alanine.
13. AMP would partially inhibit *de novo* synthesis of IMP by its allosteric inhibition of PRPP amidotransferase. The IMP formed would be directed toward GMP because AMP is an inhibitor of its own synthesis from IMP. If both AMP and GMP are adequate, the synergistic effect of the two on PRPP amidotransferase would severely inhibit *de novo* synthesis.
14. 5-Fluorouracil can be converted by the same enzyme as uracil to the mono- and triphosphate nucleotides and incorporated into RNA, disrupting many functions as well as inhibiting thymidylate synthase. That is, it is a structural analog of the normal compound. Antifolates inhibit dihydrofolate reductase so preventing the reformation of tetrahydrofolate for its multiple functions. Azaserine, as an antagonist, is an inhibitor of many enzymes that use glutamine as an amino donor.

Key Concepts

- Metabolic pathways are controlled in different nutritional and disease states to maintain sources of energy and amino acids in the blood for all tissues.
- Pathways that remove excess fuels from the blood (glycogenesis, glycolysis, fatty acids synthesis, and lipogenesis) are active in the fed state.
- Pathways that maintain adequate levels of fuels in the blood (glycogenolysis, gluconeogenesis, lipolysis, proteolysis, and ketogenesis) are active in the starved state.
- Pathways are controlled by substrate availability, allosteric effectors, covalent modification, and induction or repression of key enzymes.
- The changes in metabolism that accompany common disease states are variations on the themes that function in the fed and fasted states.

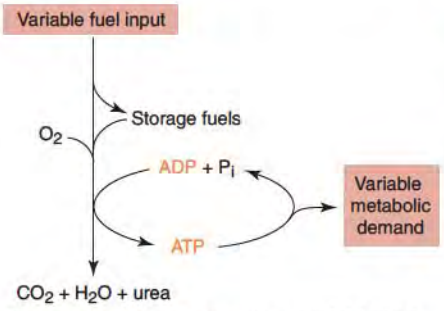

Figure 21.1 Humans can use a variable fuel input to meet a variable metabolic demand.

21.1 • INTRODUCTION

The interdependence of metabolic processes of the major tissues of the body will be stressed in this chapter. Not all of the major metabolic pathways operate in every tissue at any given time. Given the nutritional and hormonal status of a patient, it is necessary to know qualitatively which pathways are functional and how they relate to one another.

The metabolic processes of concern are glycogenesis, glycogenolysis, gluconeogenesis, glycolysis, fatty acid synthesis, lipogenesis, lipolysis, glyceroneogenesis, fatty acid oxidation, glutaminolysis, tricarboxylic acid (TCA) cycle activity, ketogenesis, amino acid oxidation, protein synthesis, proteolysis, and urea synthesis. It is important to know (1) which tissues are most active in these various processes, (2) when these processes are most active, and (3) how these processes are controlled and coordinated in different metabolic and disease states.

The best way to gain an understanding of the interrelationships of the pathways is to learn the changes in metabolism during the starve–feed cycle (Figure 21.1). This cycle allows a variable fuel and nitrogen intake to meet variable metabolic and anabolic needs. Feed refers to the intake of meals (the variable fuel input) after which the fuel is stored (as glycogen and triacylglycerol) to meet metabolic needs of fasting. An ATP cycle functions within the starve–feed cycle (Figure 21.1). Cells of the body die without the provision of continuous supply of energy for ATP synthesis to meet their needs.

Humans can consume food at a rate far greater than their basal caloric requirements; this allows them to survive from meal to meal. Unfortunately, an almost unlimited capacity to consume food is matched by an almost unlimited capacity to store it as triacylglycerol. Obesity is the consequence of excess food consumption and the commonest form of malnutrition in affluent countries (Clin. Corr. 21.1). Other forms of malnutrition are more prevalent in developing countries (Clin. Corrs. 21.2 and 21.3). The regulation of food

CLINICAL CORRELATION 21.1

Obesity and the Metabolic Syndrome

Obesity is the most common nutritional problem in the United States, in fact a majority of the U.S. population is either obese or overweight, and the problem may be even greater for children. It is a risk factor in development of diabetes mellitus, hypertension, endometrial carcinoma, osteoarthritis, cirrhosis, gallstones, and cardiovascular diseases. Clinically, the quartet of obesity, insulin resistance, dyslipidemia, and hypertension is called either syndrome X or the metabolic syndrome and contributes greatly to the high rate of cardiovascular death in Western countries. Obesity is easy to explain: An obese person has eaten more calories than he or she expended. The accumulation of massive amounts of body fat is not otherwise possible. For unknown reasons, the neural control of caloric intake to balance energy expenditure is abnormal. Rarely, obesity is secondary to a correctable disorder, such as hypothyroidism or Cushing syndrome. The latter is the result of increased secretion of glucocorticoids, which cause fat deposition in the face and trunk, with wasting of the limbs, and glucose intolerance. These effects are due to increased protein breakdown in muscle and conversion of the amino acids to glucose and fat. Less commonly, tumors, vascular accidents, or maldevelopment of the nervous system hunger control centers in the hypothalamus cause obesity. However, the rapid increase in the prevalence of obesity cannot be explained by genetic or biochemical mechanisms and must reflect cultural changes in food preparation and consumption and reduced physical activity.

The obese (*ob/ob*) mouse was discovered in the 1950s, and the defective gene cloned in 1994. This *ob* gene encodes a 146 amino-acid-secreted protein (alternatively called OB protein or leptin, for its slimming effect) that is produced in adipocytes and detectable in blood. *ob/ob* mice have a nonsense mutation in the gene and produce no leptin. Injection of leptin into them causes increased energy expenditure and reduced eating, with marked weight loss. This effect on appetite is mimicked by intracerebroventricular injection. Leptin also reduced appetite and weight of normal mice. Obese humans do not generally have defective *ob* genes, and in fact tend to have high blood levels of leptin. This suggests that their nervous system is insensitive to leptin, analogous to the insulin resistance seen in many diabetic patients.

In the most common type of obesity, the number of adipocytes does not increase, but rather they get larger as they become engorged with triacylglycerols. If obesity develops before puberty, there may also be an increase in the number of adipocytes. In this case, the hyperplasia (increase in cell number) and hypertrophy (increase in cell size) contribute to the magnitude of the obesity. Obesity in men tends to be centered on the intraabdominal (so called visceral) fat, while in women it is more likely to be on the hips. The male pattern, characterized by a high waist-to- hip circumference ratio, is more predictive of premature coronary heart disease. Moreover, visceral adipose tissue seems more resistant to suppression of lipolysis by insulin, and thus the release of fatty acids into the portal vein may contribute to the relative inability

to suppress hepatic glucose production in obesity and type 2 diabetes (see Clin. Corrs. 15.4, p. 594, and 21.6, p. 848).

The only effective treatment of obesity is reduction in the ingestion or increase in the use of calories. Practically speaking, this means dieting, since even vigorous exercise such as running only consumes 10 kcal per minute of exercise. Thus, an hour-long run (perhaps 5–6 mi) uses the energy present in about two candy bars. However, exercise programs can be useful to help motivate individuals to remain on their diets. There is interest in low-carbohydrate, high-fat, and protein diets, sometime referred to as the Atkins diet. This diet reduces carbohydrate intake to a low enough level to induce ketonemia. As weight loss progresses, carbohydrate is reintroduced until weight stabilizes. Several studies have shown that this strategy is more effective in inducing weight loss than standard calorie restriction and better at reducing triglyceride levels without raising LDL cholesterol. Beneficial effects on weight management, triglyceride levels, cholesterol levels, and blood pressure have also been achieved with high-protein, low-carbohydrate diets.

Unfortunately for individuals trying to lose weight, the body compensates for decreased energy intake with reduced formation of triiodothyronine and a decrease in the basal metabolic rate. Thus, there is a biochemical basis for the universal complaint that it is far easier to gain than to lose weight. What is more, about 95% of people who lose a significant amount of weight regain it within 1 year. Most patients who have successfully lost weight long term engage in regular exercise and weigh themselves daily (perhaps compensating for inadequate neural response to satiety signals).

CLINICAL CORRELATION 21.2

Protein–Calorie Malnutrition

Protein–calorie malnutrition is the most important and widespread nutritional problem among young children in the developing world. The clinical syndrome, called kwashiorkor, occurs mainly in children 1–3 years of age and is precipitated by weaning an infant from breast milk onto a starchy, protein-poor diet. The name originated in Ghana, and means "the sickness of the older child when the next baby is born." It is a bit of a misnomer since the major deficiency is protein, not calories. It is a consequence of feeding the child a diet adequate in calories but deficient in protein. It may become manifest when protein requirements are increased by infection, for example, malaria, helminth infestation, or gastroenteritis. It is characterized by poor growth, low plasma protein and amino acid levels, muscle wasting, edema, diarrhea, and increased susceptibility to infection. The presence of subcutaneous fat clearly differentiates it from simple starvation. Fat stores are maintained by the high carbohydrate intake and resulting high insulin levels. In fact, the high insulin level interferes with the adaptations that occur in starvation. Fat is not mobilized as an energy source, ketogenesis does not take place, and there is no transfer of amino acids from skeletal muscle to the liver, kidneys, heart, and immune cells. Lack of dietary amino acids results in diminished protein synthesis in all tissues. The liver becomes enlarged and infiltrated with fat, reflecting the need for hepatic protein synthesis for the formation and release of VLDL. In addition, protein malnutrition impairs the function of the gut, and leads to malabsorption of carbohydrate, protein, and vitamins, which accelerates the disease. The consequences depend on when in development the deficiency occurs. Children with low weight for height are called "wasted," but can make a good recovery when properly fed. Those with low height for weight are called "stunted", and never regain full height or cognitive potential.

Protein–calorie malnutrition is a problem for the elderly when they become sick. The requirement for energy and food intake of healthy elderly may decline with age. There is the risk that insufficient intake of protein and of nutrients such as iron, calcium, and vitamins will occur. Such deficiency may accelerate loss of lean body mass and strength (leading to falls), anemia, loss of bone strength (resulting in breaking of the hip during falls), and rarely, vitamin deficiency states. Chronic illnesses that are more common in the elderly frequently impair appetite, food intake, or nutrient assimilation. As a result, elderly patients are more often found to suffer from protein–calorie malnutrition than younger adults.

Protein–calorie malnutrition is common in patients with liver cirrhosis. Low serum albumin levels as a consequence of reduced hepatic synthesis are prognostic of poor survival rates. Dietary deficiency of protein coupled with loss of control of the oxidation of branched-chain amino acids (BCAA: leucine, isoleucine, valine) causes low serum BCAA levels in patients with severe liver cirrhosis. In some countries, such patients are given BCAA supplements in an effort to raise serum albumin levels without worsening blood ammonia levels. This is not standard practice in the United States for want of convincing clinical evidence of the effectiveness of this intervention.

Protein-energy under nutrition in hospital in-patients. *Br. J. Nutr.* 83:575, 2000.

CLINICAL CORRELATION 21.3

Starvation

Starvation leads to a syndrome known as marasmus. *Marasmus* is a word of Greek origin meaning "to waste." It is most frequent in children under 1 year of age. In developing countries, early weaning of infants from breast milk is a common cause. This may result from pregnancies in rapid succession, the desire of the mother to return to work, or the use of overdiluted artificial formulas (to make the expensive formulas last longer). This practice leads to insufficient intake of calories as well as protein. Likewise, diarrhea and malabsorption can develop if safe water and sterile procedures are not used in preparation of formula.

In contrast to kwashiorkor (see Clin. Corr. 21.2, p. 841), subcutaneous fat, hepatomegaly, and fatty liver are absent in marasmus because fat is mobilized for energy and muscle temporarily provides amino acids to the liver for synthesis of glucose and hepatic proteins. Low insulin levels allow the liver to oxidize fatty acids and to produce ketone bodies for other tissues. Ultimately, energy and protein reserves are exhausted, and the child starves to death. The immediate cause of death is often pneumonia, because the child is too weak to cough. Adults can suffer from marasmus because of diseases that prevent swallowing (cancer of the throat or esophagus), reduce the ability of the gut to absorb nutrients (celiac disease or Crohn disease, short-bowel syndrome from surgical resection of the gut), or interfere with access to food (strokes or dementia). Thousands of the residents confined to the Warsaw Ghetto during World War II died from starvation. Studies by Jewish physicians confined to the ghetto showed that death, when not complicated by a severe infection, occurred when substrates for gluconeogenesis could no longer be supplied by the breakdown of muscle.

A related and very common disorder is cancer cachexia, which is due to anorexia (loss of appetite, and therefore starvation) and to body wasting. The latter differs from simple starvation in that skeletal muscle is not spared and both muscle and fat is used to supply energy needs (see Clin. Corr. 21.9, p. 869).

Studies with experimental animals suggest females are more resistant to the adverse effects of starvation than males. Physical examination of survivors of the POW camps and orphanages after World War II suggest this is also true for humans. Females are usually smaller and have a lower basal metabolic rate than males, and therefore need less food per day than males. Furthermore, the evolutionary selection pressures for survival have surely been greater for females than males during the many periods of famine that have occurred over time. Since for most species many females can mate with one male, males are not needed during pregnancy and lactation, and males compete with offspring for food, survival of males is less important than survival of females for maintenance of the species during long periods of food shortage. Genes may therefore have been selected that confer females with greater resistance to starvation. Support for this notion comes from the finding that mitochondria isolated from female experimental animals are more highly differentiated, as evidenced by more enzymatic machinery for oxidative phosphorylation, than mitochondria isolated from males.

consumption is complex and not well understood. One important factor is leptin, a protein synthesized and secreted into the blood by adipocytes that regulates energy expenditure and appetite through its effects on the hypothalamus (see Clin. Corr. 21.1). The tight control needed is indicated by the calculation that eating two extra pats of butter (~100 cal) per day over caloric expenditures results in a weight gain of 10 lb per year. A weight gain of 10 lb may not sound excessive, but multiplied by 10 years it equals severe obesity!

21.2 • STARVE–FEED CYCLE

In the Well-Fed State the Diet Supplies the Energy Requirements

Figure 21.2 shows the fate of glucose, amino acids, and fat obtained from food. Glucose passes from the intestinal epithelial cells via the portal vein to the liver. Amino acids are partially metabolized in the gut before being released into portal blood. Chylomicrons containing triacylglycerol are secreted by the intestinal epithelial cells into lymphatics. The lymphatics empty into the thoracic duct, which delivers the chylomicrons to the subclavian vein and thence to the rest of the body.

In the liver, dietary glucose can be converted into glycogen by glycogenesis or into pyruvate and lactate by glycolysis or can be used in the pentose phosphate pathway for the generation of NADPH for synthetic processes. Pyruvate can be oxidized to acetyl CoA, which, in turn, can be converted into triacylglycerol or oxidized to CO_2 and water by the

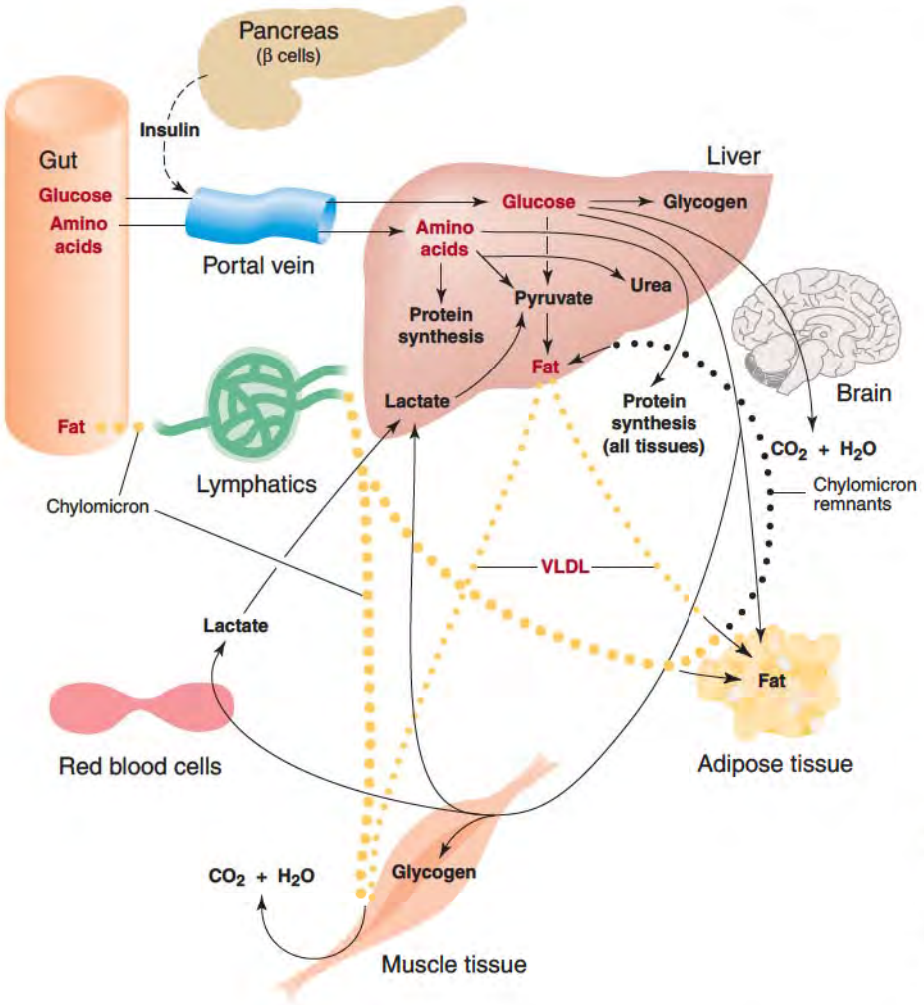

Figure 21.2 Disposition of glucose, amino acids, and fat by various tissues in the well-fed state. Chylomicrons (large yellow dots) are converted to chylomicron remnants (black dots) by the action of lipoprotein lipase in the adipose tissue and skeletal muscle. VLDL particles (small yellow dots) are converted to LDL particles (not shown) by lipoprotein lipase in these same tissues.

TCA cycle. Much of the dietary glucose passes through the liver to reach other organs, including brain, which is almost completely dependent on glucose for ATP generation, red blood cells and renal medulla, which can only carry out glycolysis, and adipose tissue, which primarily converts it into the glycerol moiety of triacylglycerol. Muscle also uses glucose, converting it to glycogen or using it in glycolysis and the TCA cycle. Lactate and pyruvate produced by glycolysis in other tissues are taken up by the liver and oxidized to CO_2 or converted to triacylglycerol. In the well-fed state, the liver uses glucose and does not engage in gluconeogenesis. Thus, the Cori cycle, conversion of glucose to lactate in peripheral tissues followed by conversion of lactate to glucose in liver, is interrupted in this state.

The intestinal cells use some dietary amino acids as an energy source but transport most of them into the portal blood for distribution. Liver removes some absorbed amino acids from the portal blood (Figure 21.2), but most pass through. This is especially important for essential amino acids, which are needed by all cells for protein synthesis. Liver metabolizes amino acids, but the K_m values of the enzymes involved are high, meaning that the amino acids have to be present in high concentration before significant catabolism can occur. In contrast, the low K_m values of tRNA charging enzymes ensures that protein synthesis can occur when amino acids are present. Excess amino acids can be oxidized completely to CO_2, urea, and water, or the intermediates generated can be used for lipogenesis. Amino acids that escape the liver are used for protein synthesis or energy in other tissues.

Dietary triacylglycerol reaches the bloodstream as chylomicrons (p. 1057), which in turn are acted on by lipoprotein lipase attached to the surface of endothelial cells in the lumen of the capillaries of various tissues, but particularly adipose tissue (Figure 21.2). This lipase hydrolyzes a large portion but not all of the triacylglycerol present in chylomicrons. The released fatty acids are taken up by the adipocytes, reesterified with glycerol 3-phosphate

(derived from glucose via glycolysis) to form triacylglycerols, and stored as fat droplets within the adipocytes. Chylomicron remnants remaining after digestion by lipoprotein lipase are cleared from the blood by the liver. Triacylglycerols present in remnants are hydrolyzed by a lysosomal lipase. The released fatty acids are reesterified with glycerol 3-phosphate (derived from free glycerol and glucose) to form triacylglycerols. Triacylglycerol produced from dietary fat in this manner along with smaller amounts of triacylglycerol produced by *de novo* synthesis from glucose and amino acids are packaged into very low-density lipoproteins (VLDL) and secreted into the blood (Figure 21.2). Like chylomicrons, VLDL is acted on by lipoprotein lipase to give fatty acids that can be used to form triacylglycerol and stored as fat droplets in adipocytes. Because of the high fat content of the human diet, most of the triacylglycerol of human adipose tissue originates from the diet rather than *de novo* lipogenesis.

The β-cells of the pancreas are very responsive to the influx of glucose and amino acids in the fed state. When glucose enters the β-cell, its oxidation raises the ATP level, closes ATP-sensitive potassium channels, depolarizes the cell, and increases intracellular calcium, leading to insulin release. β-cells release insulin during and after eating, which is essential for the metabolism of these nutrients by liver, muscle, and adipose tissue. The role of insulin in the starve–feed cycle is discussed in more detail in Section 21.3, p. 852.

In the Early Fasting State Hepatic Glycogenolysis Maintains Blood Glucose

Hepatic glycogenolysis maintains blood glucose during early fasting (Figure 21.3). Lactate, pyruvate, and alanine are diverted from oxidation and fatty acid synthesis into glucose formation, completing the Cori cycle. The alanine cycle, in which carbon and nitrogen return to the liver in the form of alanine, also becomes important (see Figure 15.32, p. 622).

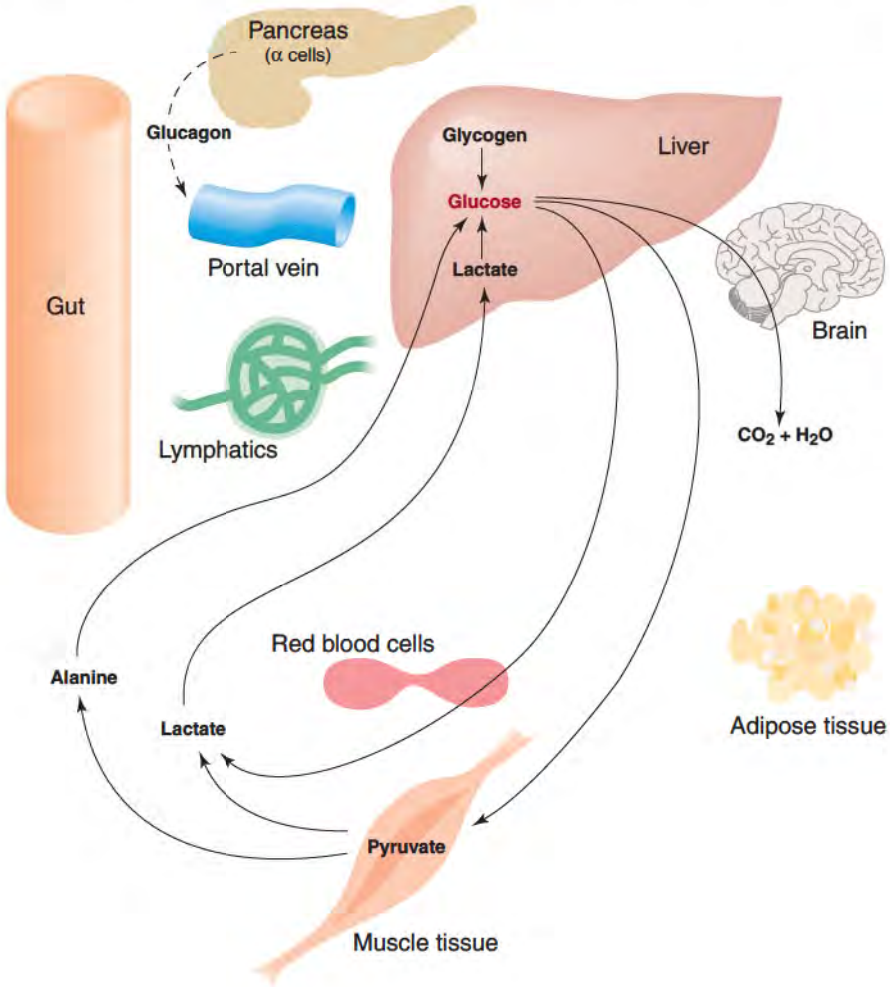

Figure 21.3 Metabolic interrelationships of major tissues in early fasting state.

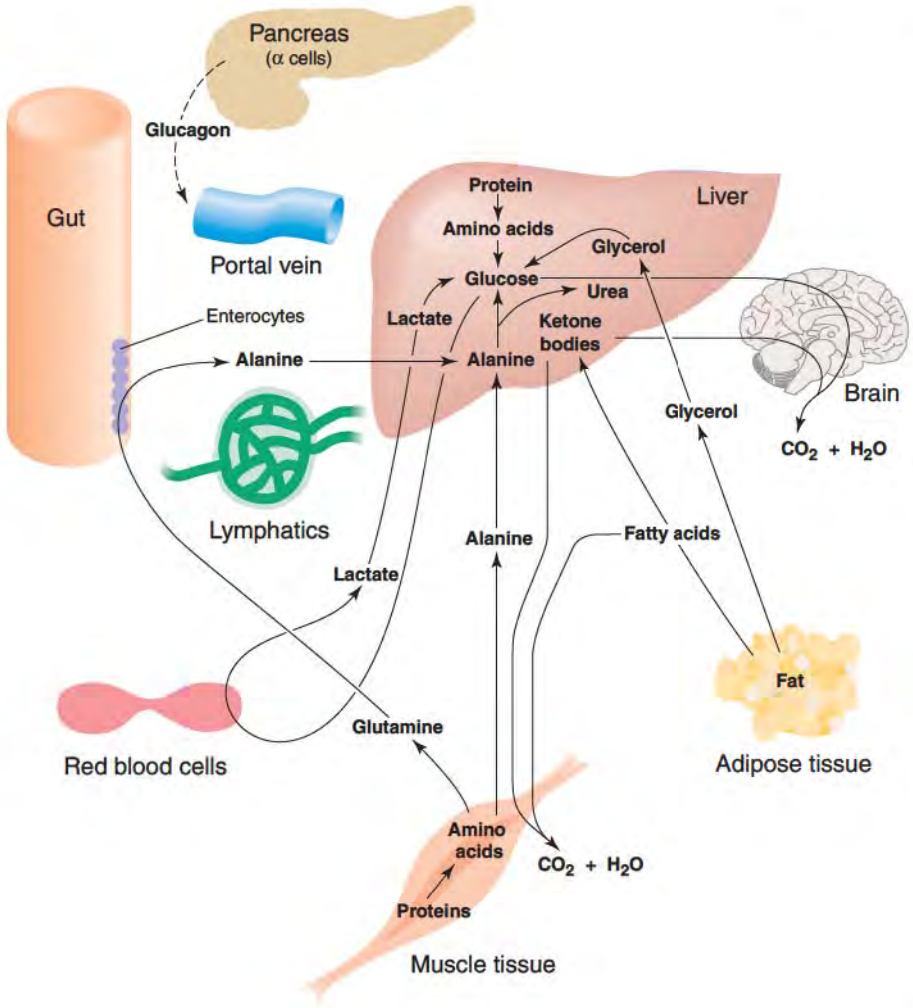

Figure 21.4 Metabolic interrelationships of major tissues in fasting state.

The Fasting State Requires Gluconeogenesis from Amino Acids and Glycerol

Since no dietary fuel enters from the gut and little glycogen is left in the liver after 10–12 h of fasting state (Figure 21.4), the body is dependent on hepatic gluconeogenesis, primarily from lactate, glycerol, and alanine. The Cori and alanine cycles play important roles, but do not provide carbon for net synthesis of glucose. This is because glucose formed from lactate and alanine by the liver merely replaces that which was converted to lactate and alanine by peripheral tissues. In effect, these cycles transfer energy from fatty acid oxidation in the liver to peripheral tissues that cannot oxidize triacylglycerol. The brain oxidizes glucose completely to CO_2 and water. Hence net glucose synthesis from some other source of carbon is mandatory in fasting. Fatty acids cannot be used for the synthesis of glucose because no pathway exists for the conversion of acetyl CoA, the two-carbon compound produced by fatty acid oxidation, into glucose. Glycerol, a by-product of lipolysis in adipose tissue, is an important substrate for glucose synthesis. However, protein, especially from skeletal muscle, supplies most of the carbon needed for net glucose synthesis. Proteins are hydrolyzed within muscle cells, and most amino acids are partially metabolized. Of the amino acids, alanine and glutamine are released in the largest amounts. The other amino acids are for the most part metabolized to intermediates (pyruvate and α-ketoglutarate), which can yield alanine and glutamine. Branched-chain amino acids are a major source of nitrogen for the production of alanine and glutamine in muscle. Branched-chain α-keto acids produced by transamination are partially released into the blood for uptake by the liver, which produces glucose from the α-keto acid of valine, ketone bodies from that of leucine, and both glucose and ketone bodies from that of isoleucine.

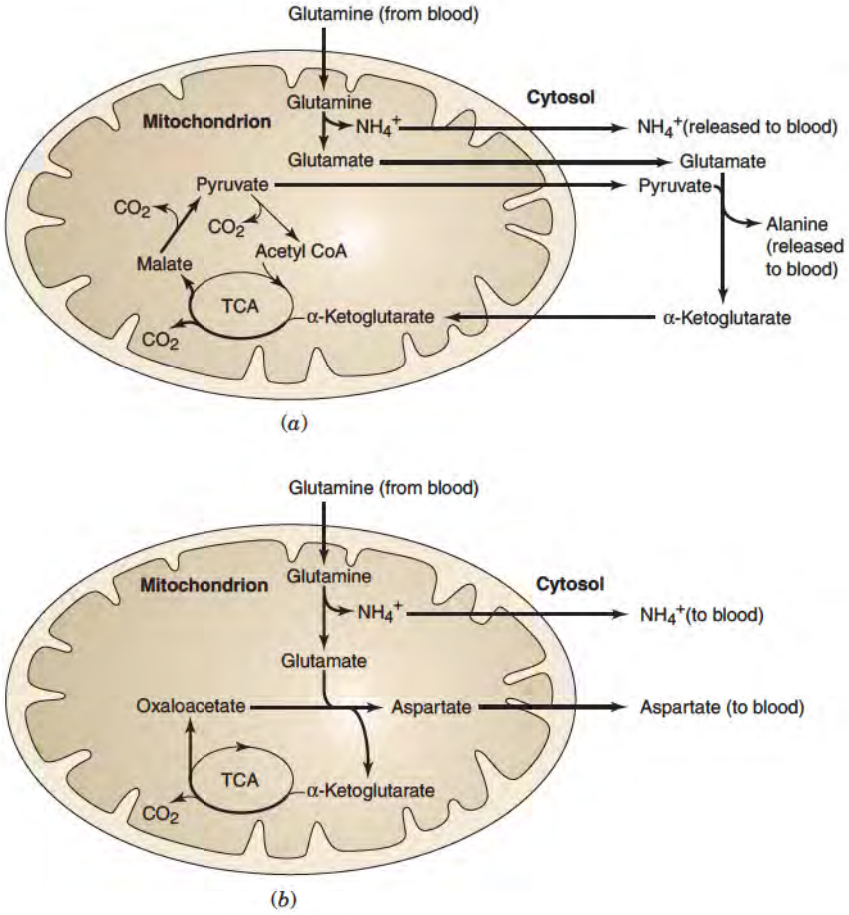

Figure 21.5 Glutamine catabolism by rapidly dividing cells. (*a*) Enterocytes. (*b*) Lymphocytes. Redrawn from Duée, P.-H., Darcy-Vrillon, B., Blachier, F., and Morel, M.-T. Fuel selection in intestinal cells. *Proc. Nutr. Soc.* 54:83, 1995.

Part of the glutamine released from muscle is used by intestinal epithelium, lymphocytes, and macrophages. Glutamine is an important fuel for enterocytes and lymphocytes, which divide rapidly and thus require it for synthesis of pyrimidines and purines. In this process, glutamine is converted to glutamate, which is transaminated with pyruvate to form α-ketoglutarate and alanine. In the TCA cycle, the α-ketoglutarate is converted to malate, which is then converted to pyruvate by malic enzyme, generating the pyruvate needed for alanine formation by enterocytes. This pathway is called glutaminolysis because glutamine is only partially oxidized (Figure 21.5a). Glutaminolysis, with aspartate as the major end product, is also used by lymphocytes and macrophages to meet a large portion of their energy needs (Figure 21.5*b*).

Synthesis of glucose in the liver during fasting is closely linked to synthesis of urea. Most amino acids can give up their amino nitrogen by transamination with α-ketoglutarate, forming glutamate and a new α-keto acid, which often can be utilized for glucose synthesis. Glutamate provides the two forms of nitrogen required for urea synthesis: ammonia from oxidative deamination by glutamate dehydrogenase, and aspartate from transamination of oxaloacetate by aspartate aminotransferase. An important source of ammonia and precursors of ornithine such as citrulline is the gut mucosa (described in Section 21.4, p. 863).

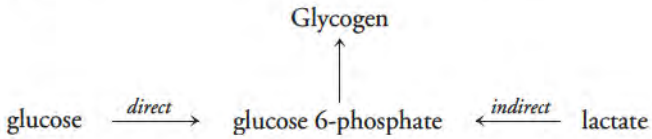
Because of low blood insulin levels during fasting, lipolysis is greatly activated in adipose tissue, raising the blood level of fatty acids, which are used in preference to glucose by many tissues. In heart and muscle, oxidation of fatty acids inhibits glycolysis and pyruvate oxidation. In liver, fatty acid oxidation provides most of the ATP needed for gluconeogenesis. Very little acetyl CoA generated by fatty acid oxidation in liver is oxidized completely. Rather, it is converted into ketone bodies by liver mitochondria. Ketone bodies (acetoacetate and β-hydroxybutyrate) are released into the blood and are a source of energy for many tissues. Like fatty acids, they are preferred to glucose by many tissues. Fatty acids are not oxidized by the brain as they cross the blood–brain barrier poorly. Once their blood

concentration is high enough, ketone bodies enter the brain and serve as an alternative fuel. They are unable, however, to replace completely the brain's need for glucose. Ketone bodies may also suppress proteolysis and branched-chain amino acid oxidation in muscle and decrease alanine release. This decreases muscle wasting and reduces the amount of glucose synthesized in liver. As long as high ketone body levels are maintained by hepatic fatty acid oxidation, there is less need for glucose, less need for gluconeogenic amino acids, and less need for breaking down precious muscle tissue.

This may be because insulin levels remain high enough to suppress partially muscle proteolysis as long as glucose levels remain high enough to stimulate some release of insulin from the pancreas. The working relationship between the liver, muscle, and adipose tissue in providing glucose for the brain are shown in Figure 21.4, p. 845. Liver synthesizes the glucose, muscle and gut supply the substrate (alanine), and adipose tissue supplies the ATP (via fatty acid oxidation in the liver) needed for hepatic gluconeogenesis. This cooperation among major tissues is dependent on the appropriate blood hormone levels. Glucose levels are lower in fasting, reducing the secretion of insulin but favoring release of glucagon from the pancreas and epinephrine from the adrenal medulla. Fasting also reduces formation of triiodothyronine, the active form of thyroid hormone, from thyroxine. This reduces the daily basal energy requirements by up to 25%. This response is useful for survival, but makes weight loss more difficult than weight gain (see Clin. Corr. 21.1).

In the Early Refed State Glycogen Is Formed by the Indirect Pathway

Triacylglycerol is metabolized as described for the well-fed state. In contrast, the liver extracts glucose poorly and, in fact, remains in the gluconeogenic mode for a few hours after feeding. Rather than providing blood glucose, however, hepatic gluconeogenesis provides glucose 6-phosphate for glycogenesis. This means that liver glycogen is not entirely repleted after a fast by direct synthesis from blood glucose. Rather, glucose is catabolized in peripheral tissues to lactate, which is converted in the liver to glycogen by gluconeogenesis, that is, indirectly:



Gluconeogenesis from amino acids entering from the gut also plays an important role in reestablishing liver glycogen levels by the indirect pathway. After the rate of glucose synthesis declines, liver glycogen is sustained by direct synthesis from blood glucose.

Important Interorgan Metabolic Interactions

The intestinal epithelium converts glutamine to citrulline (Figure 21.6); it is the only tissue that expresses an ATP-dependent glutamate reductase necessary for this conversion.

$$\text{Glutamate} + \text{NADPH} + \text{H}^+ + \text{ATP} \rightarrow \text{glutamate semialdehyde} + \text{NADP}^+ + \text{ADP} + \text{Pi}$$

The gut also converts dietary arginine to citrulline. Citrulline released from the gut passes through the liver and is converted by the kidney to arginine, which can be converted to creatine or released into the blood. This pathway can be viewed as a way to reduce the release of arginine and ammonia in the portal blood, both of which stimulate ureagenesis. This may be particularly important under conditions of low protein intake. In addition, citrulline is a better source of arginine in conditions of small bowel disease (such as small bowel resection or celiac disease), but may not be utilized normally in renal failure. The liver uses arginine to generate ornithine, which expands the capacity of the urea cycle during periods of increased protein intake. The liver irreversibly converts ornithine into glutamate:

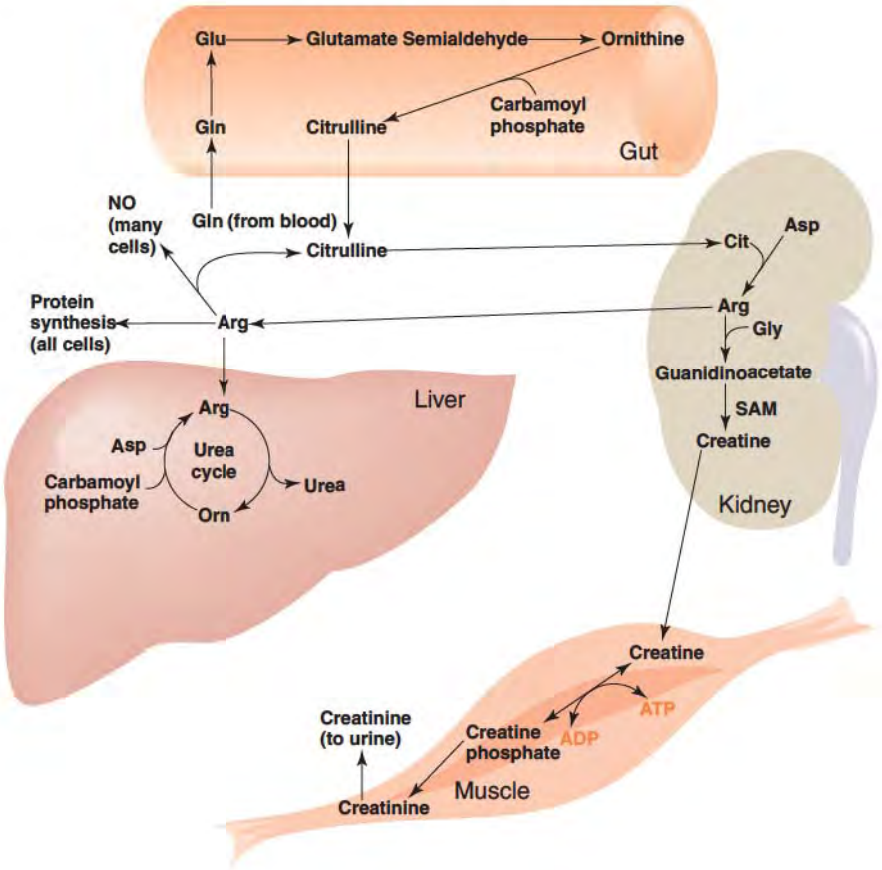


Figure 21.6 Gut and kidney function together in synthesis of arginine from glutamine. Abbreviations: Cit, citrulline; Arg, arginine; Asp, aspartate; Gln, glutamine; Glu, glutamate; NO, nitric oxide; Gly, glycine; Orn, ornithine; and SAM, *S*-adenosylmethionine.

$$\text{Ornithine} \xrightarrow{\text{Transamination}} \text{Glutamate semialdehyde} \xrightarrow{\text{Oxidation}} \text{Glutamate}$$

Depletion of ornithine in this way inhibits urea synthesis. Replenishment of ornithine is completely dependent on a source of arginine. Thus, urea synthesis in the liver is dependent on citrulline and arginine produced by the gut and kidney, respectively. Arginine is also used by many cells for the production of nitric oxide (NO) (Figure 21.6; see p. 848). The arginine generated from citrulline in the kidney is used to synthesize creatine (Figure 21.6). Glycine transamidinase (GTA) generates guanidinoacetate from arginine and glycine (p. 789). GTA is found predominantly in renal cortex, pancreas, and liver. After methylation using the methyl donor *S*-adenosylmethionine (SAM), creatine is formed. This is quantitatively the most important use of SAM in the body. One to two grams of creatine are synthesized per day. Creatine then circulates to other tissues, and accumulates in muscle, where it serves as a high-energy reservoir when phosphorylated to creatine phosphate. This undergoes nonenzymatic conversion to creatinine, which is released to the bloodstream and removed by the kidney. Excretion of creatinine is used clinically both as a measure of muscle mass and of renal function.

Glutathione (GSH) is important in detoxification of endogenously generated peroxides and exogenous chemical compounds (p. 789). Liver is a major synthesizer of GSH from glutamate, cysteine, and glycine (see Figure 19.77, p. 790). Synthesis is limited by the availability of cysteine. Plasma cysteine is not taken up well by liver, which uses dietary methionine to form cysteine via the cystathionine pathway (p. 770). Hepatic GSH is released to the bloodstream and bile. Kidney removes a substantial amount of plasma GSH. Enterocytes may be able to take up biliary-excreted GSH from the intestinal lumen. Release to plasma is the same in fed and fasting states, providing a stable source of this compound and its constituent amino acids, especially cysteine, for most tissues of the body.

Carnitine is derived from lysyl residues of various proteins, which are *N*-methylated using SAM to form trimethyllysyl-residues (Figure 21.7 and p. 849). Trimethyllysine is released when the proteins are degraded. It is hydroxylated and then cleaved, releasing glycine and γ-butyrobetaine aldehyde. The latter is oxidized to γ-butyrobetaine and then

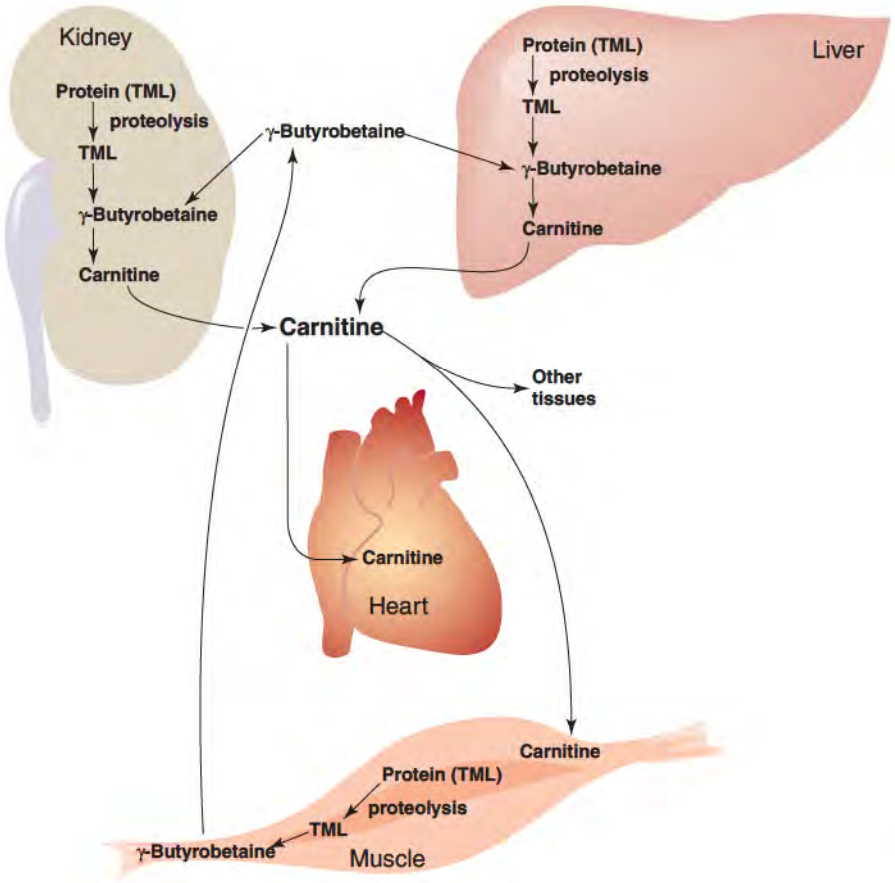

Figure 21.7 Kidney and liver provide carnitine for other tissues. Abbreviations: (TML), trimethyllysyl residues in protein molecules; TML, free trimethyllysine.

hydroxylated to form carnitine. Kidney and to a lesser extent liver carry out the complete pathway and supply other tissues, especially muscle and heart, with carnitine. Skeletal muscle can form γ-butyrobetaine, but must release it for conversion to carnitine by liver or kidney.

Energy Requirements, Reserves, and Caloric Homeostasis

The average person leading a sedentary life consumes 180–280 g of carbohydrate, 70–100 g of protein, and 70–100 g of fat daily. This meets a daily energy requirement of 1600–2400 kcal. As shown in Table 21.1, the energy reserves of an average-sized person are considerable. They are called on between small meals and overnight to maintain blood glucose. Although glycogen can be mobilized rapidly, glycogen reserves are small relative to fat reserves (Table 21.1). Fat stores are called on only during more prolonged fasting. Those of obese subjects can amount to 80 kg, adding another 585,000 kcal to their energy reserves. Protein is listed in Table 21.1 as a reserve of energy because it can be used to provide amino acids for oxidation. Recall that protein is not dispensable like triacylglycerol and glycogen and is utilized by the body for energy more reluctantly. The constant availability of fuels in the blood is termed caloric homeostasis, which, as illustrated in Table 21.2, means that regardless of whether a person is well-fed, fasting, or starving to death, the blood contains fuels in amounts that on combustion in cells of the body, provide a comparable amount of ATP. Note that blood glucose concentrations are controlled within very tight limits, whereas fatty acid and ketone body concentrations in the blood can vary by one or two orders of magnitude, respectively. Glucose is carefully regulated because of the absolute need of the brain for this substrate. If the blood glucose level falls too low (< 1.5 mM), coma and death will follow shortly unless the glucose concentration is restored. On the other hand, hyperglycemia must be avoided because glucose will be lost in the urine, resulting in dehydration and sometimes hyperosmolar, hyperglycemic coma (Clin. Corr. 21.4). Chronic hyperglycemia results in glycation of many proteins and endothelial dysfunction, which contributes to the complications of diabetes (Clin. Corr. 21.5). The changes in insulin/glucagon ratio shown in Table 21.2 are crucial for the maintenance of caloric homeostasis. Simply stated,

TABLE 21.1 • Energy Reserves of Humans[a]

		Fuel Reserves	
Stored Fuel	*Tissue*	*(g)*	*(kcal)*
Glycogen	Liver	70	280
Glycogen	Muscle	120	480
Glucose	Body fluids	20	80
Fat	Adipose	15,000	135,000
Protein	Muscle	6,000	24,000

[a]Data are for a normal subject weighing 70 kg. Carbohydrate supplies 4 kcal/g; fat, 9 kcal/g; protein, 4 kal/g.

TABLE 21.2 • Substrate and Hormone Levels in Blood of Well-Fed, Fasting, and Starving Humans[a]

Hormone or Substrate (units)	*Very Well Fed*	*Postabsorptive 12 hours*	*Fasted 3 days*	*Starved 5 weeks*
Insulin (μU/mL)	40	15	8	6
Glucagon (pg/mL)	80	100	150	120
Insulin/glucagon ratio (μU/pg)	0.50	0.15	0.05	0.05
Glucose (mM)	6.1	4.8	3.8	3.6
Fatty acids (mM)	0.14	0.6	1.2	1.4
Acetoacetate (mM)	0.04	0.05	0.4	1.3
β-Hydroxybutyrate (mM)	0.03	0.10	1.4	6.0
Lactate (mM)	2.5	0.7	0.7	0.6
Pyruvate (mM)	0.25	0.06	0.04	0.03
Alanine (mM)	0.8	0.3	0.3	0.1
ATP equivalents (mM)	262	235	301	428

Source: From Ruderman, N. B., Aoki, T. T., and Cahill, G. F. Jr. Gluconeogenesis and its disorders in man. In: R. W. Hanson and M. A. Mehlman (Eds.), *Gluconeogenesis, Its Regulation in Mammalian Species.* New York: Wiley, 1976, p. 515.

[a]Data are for normal-weight subjects except for the 5-week starvation values, which are from obese subjects undergoing therapeutic starvation. ATP equivalents were calculated on the basis of the ATP yield expected on complete oxidation of each substrate to CO_2 and H_2O: 32 molecules of ATP for each molecule of glucose; 106 for the average fatty acid (palmitate); 19 for acetoacetate; 21.5 for β-hydroxybutyrate; 15 for lactate; 12.5 for pyruvate; and 13 (corrected for urea formation) for alanine.

CLINICAL CORRELATION 21.4

Hyperglycemic, Hyperosmolar Coma

Patients with type 2 diabetes (see Clin. Corrs. 15.4, p. 594, and 21.6, p. 848) sometimes develop a condition called hyperglycemic, hyperosmolar coma. This is particularly common in the elderly and may occur in individuals under metabolic stress who were not previously recognized as having diabetes. Hyperglycemia, perhaps worsened by failure to take insulin or hypoglycemic drugs, an infection, or a coincidental medical problem such as a heart attack, leads to urinary losses of water, glucose, and electrolytes (sodium, chloride, and potassium). This osmotic diuresis reduces the circulating blood volume, a physiological stress that releases hormones that worsen insulin resistance and hyperglycemia. In addition, elderly patients may be less able to sense thirst or to obtain fluids. Over the course of several days, they can become extremely hyperglycemic (glucose >1000 mg/dL), dehydrated, and comatose. Ketoacidosis does not develop in these patients, possibly because free fatty acids are not always elevated or because adequate insulin concentrations exist in the portal blood to inhibit ketogenesis (although not high enough to inhibit gluconeogenesis). Therapy is aimed at restoring water and electrolyte balance and correcting the hyperglycemia with insulin, and identifying the underlying cause. Mortality from this syndrome is considerably higher than that of diabetic ketoacidosis.

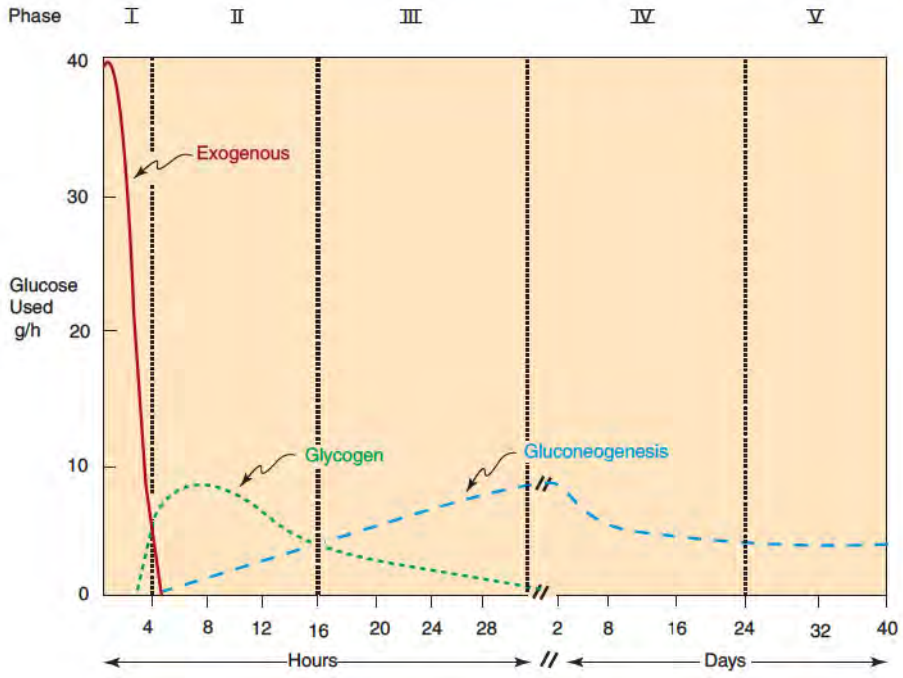
well-fed individuals have high insulin/glucagon ratios that favor storage of glycogen and triacylglycerol, while starving individuals have low insulin/glucagon ratios that stimulate glycogenolysis, lipolysis, ketogenesis, proteolysis, and gluconeogenesis.

The Five Phases of Glucose Homeostasis

Figure 21.8 summarizes the work of Cahill and his colleagues on obese patients undergoing long-term starvation for weight loss. It illustrates the effects of starvation on glucose homeostasis, and it is divided arbitrarily into five phases. Phase I is the well-fed state, in which glucose is provided by dietary carbohydrate. Once this supply is exhausted, hepatic



Phase	ORIGIN OF BLOOD GLUCOSE	TISSUES USING GLUCOSE	MAJOR FUEL OF BRAIN
I	Exogenous	All	Glucose
II	Glycogen Hepatic gluco–neogenesis	All except liver. Muscle and adipose tissue at diminished rates	Glucose
III	Hepatic gluconeogenesis Glycogen	All except liver. Muscle and adipose tissue at rates intermediate between II and IV	Glucose
IV	Gluconeogenesis, hepatic and renal	Brain, RBCs, renal medulla. Small amount by muscle	Glucose, ketone bodies
V	Gluconeogenesis, hepatic and renal	Brain at a diminished rate, RBCs, renal medulla	Ketone bodies, glucose

Figure 21.8 The five phases of glucose homeostasis.
Reproduced with permission from Ruderman, N. B., Aoki, T. T., and Cahill, G. F., Jr. Gluconeogenesis and its disorders in man, in R. W. Hanson, and M. A. Mehlman (Eds.), *Gluconeogenesis, Its Regulation in Mammalian Species.* New York: Wiley, 1976, 515.

glycogenolysis maintains blood glucose levels during phase II. As this supply of glucose starts to dwindle, hepatic gluconeogenesis from lactate, glycerol, and alanine becomes increasingly important until, in phase III, gluconeogenesis is the major source of blood glucose. These changes occur within 20 h or so of fasting, depending on how well-fed the individual was prior to the fast, how much hepatic glycogen was present, and the sort of physical activity occurring during the fast. Several days of fasting lead to phase IV, when dependence on gluconeogenesis decreases. By now, ketone bodies have accumulated to high enough concentrations for them to enter the brain and meet some of its energy needs. Renal gluconeogenesis also becomes significant in this phase. Phase V occurs after very prolonged starvation of extremely obese individuals and is characterized by even less dependence on gluconeogenesis. In this phase, the energy needs of almost every tissue are largely met by fatty acid or ketone body oxidation.

CLINICAL CORRELATION 21.5

Hyperglycemia and Protein Glycation

Glycation of enzymes changes their activity, solubility, and susceptibility to degradation. In the case of hemoglobin A, glycation occurs by a nonenzymatic reaction between glucose and the amino-terminal valine of the β-chain. A Schiff base forms between the aldehyde carbon of glucose and the free amino group of this valine, followed by a rearrangement of the molecule to give a 1-deoxyfructose attached to the valine. The reaction is favored by high glucose levels and the resulting protein, called hemoglobin A_{1c}, is a good index of how high a person's average blood glucose concentration has been over the previous several weeks. The concentration of hemoglobin A_{1c} increases in uncontrolled diabetes and is low in patients who control their glucose level closely.

Glycation of proteins may contribute to the medical complications of diabetes (see Clin. Corrs. 15.4, p. 594, and 21.6, p. 866), for example, coronary heart disease, retinopathy, nephropathy, cataracts, and neuropathy. Increased glycation of lens proteins may contribute to the development of diabetic cataracts. Collagen, laminin, vitronectin, and other matrix proteins can become glycated, with alterations in self-assembly and binding of other matrix molecules. Advanced glycation end products (AGEs) present in the circulation have specific receptors (receptors for AGEs [RAGEs]), through which they stimulate inflammatory reactions. It is likely that RAGE-related phenomena underlie the medical complications of diabetes mentioned above. Compounds which inhibit the formation of AGEs (e.g., aminoguanidine) or which block the RAGE are being tested for their ability to prevent diabetic complications.

Other metabolic abnormalities are responsible for the complications of diabetes, including activation of stress kinases (via increased levels of diacylglycerol and ceramide) and activation of the hexosamine pathway. These abnormalities have been linked to glucose-induced formation of reactive oxygen species by the mitochondria, opening new possibilities for therapies to prevent the complications.

A unifying mechanism. *Diabetes* 54:1615, 2005; and Yan, S. F., Ramasamy, R., and Schmidt, A. M. Mechanisms of disease: Advanced glycation end products and their receptor in inflammation and diabetes complications. *Nat. Clin. Pract. Endocrinol. Metab.* 4:285, 2008.

As long as ketone body concentrations are high and glucose levels are maintained, proteolysis will be somewhat restricted, perhaps by small amounts of insulin still produced by the pancreas, and conservation of muscle proteins and enzymes will occur. This continues until practically all of the fat is used up and ketone body levels fall. After all of the fat is gone, the body has to use muscle protein to maintain blood glucose. Before it's gone, you're gone (see Clin. Corr. 21.3, p. 842).

21.3 • MECHANISMS INVOLVED IN SWITCHING LIVER METABOLISM BETWEEN THE WELL-FED AND STARVED STATES

The liver of a well-fed person actively synthesizes glycogen and triacylglycerol; such a liver is glycogenic, glycolytic, and lipogenic. In contrast, the liver of the fasting person is glycogenolytic, gluconeogenic, ketogenic, and proteolytic. The strategy employed is to store calories when food is available and mobilize them when the rest of the body is in need. The liver is moved between these metabolic extremes by a variety of regulatory mechanisms: substrate supply, allosteric effectors, covalent modification, and **induction–repression** of enzymes.

Substrate Availability Controls Many Metabolic Pathways

This mechanism of control is often ignored. However, the concentration of fatty acids in blood entering the liver is a major determinant of the rate of ketogenesis. Glucose synthesis by the liver is affected by the rate at which gluconeogenic substrates flow to the liver. Delivery of amino acids to the liver in diabetes, because of accelerated and uncontrolled proteolysis, stimulates gluconeogenesis and exacerbates hyperglycemia. On the other hand, failure to supply the liver adequately with glucogenic substrate explains some types of **hypoglycemia,** such as that observed during pregnancy or advanced starvation. Urea synthesis is also regulated by substrate supply. Amino acid metabolism in the intestine provides a substantial fraction of the ammonia used by the liver for urea production. The intestine releases citrulline as discussed, the metabolic precursor of ornithine. A larger ornithine pool

permits increased urea synthesis after a high protein meal. In protein deficiency, the rate of urea formation declines.

We can conclude that substrate supply is a major determinant of the rate at which virtually every metabolic process of the body operates. However, variations in substrate supply are not sufficient to account for the marked changes in metabolism that must occur in the starve–feed cycle. Finer-tuning of the pathways is required.

Allosteric Effectors Regulate Key Enzymes

Figures 21.9 and 21.10 summarize the effects of allosteric effectors in the liver in well-fed and starved states, respectively. As shown in Figure 21.9, glucose activates glucokinase (indirectly by promoting its translocation from the nucleus to the cytoplasm [p. 606]), thereby promoting phosphorylation of glucose.

Glucose also inactivates glycogen phosphorylase and activates glycogen synthase indirectly, thereby preventing degradation and promoting synthesis of glycogen. Fructose 2,6-bisphosphate stimulates 6-phosphofructo-1-kinase and inhibits fructose 1,6-bisphosphatase, thereby stimulating glycolysis and inhibiting gluconeogenesis. Fructose 1,6-bisphosphate activates pyruvate kinase, thereby stimulating glycolysis, and pyruvate activates the pyruvate dehydrogenase complex (indirectly by inhibition of pyruvate dehydrogenase kinase (p. 551)). Citrate activates **acetyl-CoA carboxylase**, thereby stimulating fatty acid synthesis and malonyl CoA inhibits **carnitine palmitoyltransferase I**, thereby inhibiting fatty acid oxidation.

As shown in Figure 21.10, acetyl CoA stimulates gluconeogenesis in the fasted state by activating pyruvate carboxylase and inhibiting the pyruvate dehydrogenase complex (indirectly through stimulation of pyruvate dehydrogenase kinase (p. 551)). Long-chain acyl CoA

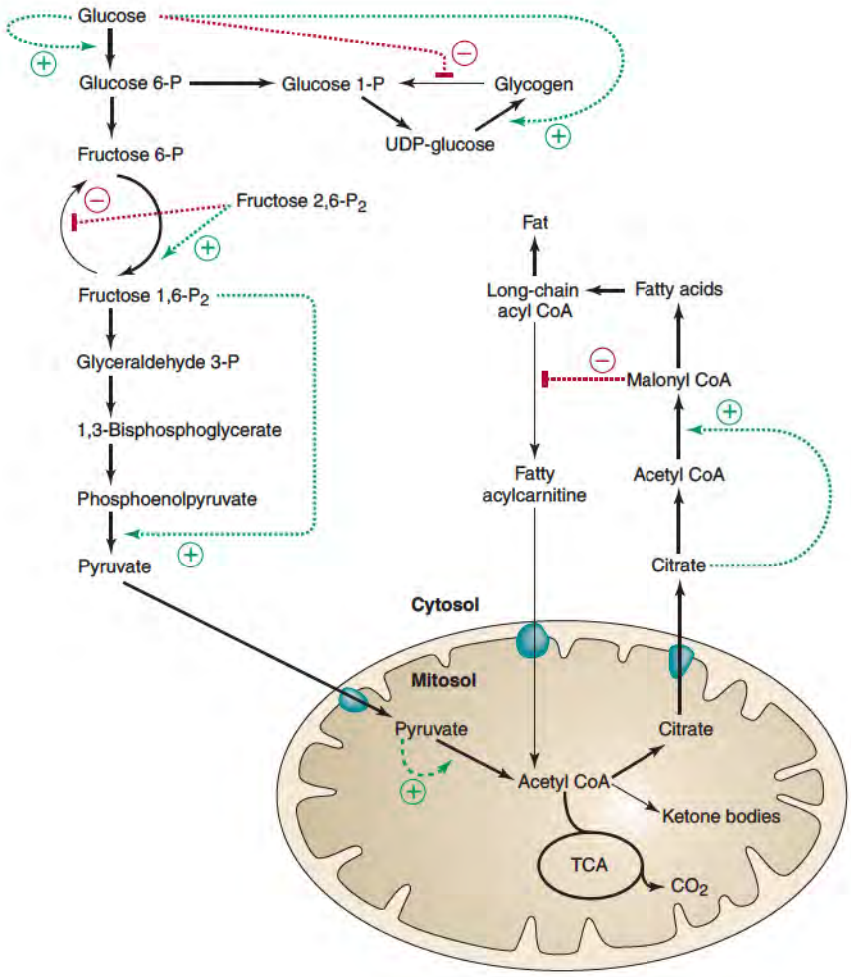


Figure 21.9 Control of hepatic metabolism by allosteric effectors in the well-fed state.

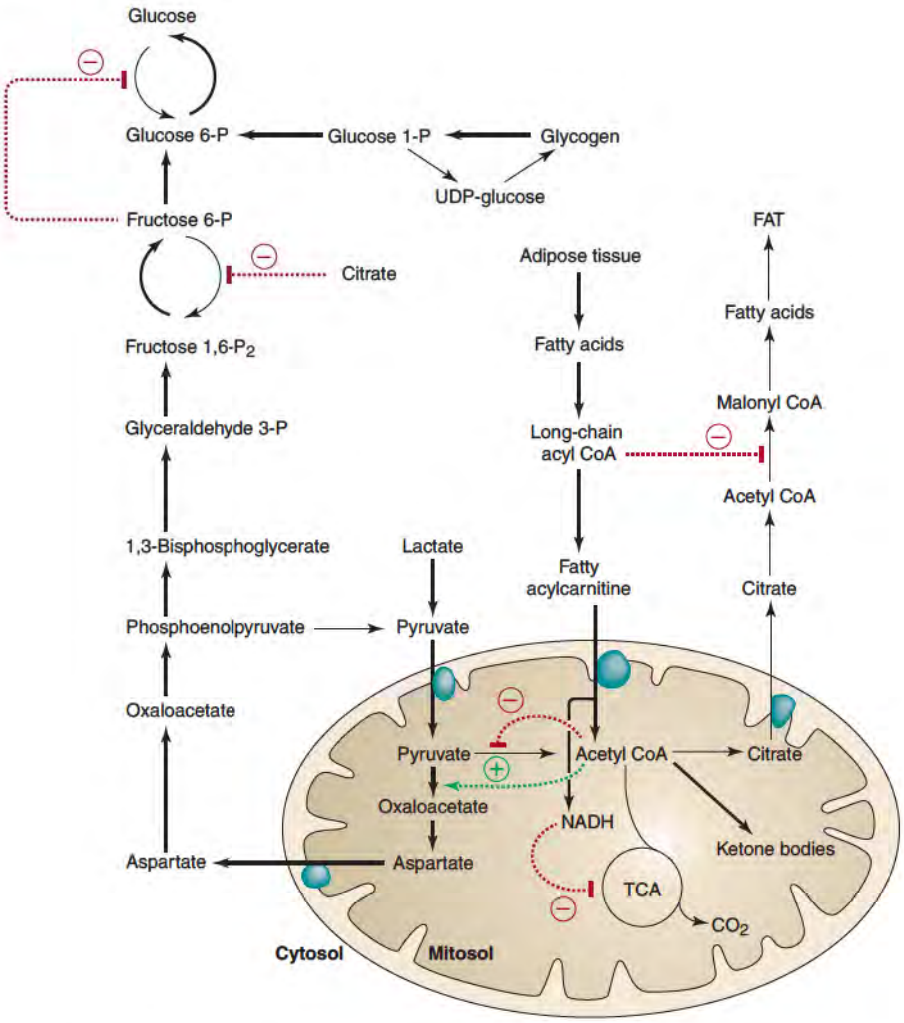

Figure 21.10 **Control of hepatic metabolism by allosteric effectors in the fasting state.**

esters inhibit acetyl-CoA carboxylase, which lowers the level of malonyl CoA and increases carnitine palmitoyltransferase I activity and fatty acid oxidation. Fructose 6-phosphate inhibits glucokinase (indirectly by promoting its translocation from the cytoplasm to the nucleus [p. 606]). Citrate, which is increased in concentration as a consequence of greater fatty acid oxidation, inhibits 6-phosphofructo-1-kinase and 6-phosphofructo-2-kinase (not shown), and NADH produced by fatty acid oxidation inhibits tricarboxylic acid cycle.

Allosteric effectors also regulate flux through metabolic pathways in nonhepatic tissues. Citrate for example serves as a sensor of excess fuel availability in a number of tissues. As negative effector for 6-phosphofructo-1-kinase and a positive effector for acetyl-CoA carboxylase, citrate regulates flux through both glycolysis and fatty acid oxidation. The latter effect is indirect, involving citrate activation of acetyl-CoA carboxylase, which increases the level of malonyl CoA, a negative effector of carnitine palmitoyltransferase I. Since glucose and fatty acid catabolism increase citrate levels and both can be inhibited by citrate, cells can sense the amount of fuel available for catabolism by their citrate level.

Malonyl CoA in the liver is an intermediate in fatty acid synthesis and a regulator of fatty acid oxidation via its negative effect on carnitine palmitoyltransferase I (p. 691). Malonyl CoA is also produced in other tissues, for example, skeletal muscle and heart, but its only purpose here is regulation of carnitine palmitoyltransferase I. Steady-state levels of malonyl CoA are set by the relative activities of acetyl-CoA carboxylase (ACC) and malonyl-CoA decarboxylase (MDC) (Figure 21.11).

cAMP is an important allosteric effector that is greatly increased in liver during starvation. It is not shown in Figures 21.9 and 21.10 because it is part of the signaling mechanism responsible for bringing about phosphorylation of enzymes subject to covalent modification.

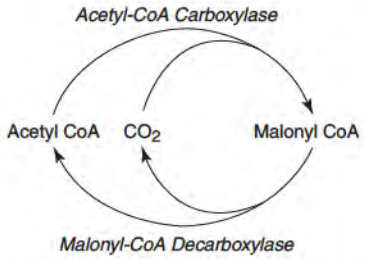

Figure 21.11 **Relative activities of acetyl-CoA carboxylase and malonyl-CoA decarboxylase determine the concentration of malonyl CoA.**

AMP is another important allosteric effector not shown in Figures 21.9 or 21.10. Its concentration is maintained very low in both the fed and the starved state. The high ATP concentration usually present in cells keeps AMP low by driving the reaction catalyzed by adenylate kinase to the right by mass action: ATP + AMP $\rightleftharpoons$ 2ADP. However, conditions that induce an energy deficit in cells, for example, hypoxia, excessive demand for energy, or muscle contraction during exercise, cause the reaction catalyzed by adenylate kinase to shift to the left as ATP decreases. The resulting increase in AMP causes activation of glycogen phosphorylase and 6-phosphofructo-1-kinase and inhibition of fructose-1,6-bisphosphatase by allosteric mechanisms (p. 413), thereby increasing glycogenolysis and glycolysis which combine to increase the rate of ATP production. The increase in AMP also activates **AMP-activated protein kinase** (**AMPK**), which also promotes the recovery of normal ATP levels by the phosphorylation of a number of regulatory enzymes.

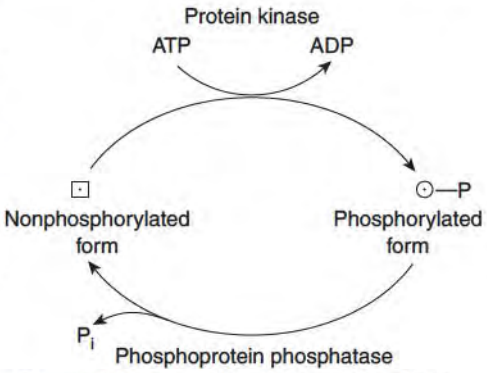

Figure 21.12 Regulation of the activity of key enzymes by covalent modification. The symbols ⊡ and ⊙-P designate the nonphosphorylated and phosphorylated states of enzymes, respectively.

Covalent Modification Regulates Key Enzymes

The activities of many enzymes are modified by covalent modification, especially by phosphorylation of serine and threonine residues (Figure 21.12 and p. 413). Some important points about regulation by this type of control are (1) some enzymes undergo phosphorylation on one or more serine or threonine residues by protein kinases that are also subject to regulation; (2) dephosphorylation of enzymes is carried out by phosphoprotein phosphatases that are also subject to regulation; (3) phosphorylation status affects the catalytic activities of the enzymes; (4) some enzymes are active in the dephosphorylated state, others in the phosphorylated state; (5) cAMP signals the phosphorylation of many enzymes by activating **protein kinase A** (cAMP-dependent protein kinase) (Figure 21.13); (6) glucagon and α-adrenergic agonists (epinephrine) activate protein kinase A by increasing cAMP levels (Figure 21.13); (7) AMP also signals the phosphorylation of many enzymes by activating AMPK (AMP-activated protein kinase) (Figure 21.14); (8) stress (extra work) imposed on a cell that causes energy deprivation results in an increase in AMP concentration and activation of AMPK (Figure 21.14); (9) insulin (p. 615) opposes the action of protein kinase A and AMPK by activating phosphoprotein phosphatases; (10) metabolic enzymes are dephosphorylated in the fed state because the insulin/glucagon ratio is high and both cAMP and AMP are low; (11) metabolic enzymes are phosphorylated in the fasted state because the insulin/glucagon ratio is low and cAMP is increased (see Figure 21.13); and (12) metabolic enzymes are phosphorylated in energy-deprived states because AMP levels are increased (see Figure 21.14).

The hepatic enzymes subject to covalent modification are all relatively dephosphorylated in well-fed animals (Figure 21.15). Insulin is high but glucagon is low in the blood, resulting in low cAMP levels in the liver. A resulting low protein kinase A activity and high phosphoprotein phosphatase activity induce the dephosphorylated state of the enzymes

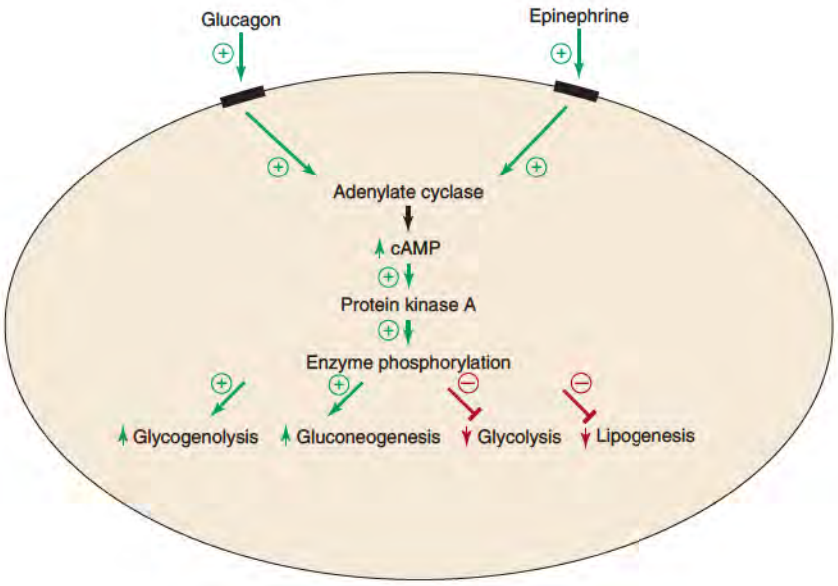

Figure 21.13 Glucagon and epinephrine stimulate glycogenolysis and gluconeogenesis and inhibit glycolysis and lipogenesis in liver.

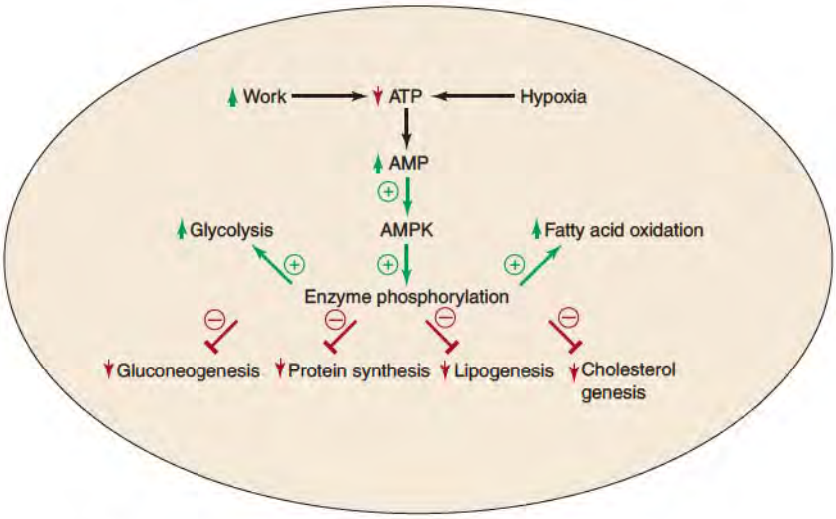

Figure 21.14 Activation of AMPK shuts down ATP-requiring processes and stimulates ATP-producing processes.

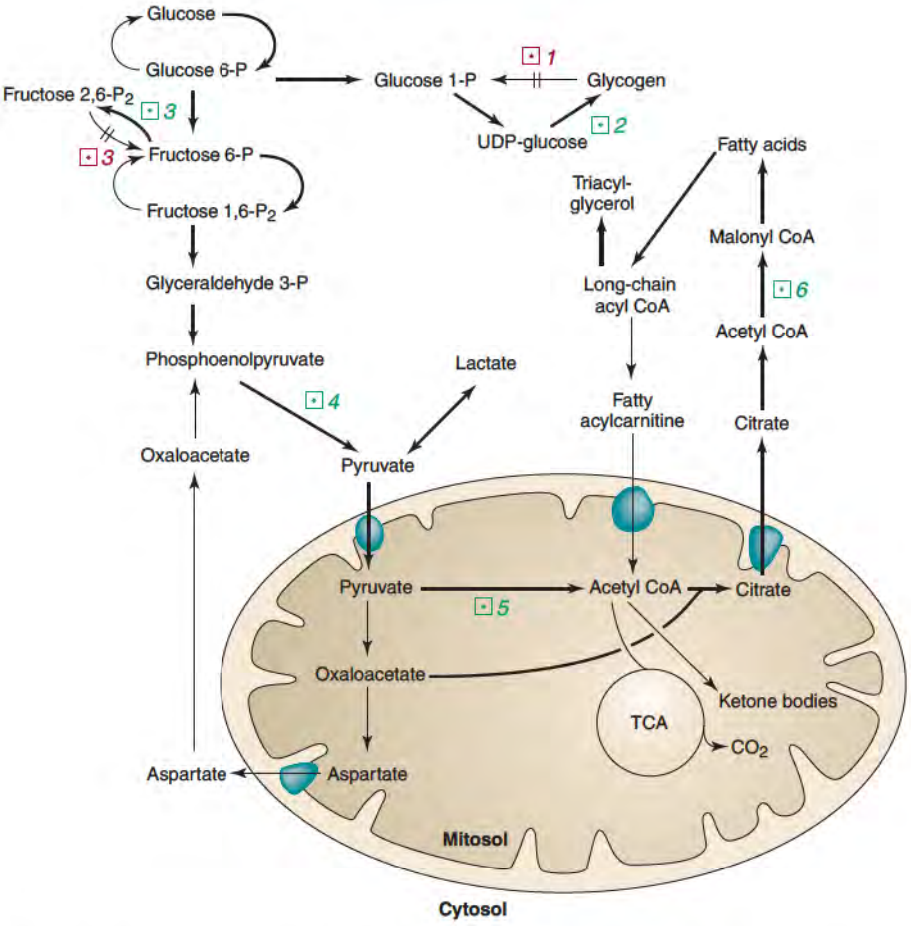

Figure 21.15 Control of hepatic metabolism by covalent modification in the well-fed state. Dephosphorylated mode is indicated by ⊡. The enzymes subject to covalent modification are (1) glycogen phosphorylase, (2) glycogen synthase, (3) 6-phosphofructo-2-kinase/fructose- 2,6-bisphosphatase (bifunctional enzyme), (4) pyruvate kinase, (5) pyruvate dehydrogenase; and (6) acetyl-CoA carboxylase.

(glycogen synthase, glycogen phosphorylase, phosphorylase kinase, 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase, pyruvate kinase, and acetyl-CoA carboxylase) regulated by covalent modification in the liver.

Although not regulated by protein kinase A, the phosphorylation state of the pyruvate dehydrogenase complex changes in parallel with the enzymes identified in Figure 21.15 because of low activity of pyruvate dehydrogenase kinase in the well-fed state. Glycogen synthase, 6-phosphofructo-2-kinase, pyruvate kinase, pyruvate dehydrogenase, and acetyl-CoA carboxylase are active in the dephosphorylated state whereas glycogen phosphorylase, phosphorylase kinase (not identified in Figure 21.15), and fructose 2,6-bisphosphatase are all inactive. As a consequence of the dephosphorylated state of these enzymes, glycogenesis,

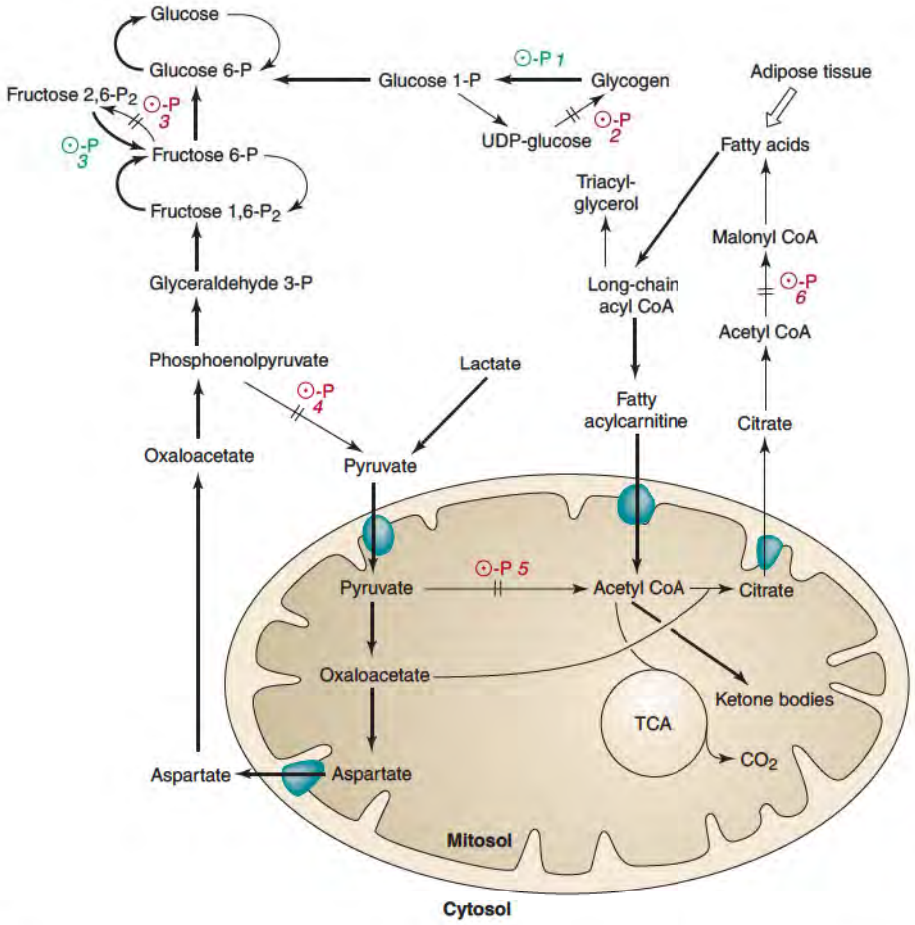

Figure 21.16 Control of hepatic metabolism by covalent modification in the fasting state. Phosphorylated mode is indicated by ⊙ -P. Numbers refer to the same enzymes as in Figure 21.15.

glycolysis, and lipogenesis are greatly favored in the liver of the well-fed animal whereas the opposing pathways (glycogenolysis, gluconeogenesis, and ketogenesis) are inhibited.

As shown in Figure 21.16, the hepatic enzymes subject to covalent modification are all relatively phosphorylated in the fasting animal. Insulin level in the blood is low but glucagon is high, resulting in high cAMP levels in the liver. This activates protein kinase A and inactivates phosphoprotein phosphatase. The net effect is a greater degree of phosphorylation of the regulatory enzymes than in the well-fed state. Three enzymes (glycogen phosphorylase, phosphorylase kinase, and fructose 2,6-bisphosphatase) are activated as a consequence of phosphorylation. All other enzymes subject to covalent modification are inactivated. As a result, glycogenolysis, gluconeogenesis, and ketogenesis dominate and glycogenesis, glycolysis, and lipogenesis are shut down.

Metabolic enzymes are also regulated through phosphorylation by AMP-activated protein kinase (AMPK) as summarized in Figures 21.14, p. 856, and 21.17. AMPK is activated by an increase in AMP concentration, which is set by the energy status of cells. Under conditions of high-energy demand that decreases ATP and therefore increases AMP, AMPK turns off anabolic pathways that consume ATP and turns on catabolic pathways that generate ATP. As shown in Figure 21.17, AMPK inhibits fatty acid synthesis by phosphorylating acetyl-CoA carboxylase, inhibits triacylglycerol synthesis by phosphorylating glycerol-3-phosphate acyltransferase, inhibits cholesterol synthesis by phosphorylating 3-hydroxy-3-methylglutaryl-CoA reductase, and inhibits glycogen synthesis by phosphorylating glycogen synthase. AMPK also inhibits protein synthesis (not shown) by phosphorylating components of the mTOR (mammalian target of rapamycin) pathway that activate mRNA translation. The strategy is to minimize use of ATP by all pathways not immediately essential for cell survival. At the same time, AMPK promotes ATP generation by fatty acid oxidation by lowering the concentration of malonyl CoA, a potent allosteric inhibitor of carnitine palmitoyl-transferase 1 (p. 691). This is achieved by phosphorylation-mediated inactivation of acetyl-CoA carboxylase and activation of malonyl-CoA decarboxylase by AMPK.

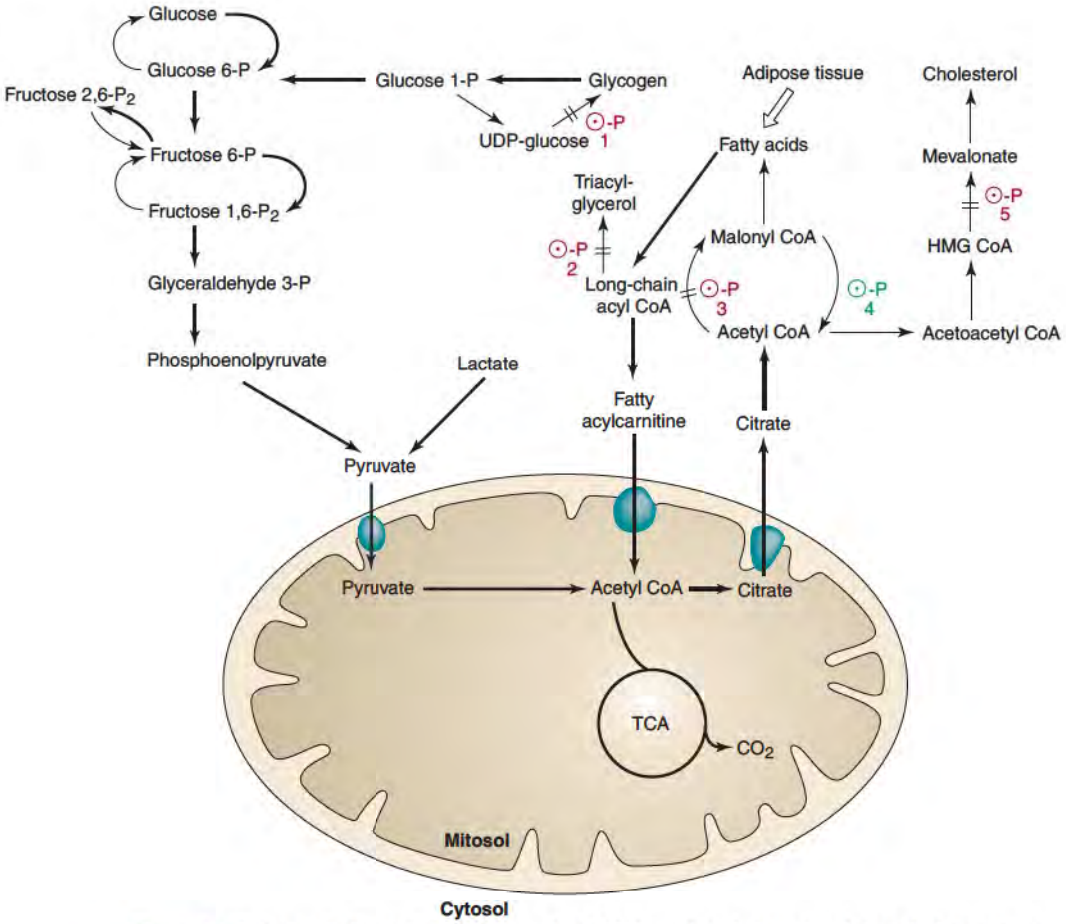

Figure 21.17 Control of hepatic metabolism by AMPK-mediated phosphorylation during energy deprivation. Phosphorylated mode is indicated by ⊙-P. The enzymes phosphorylated by AMPK are (1) glycogen synthase, (2) glycerol-3-phosphate acyltransferase, (3) acetyl-CoA carboxylase, (4) malonyl-CoA decarboxylase, and (5) 3-hydroxy-3-methylglutaryl-CoA (HMG CoA) reductase.

Adipose tissue responds almost as dramatically as liver to the starve–feed cycle. Pyruvate kinase, the pyruvate dehydrogenase complex, acetyl-CoA carboxylase, and hormone-sensitive lipase (not found in liver) are dephosphorylated in adipose tissue in the well-fed state. The first three enzymes are active while hormone-sensitive lipase is inactive in this state. A high insulin level in the blood and a low cAMP concentration in adipose tissue are important determinants of the phosphorylation state of these enzymes, which favors lipogenesis in the well-fed state. During fasting, a decrease in the insulin level and an increase in epinephrine shut down lipogenesis and activate lipolysis because of phosphorylation of these enzymes. In this manner, adipose tissue is transformed from a fat storage tissue into a source of fatty acids for oxidation in other tissues and glycerol for gluconeogenesis in the liver.

Covalent modification of enzymes in skeletal muscle is also important in the starve–feed cycle. Glycogen synthase, glycogen phosphorylase, pyruvate dehydrogenase complex, acetyl-CoA carboxylase, and malonyl-CoA decarboxylase are dephosphorylated in the fed state. This, along with insulin-mediated stimulation of glucose uptake by glucose transporter 4 (GLUT4) (p. 858), favors glucose uptake, glycogen synthesis, and complete oxidation by skeletal muscle. The increase in malonyl-CoA favored by the combination of an active acetyl-CoA carboxylase and an inactive malonyl-CoA decarboxylase limits fatty acid oxidation at the level of carnitine palmitoyltransferase 1. During fasting, conservation of glucose, lactate, alanine, and pyruvate is crucial for survival. Tissues of the body that can use alternative fuels invariably shut down their use of glucose and three-carbon compounds that can be used for the synthesis of glucose. Increased availability of fatty acids and enzymatic activity for oxidation spares glucose in the starved state. The latter is due to decreased malonyl CoA levels and therefore less inhibition of carnitine palmitoyl-transferase 1 induced by phosphorylation-mediated inactivation of acetyl-CoA carboxylase and activation of malonyl-CoA

decarboxylase. Regulation of the utilization of glucose by fatty acid catabolism has been named the glucose–fatty acid cycle. Inactivation of the pyruvate dehydrogenase complex in skeletal muscle by phosphorylation is the key to conservation of glucose and three carbon compounds for hepatic gluconeogenesis during fasting. This is mediated by pyruvate dehydrogenase kinase (p. 551), which is induced to a higher level of expression and stimulated to greater activity by its allosteric effectors acetyl CoA and NADH produced by fatty acid oxidation.

Exercise induces profound effects on metabolic pathways in skeletal muscle. The energy demand of muscle contraction increases AMP and activates AMPK. AMPK stimulates the transport of vesicles bearing GLUT4 to the plasma membrane for greater glucose uptake and catabolism for ATP production. AMPK-mediated phosphorylations also decrease malonyl CoA by inactivating acetyl-CoA carboxylase and activating malonyl-CoA decarboxylase (see Figures 21.14, p. 856, and 21.17). Less malonyl CoA results in greater carnitine palmitoyltransferase 1 activity and fatty acid oxidation to help meet muscle's need for ATP for contraction.

Covalent modification, like allosteric effectors and substrate supply, is a short-term regulatory mechanism, operating on a minute-to-minute basis. On a longer time scale, enzyme activities are controlled at the level of expression, most frequently by the rate of gene transcription.

Changes in the Amounts of Key Enzymes Provide Long-Term Adaptation

Whereas allosteric effectors and covalent modification affect either the K_m or V_{max} of an enzyme, enzyme activity is also regulated by the rate of its synthesis or degradation, and thus the quantity of enzyme in a cell. For example, in a person maintained in a well-fed or overfed condition, the liver has increased amounts of enzymes involved in triacylglycerol synthesis (Figure 21.18). Many enzymes are induced by an increase in the insulin/glucagon ratio and glucose in the blood. These include glucokinase, 6-phospho-1-fructokinase, and pyruvate kinase for faster rates of glycolysis; glucose 6-phosphate dehydrogenase, 6-phosphogluconate

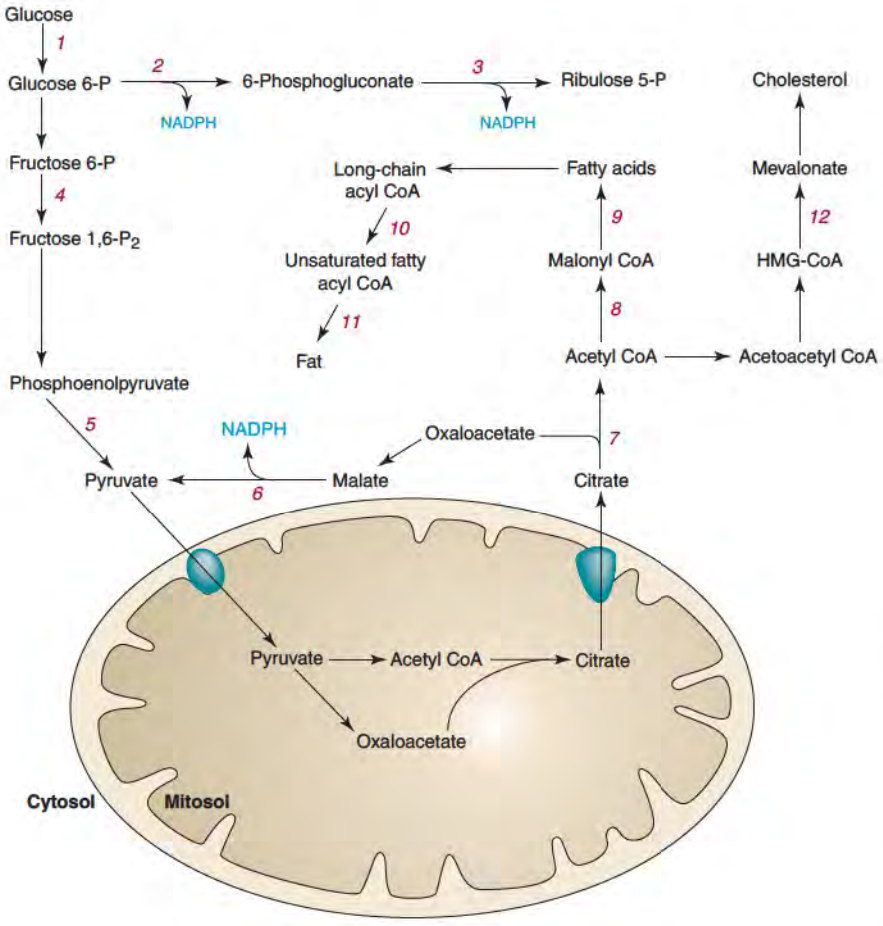

Figure 21.18 Hepatic enzymes induced in the well-fed state. The inducible enzymes are numbered (1) glucokinase, (2) glucose 6-phosphate dehydrogenase, (3) 6-phosphogluconate dehydrogenase, (4) 6-phosphofructo-1-kinase, (5) pyruvate kinase, (6) malic enzyme, (7) citrate cleavage enzyme, (8) acetyl-CoA carboxylase, (9) fatty acid synthase, (10) Δ^9-desaturase, (11) glycerol-3-phosphate acyltransferase, and (12) 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase.

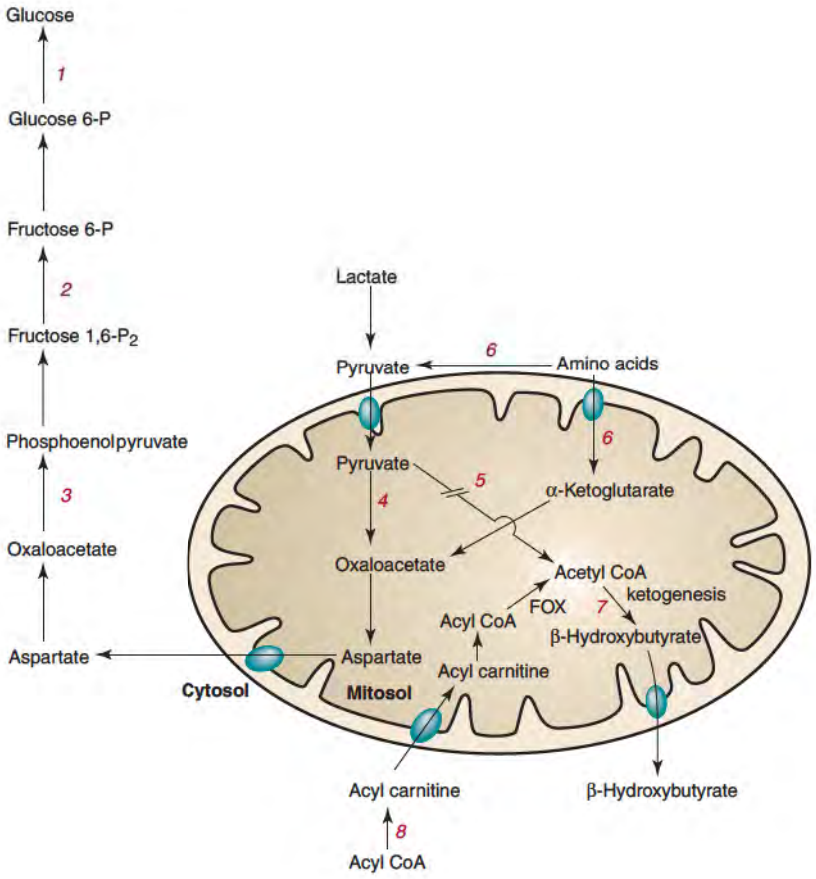

Figure 21.19 Hepatic enzymes induced in the fasted state. The inducible enzymes are numbered (1) glucose 6-phosphatase, (2) fructose 1,6-bisphosphatase, (3) phosphoenolpyruvate carboxykinase, (4) pyruvate carboxylase, (5) pyruvate dehydrogenase kinase, (6) various aminotransferases, (7) mitochondrial 3-hydroxy-3-methylglutaryl-CoA synthase, and (8) carnitine palmitoyltransferase I. Parallel lines intersecting arrow from pyruvate to acetyl CoA denote inhibition (due to phosphorylation) of the pyruvate dehydrogenase complex due to induction of pyruvate dehydrogenase kinase. Abbreviation: FOX, fatty acid oxidation.

dehydrogenase, and malic enzyme to provide greater quantities of the NADPH required for synthesis of fatty acids and cholesterol; citrate cleavage enzyme, acetyl-CoA carboxylase, fatty acid synthase, and Δ^9-desaturase for fatty acid synthesis; 3-hydroxy-3-methylglutaryl-CoA reductase for cholesterol synthesis; and glycerol 3-phosphate acyltransferase for triacylglycerol and phospholipid synthesis. At the same time, phosphoenolpyruvate carboxykinase, pyruvate dehydrogenase kinase, pyruvate carboxylase, fructose 1,6-bisphosphatase, glucose 6-phosphatase, and some aminotransferases are decreased in amount.

In fasting, the lipogenic enzymes decrease dramatically in quantity, while those that favor gluconeogenesis (glucose-6-phosphatase, fructose 1,6-bisphosphatase, phosphoenolpyruvate carboxykinase, pyruvate carboxylase, and various amino transferases) are remarkably induced (Figure 21.19). Starvation also induces pyruvate dehydrogenase kinase, responsible for phosphorylation and inactivation of the pyruvate dehydrogenase complex, which prevents conversion of pyruvate to acetyl CoA, thereby conserving lactate, pyruvate, and the carbon of some amino acids for glucose synthesis. Induction of carnitine palmitoyltransferase I and mitochondrial 3-hydroxy-3-methylglutaryl-CoA synthase likewise increases the capacity of the liver for fatty acid oxidation and ketogenesis. This is particularly important because fatty acid oxidation is the primary source of the ATP needed for hepatic glucose synthesis. Enzymes of the urea cycle and other amino acid metabolizing enzymes such as liver glutaminase, tyrosine aminotransferase, serine dehydratase, proline oxidase, and histidase are induced for disposal of nitrogen, as urea, generated from the amino acids used in gluconeogenesis.

Regulation of the rate of gene transcription is the primary way by which changes in enzyme amounts are controlled. In the well-fed state, the genes for synthesis of fatty acids are controlled by sterol-response-element-binding proteins (**SREBP**) and carbohydrate-response-element-binding protein (**ChREBP**). In the well-fed state an increase in insulin signals an increase in SREBP-1c (Figure 21.20), which functions as a transcription factor to increase transcription of the genes encoding the lipogenic enzymes. Under the same conditions, an increase in glucose indirectly increases the effectiveness of ChREBP, which also functions as a transcription factor for genes encoding lipogenic enzymes (Figure 21.20). ChREBP is subject to regulation by phosphorylation/dephosphorylation, with the phosphorylated form being

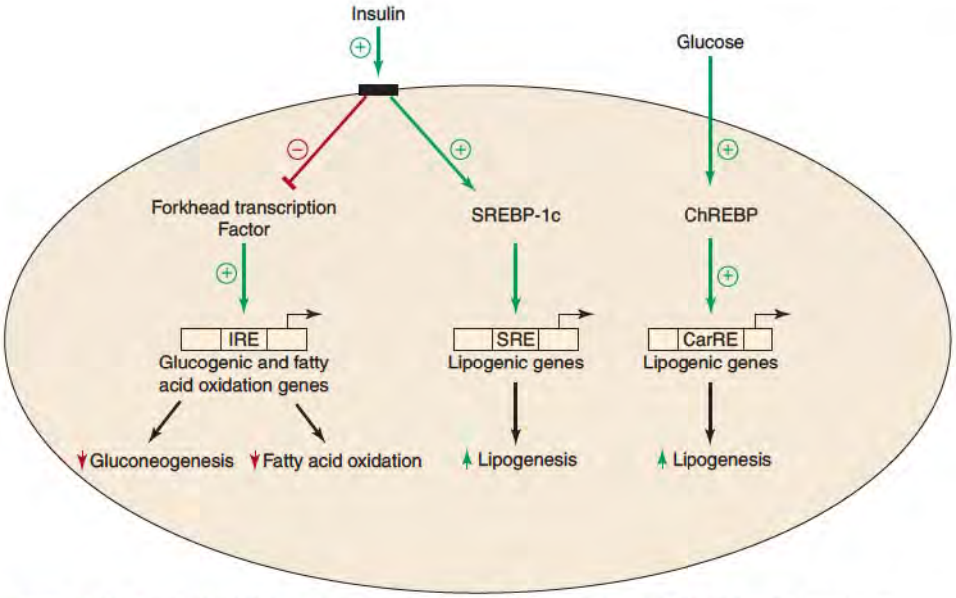

Figure 21.20 Regulation of gene transcription in liver by insulin and glucose. Insulin inactivates forkhead transcription factor by a signaling pathway involving activation of the insulin receptor, phosphorylation of insulin receptor substrate (IRS), activation of phosphatidylinositol-3-kinase (PI3K), and activation of protein kinase B (see Figure 13.33, p. 536). Abbreviations: IRE, insulin responsive element; SRE, SREBP-1c responsive element; and CarRE, carbohydrate responsive element.

inactive and sequestered outside of the nucleus. Activation of a phosphoprotein phosphatase by a metabolite of glucose results in dephosphorylation of ChREBP, which is transported into the nucleus where it increases transcription of genes encoding the lipogenic enzymes. Glucagon acts in opposition to insulin and glucose by signaling activation via cAMP of protein kinase A, which phosphorylates ChREBP, rendering it ineffective. Protein kinase A also phosphorylates **c**AMP-**r**esponse-**e**lement(CRE)-**b**inding (CREB) protein, a transcription factor that inhibits transcription of the genes encoding the lipogenic enzymes (Figure 21.21).

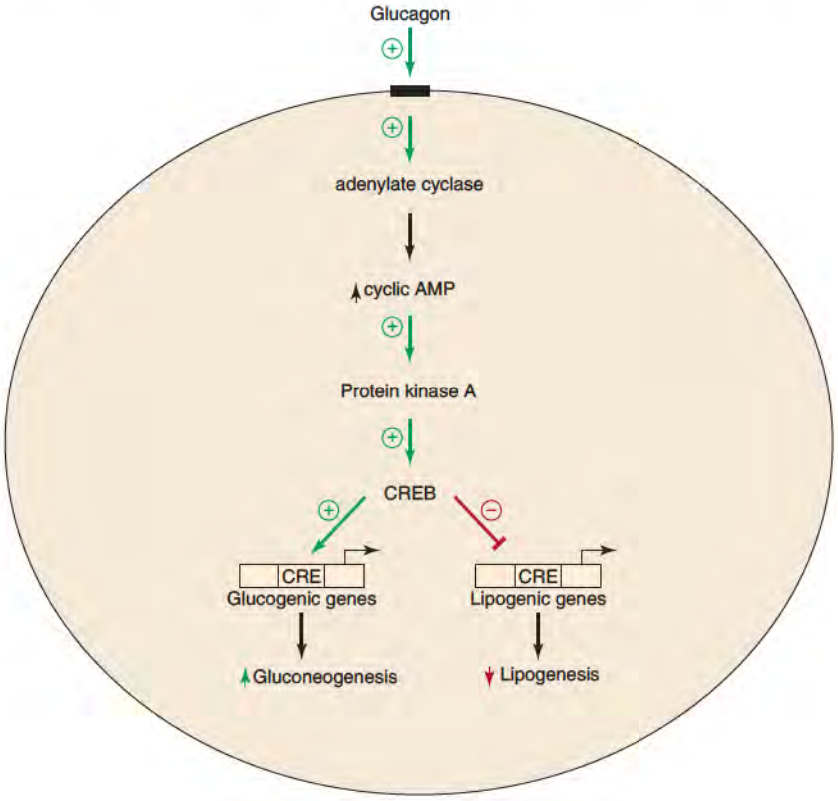

Figure 21.21 Regulation of gene transcription in liver by glucagon. Glucagon activates protein kinase A by the pathway given in Figure 21.13. Abbreviation: CRE, CREB responsive element.

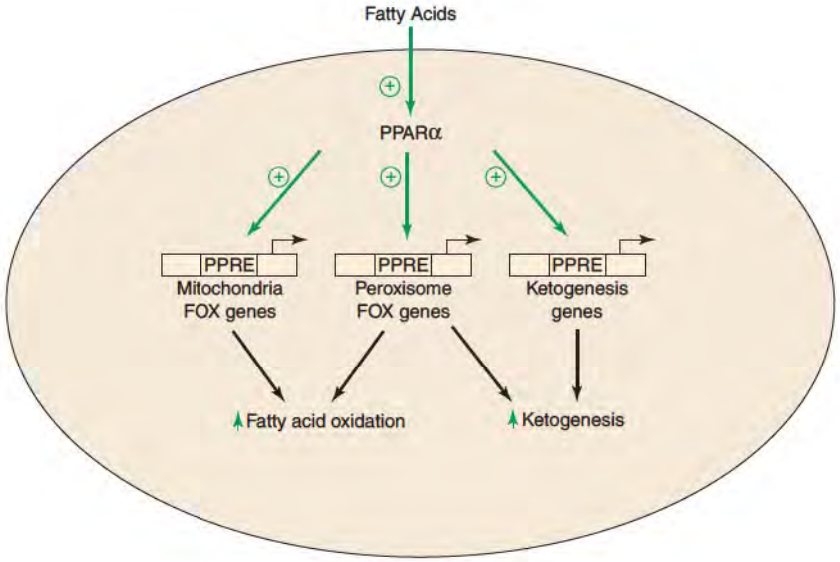

Figure 21.22 PPARα activation by fatty acids promotes transcription of fatty acid oxidation (FOX) and ketogenesis genes. Abbreviation: PPRE, PPAR responsive element

A second form of SREBP designated SREBP-2, regulates cholesterol synthesis (p. 727). When levels of cholesterol fall in cells, SREBP, which is anchored in the endoplasmic reticulum, moves to the Golgi apparatus where it is cleaved by a protease, releasing the N-terminal fragment (SREBP-2) that acts as a transcriptional activator of genes encoding for cytosolic 3-hydroxy-3-methylglutaryl-CoA synthase, 3-hydroxy-3-methylglutaryl-CoA reductase, squalene synthase, and the LDL receptor.

Glucagon promotes the transcription of genes encoding gluconeogenic enzymes via activation of adenylate cyclase, protein kinase A, and the transcription factor CREB (Figure 21.21). Insulin opposes this action of glucagon. Several mechanisms are involved but one of the most important involves inhibition of the activity of forkhead transcription factors that are required for the transcription of the genes encoding insulin response elements (IRE) and gluconeogenic enzymes (see Figure 21.20). Energy deficiency leads to inhibition of fat, cholesterol, and glucose synthesis by liver cells. Activation of AMPK by AMP both reduces the transcription of SREBP and inhibits its transcriptional activity and therefore inhibits both fat and cholesterol synthesis (Figure 21.20). Activation of AMPK also inhibits the transcriptional activity of **h**epatic **n**uclear **f**actor **4**α (HNF4α), which is required for transcription of genes encoding gluconeogenic enzymes.

Peroxisome **p**roliferator-**a**ctivated **r**eceptor α (PPARα), a member of the nuclear receptor family, is a receptor for fatty acids, is expressed at high levels in tissues (liver, kidney, and heart) with high capacity for fatty acid oxidation. Polyunsaturated fatty acids stimulate the receptor to activate transcription of genes involved in disposal of fatty acids (Figure 21.22) which contain a **p**eroxisome **p**roliferation **r**esponse **e**lement (PPRE) in their promoters, including those for enzymes of the peroxisomal, microsomal, and mitochondrial fatty acid oxidation (FOX) systems, apolipoprotein genes needed for export of hepatic triacylglycerol as VLDL, and enzymes of ketogenesis. In adipose tissue, the PPARγ isoform is expressed. When activated (perhaps by fatty acid derivatives such as prostaglandins), it orchestrates the differentiation of preadipocytes to adipocytes, increasing the ability to store triacylglycerol. The activity of both forms of PPAR is augmented by the PPARγ-coactivator 1-alpha (PGC-1α), which is induced by cAMP and activated by phosphorylation mediated by AMPK. These adaptive changes also influence the effectiveness of the short-term regulatory mechanisms. For example, in long-term starvation or uncontrolled diabetes, changing the concentration of the allosteric effectors for acetyl-CoA carboxylase will have little effect when the enzyme is virtually absent due to down-regulation of the expression of its gene. A chronically starved person cannot effectively utilize a load of glucose because of the absence of the key enzymes needed for glucose metabolism. This is the glucose intolerance of starvation. A glucose load, however, will set into motion the necessary adaptations and reestablishment of short-term regulatory mechanisms.

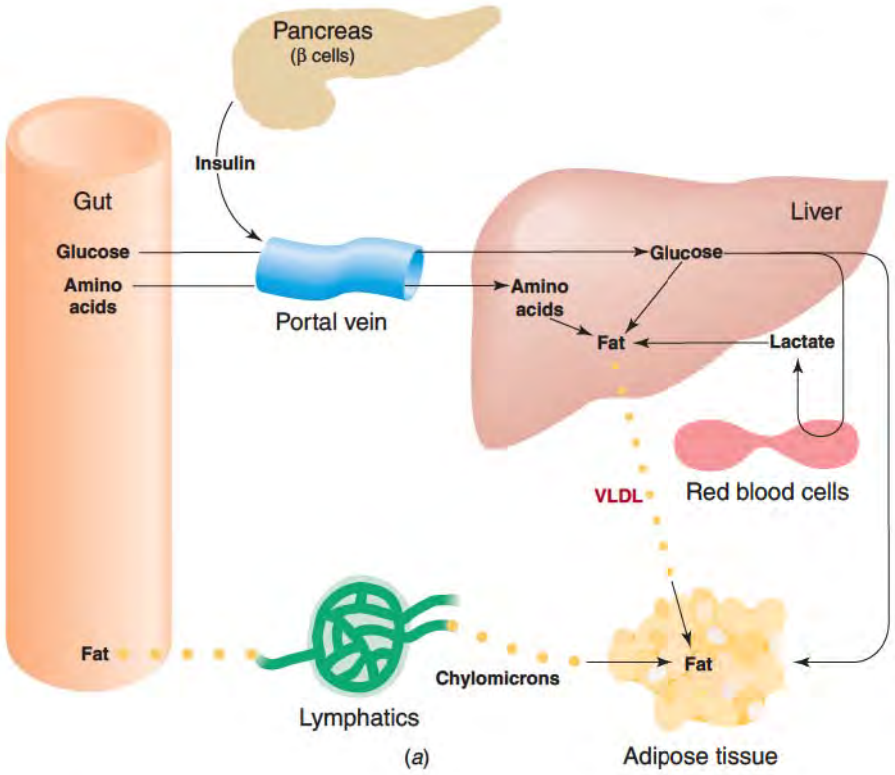

Figure 21.23 Metabolic interrelationships of tissues in various nutritional, hormonal, and disease states: Obesity.

21.4 • INTERRELATIONSHIP OF TISSUES IN NUTRITIONAL AND HORMONAL STATES

Many changes that occur in the different nutritional and hormonal states are variations on the starve–feed cycle. Some examples are given in Figure 21.23. Others are obvious, for example, the rapid growth of a child, when amino acids are directed away from catabolism and into protein synthesis. The changes that occur in some physiologically important situations, however, are rather subtle and poorly understood. For instance, in aging there appears to be a decreased sensitivity of the major tissues of the body to hormones, with decreased ability of tissues to respond normally during the starve–feed cycle. Whether this is a contributing factor to or a consequence of the aging process is not known.

Obesity

Figure 21.23 illustrates the metabolic interrelationships prevailing in an obese person. Body fat originates primarily from the diet. Only small amounts are synthesized in the liver and transported to the adipose tissue or synthesized in adipocytes. Obesity results from overeating. It follows from being too long in the well-fed state because of the amount of food consumed. The fasting phase of the starve–feed cycle is too short to use up the fat stored by the body during the feeding phase of the cycle (see Clin. Corr. 21.1, p. 840).

Obesity is epidemic in the affluent countries of the world. Enticing food is plentiful and cheap. Obesity needs to be aggressively treated to prevent progression to the metabolic syndrome, type 2 diabetes mellitus, and cardiovascular disease. Unfortunately, there is no effective intervention other than dieting. Metabolic syndrome, strongly associated with the development of early atherosclerosis, refers to a constellation of medical problems, including abdominal obesity, elevated blood pressure, high blood lipids, and insulin resistance.

Obesity frequently causes insulin resistance. In some patients, the number or affinity of insulin receptors is reduced, while others have normal insulin binding, but abnormal postreceptor responses, such as the activation of glucose transport. Generally, the quantity of body fat is proportional to the degree of insulin resistance. Some of the resistance is due to peptides (TNFα and resistin) produced by adipocytes that are known to oppose the

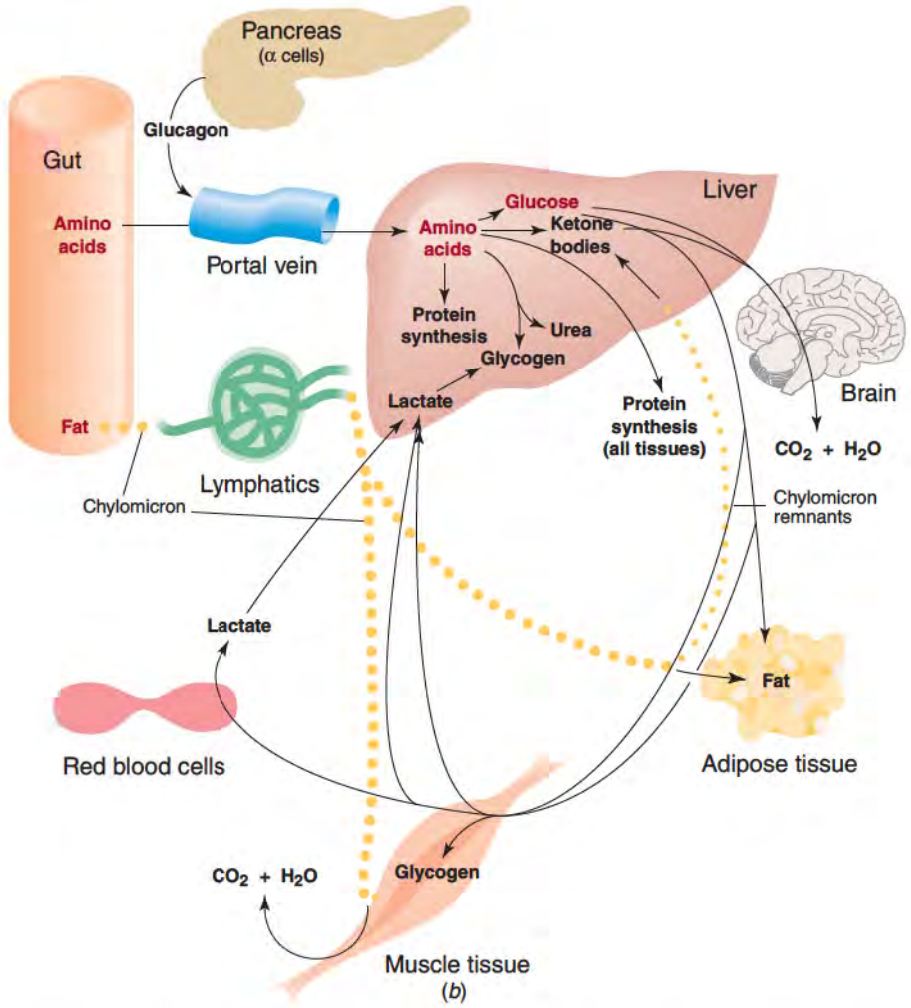

Figure 21.24 Metabolic interrelationships of tissues in dieting.

action of insulin. An additional adipokine, adiponectin, is reduced in obesity, which may also contribute to insulin resistance. Plasma insulin levels are often greatly elevated in obese individuals, a harbinger for the development of type 2 diabetes mellitus.

Dieting

To lose weight requires a negative energy balance, which means fewer calories must be consumed than are expended each day. Consuming less food with the same macronutrient composition has little effect on the starve–feed cycle, other than the length of time in the well-fed state. The responsibilities of tissues will stay the same in the well-fed state (see Figure 21.2, p. 843), except that less glycogen and triacylglycerol will be stored and the switch to the function of tissues in the fasted state (see Figure 21.4, p. 845) will occur sooner after meals. Another way to lose weight, long advocated by most health agencies, is to cut calories by specifically reducing the amount of fat consumed. Again, the well-fed state of tissues will stay the same except for a reduction in stored triacylglycerol. The switch to the fasting state will occur sooner after meals, unless the decrease in fat intake has been compensated by an increase in carbohydrate intake, a common problem for dieters. Another way to lose weight, originally advocated by Robert Atkins, is to decrease specifically the amount of carbohydrate consumed. The Atkins controlled-carbohydrate diet and variations thereof, frequently called the very low-carbohydrate ketogenic diet, produces interesting effects on tissues. On this diet, intake of protein is high, fat is moderate, and carbohydrate is extremely low (< 50 g/day; < 10% of a 2000 kcal/day diet). The metabolic functions of tissues in the fed state for an individual on such a diet are summarized in Figure 21.24. The fasting state is little changed from that of other diets, but the almost complete lack of dietary carbohydrate requires that the liver remain gluconeogenic as well as ketogenic in the fed

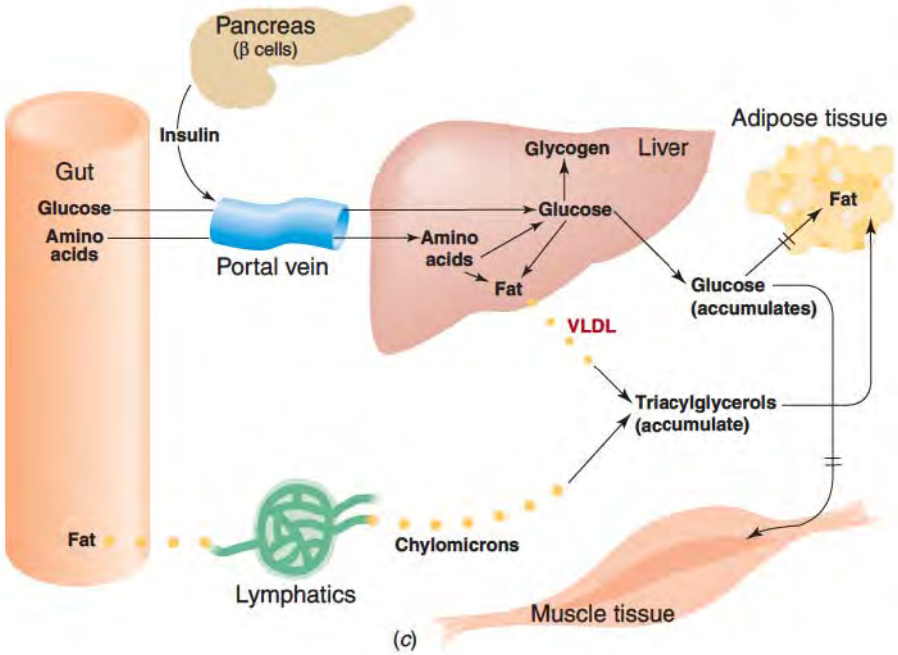

Figure 21.25 Metabolic interrelationships of tissues in type 2 diabetes mellitus.

state. Little rise in blood glucose and a less than normal rise in insulin occur in response to meals. Amino acids present in excess beyond that needed for protein synthesis are converted to liver glycogen, blood glucose, and ketone bodies. Large amounts of amino acids coming from the gut minimize the need for release of amino acids from peripheral tissues for hepatic gluconeogenesis. Fatty acids delivered to the liver in chylomicron remnants are primarily converted to ketone bodies to provide ATP for gluconeogenesis. Glucose and ketone bodies are therefore produced in both the fed and fasted states. Although it would seem that overproduction and/or underutilization of ketone bodies could cause ketoacidosis, as it does in type 1 diabetes (p. 865), the need for a supply of energy in the form of ketone bodies in peripheral tissues largely balances the production of ketone bodies by the liver. The low-carbohydrate diet has been tested in controlled trials, which have been relatively short term (6–12 mon): Weight loss is somewhat more rapid than achieved with low-fat, low-calorie diets, but the extent of weight loss, compliance with the diet, and tendency to regain weight are similar. Of interest, this diet didn't increase blood cholesterol or LDL levels, and improved VLDL and HDL levels better than low-fat, low-calorie diets.

Type 2 Diabetes Mellitus

Figure 21.25 shows the metabolic interrelationships characteristic of a person with type 2 diabetes mellitus. These individuals are resistant to insulin and have insufficient production of insulin to overcome the resistance (Clin. Corr. 21.6). The majority of patients are obese, and although their insulin levels often are high, they are not as high as those of nondiabetic but similarly obese individuals. Hence, β-cell failure and insulin resistance are components of this form of diabetes. Although the body still produces insulin in type 2 diabetes, it is not enough to control glucose production by the liver or promote uptake of glucose by the skeletal muscle. Hyperglycemia results for both reasons. The normal increase in fructose 2,6-bisphosphate and down-regulation of phosphoenolpyruvate carboxykinase does not occur in these patients. Translocation of intracellular vesicles bearing GLUT4 to the plasma membrane in response to insulin is decreased in the skeletal muscle and adipose tissue of these patients. Ketoacidosis rarely develops, perhaps because enough insulin is present to prevent uncontrolled release of fatty acids from adipocytes and fatty acids reaching the liver or synthesized *de novo* are directed into triacylglycerol. Hypertriacylglycerolemia is characteristic and usually results from an increase in VLDL without hyperchylomicronemia. This is most likely explained by hepatic synthesis of fatty acids and diversion of fatty acids reaching the liver into triacylglycerol and VLDL. Concurrent lipogenesis and gluconeogenesis should never occur but result in this disease from a state of mixed insulin resistance of

CLINICAL CORRELATION 21.6

Diabetes Mellitus, Type 2

Type 2 diabetes mellitus accounts for 80%–90% of the diagnosed cases of diabetes (see Clin. Corr. 15.4, p. 609). It usually occurs in middle-aged to older obese people and is characterized by hyperglycemia, often with hypertriglyceridemia and other features of the metabolic syndrome (see Clin. Corr. 21.1, p. 840). The ketoacidosis characteristic of type 1 diabetes is usually not observed, although some patients can develop transient episodes of ketoacidosis. They tend to develop many of the same complications as type 1 diabetes patients (see Clin. Corr. 21.8, p. 868), that is, nerve, eye, kidney, and coronary artery disease. Increased levels of VLDL are probably the result of increased hepatic triacylglycerol synthesis stimulated by hyperglycemia and hyperinsulinemia. Insulin is present at normal to elevated levels in this form of the disease. Obesity often precedes the development of type 2 diabetes and is the major contributing factor. Obese patients are usually hyperinsulinemic and have high levels of free fatty acids, which impair insulin action. Recent data implicate increased levels of tumor necrosis factor α (TNFα) and resistin and reduced secretion of adiponectin by adipocytes of obese individuals as a cause of insulin resistance. The greater the adipose tissue mass, the greater the production of TNFα and resistin, which acts to impair insulin receptor function. The higher the basal level of plasma insulin, the fewer receptors present on the plasma membranes of target cells, and there are defects within insulin-responsive cells at sites beyond the receptor, for example, the ability of insulin to recruit glucose transporters (GLUT4) from intracellular sites to the plasma membrane. As a consequence, insulin levels remain high, but glucose levels are poorly controlled. Even though the insulin level is high, it is not as high as in a person who is obese but not diabetic. In other words, there is a relative deficiency in the insulin supply from the pancreatic β cells. This disease is caused, therefore, not only by insulin resistance but also by impaired beta cell function resulting in relative insulin deficiency. Diet alone or bariatric surgery to induce weight loss can control the disease in the obese diabetic. If the patient can be motivated to lose weight, insulin receptors will increase in number, and the postreceptor abnormalities will improve, which will increase tissue sensitivity to insulin and glucose tolerance. There are now a multitude of medications that either sensitize peripheral tissue to insulin action (thiazolidinediones), reduce hepatic gluconeogenesis (metformin), or stimulate insulin secretion from beta cells (sulfonylureas), but ultimately many type 2 diabetes patients require exogenous insulin injections to control blood sugar. The most recent class of drugs to treat type 2 diabetes are based on the incretin effect, that is, the stimulation of beta cell growth and release of insulin caused by the gastrointestinal hormone incretin (also called glucagon-like peptide 1 or GLP-1). GLP-1 and its analogs only augment glucose-stimulated insulin release which reduces the risk of hypoglycemia. GLP-1 has a short plasma half-life because of degradation by dipeptidyl peptidase-4 (DPP-4). GLP-1 analogs resistant to degradation, and inhibitors of DPP-4, which increase endogenous levels of GLP-1, are entering clinical practice.

the insulin signaling pathways controlling these processes. A defect in the insulin-signaling pathway controlling gluconeogenesis prevents suppression of hepatic glucose production (via PI_3 kinase, p. 535) in the face of high insulin levels. A more responsive insulin-signaling pathway controlling fatty acid synthesis and esterification (via SREBP-1c, p. 727) leads to overproduction of triacylglycerol.

Diet, exercise, and weight control are the first choices for treating type 2 diabetes. When blood glucose cannot be controlled by this means, several prescription medications (**metformin,** glipizide, or rosiglitazone) are available. In spite of insulin resistance, exogenous insulin is the most effective medication and often must be administered to control the blood glucose level of these patients. Tight control by intensive therapy is desirable, but it increases the risk of life-threatening hypoglycemia (Clin. Corr. 21.7).

Type 1 Diabetes Mellitus

Figure 21.26 shows the metabolic interrelationships in type 1 diabetes mellitus (Clin. Corr. 21.8). In contrast to type 2, there is complete absence of insulin production by the pancreas in this disease. Since the insulin/glucagon ratio cannot increase, the liver is always gluconeogenic and ketogenic and cannot properly buffer blood glucose levels. Indeed, since hepatic gluconeogenesis is continuous, the liver contributes to hyperglycemia in the well-fed state. In muscle and adipose tissue, GLUT4 remains sequestered within cells. Accelerated gluconeogenesis, fueled by uncontrolled proteolysis in skeletal muscle, maintains the hyperglycemia even in the starved state. Uncontrolled lipolysis in adipose tissue increases

CLINICAL CORRELATION 21.7

Hypoglycemia and Diabetes

The microvascular and macrovascular complications that increase morbidity and mortality in type 1 and 2 diabetic patients can be reduced by tight control of blood glucose concentration. Tight control requires intensive therapy, with either insulin or a combination of prescription medications that maintains an average blood glucose comparable to that of nondiabetic individuals (no more than 120 mg/dL). Although not appropriate for every person with diabetes, for example, the young who are still developing, tight control requires frequent self-monitoring of blood glucose concentration, resolute compliance, and a good understanding of the effects of physical activity and diet. Since available technology for insulin delivery cannot match the normal pattern of insulin secretion from the pancreas, intensive control therapy greatly increases the likelihood of life-threatening hypoglycemic episodes. Indeed, the threat of hypoglycemia is a major impediment against maintaining tight control of blood glucose. Severe hypoglycemia can result in neurological dysfunction, coma, convulsions, cardiac arrhythmia, and sudden death. In fact, in a recent clinical trial (ACCORD, Action to Control Cardiovascular Risk in Diabetes), extremely tight control of blood glucose was concluded to be inadvisable in very high-risk type 2 diabetic patients.

Hypoglycemia triggers a series of counterregulatory responses that are designed to prevent blood glucose from falling to dangerously low concentrations. These occur sequentially, beginning in most individuals when blood glucose levels fall below a threshold of 65 mg/dL. Suppression of insulin secretion from the pancreas occurs first. This is effective in normal individuals but not in patients with diabetes using insulin. As hypoglycemia worsens, counterregulatory hormones are released, first glucagon from the alpha cells of the pancreas, followed by epinephrine from the adrenal medulla and growth hormone from the anterior pituitary, and finally cortisol from the adrenal cortex. Glucagon and epinephrine stimulate hepatic glycogenolysis and gluconeogenesis; growth hormone stimulates adipose tissue lipolysis, which provides substrate (glycerol) and energy (fatty acids for the synthesis of ATP) required for hepatic gluconeogenesis; and cortisol promotes transcription of genes encoding enzymes (e.g., phosphoenolpyruvate carboxykinase) required for hepatic gluconeogenesis.

Hypoglycemia is detected by glucose-sensing neurons of the ventromedial hypothalamus. The reduced availability of glucose reduces glucose catabolism in these neurons, resulting in lower ATP and higher AMP concentrations. Subsequent activation of AMP-activated protein kinase triggers nerve activity that initiates release of counterregulatory hormones. The increase in blood level of epinephrine induces symptoms (tachycardia, palpitations, unsteadiness, and sweating) that patients recognize as warning signs of hypoglycemia. Immediate consumption of carbohydrate, for example, Life Saver candies, or the injection of glucagon (1 mg intramuscularly) usually prevents progression to severe hypoglycemia. Unfortunately, for reasons that are not understood, repeated episodes of hypoglycemia in diabetic patients often induce "hypoglycemia unawareness," a condition in which release of the counterregulatory hormones and the symptoms of distress no longer occur in response to mild hypoglycemia. Tight control of blood glucose is not advisable in such patients.

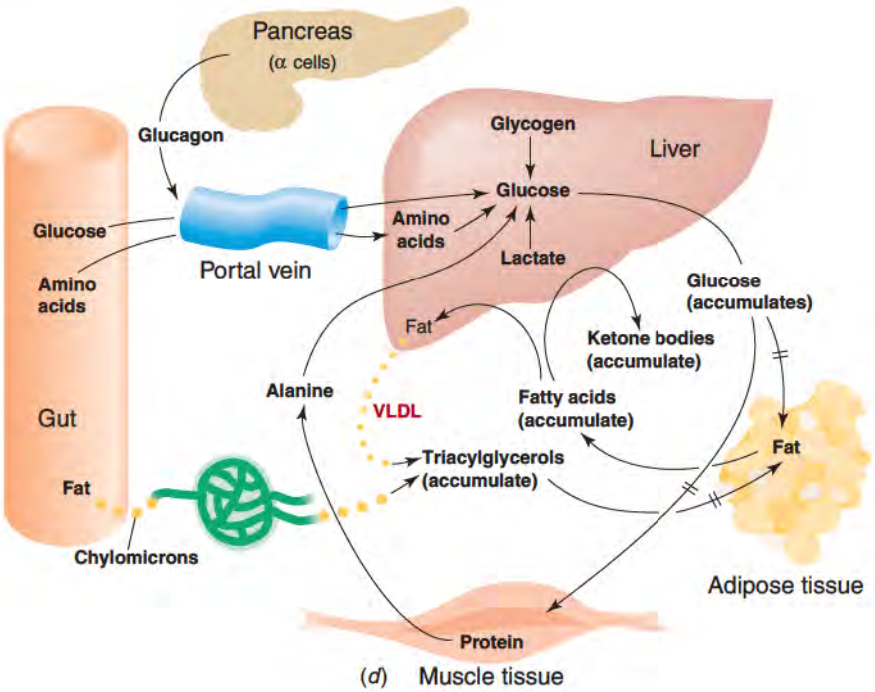

Figure 21.26 Metabolic interrelationships of tissues in type 1 diabetes mellitus.

CLINICAL CORRELATION 21.8

Diabetes Mellitus, Type 1

Type 1 diabetes mellitus usually appears in childhood or in the teens, but it is not limited to these patients (see Clin. Corr. 15.4, p. 609). Insulin secretion is very low because of defective beta cell function, the result of an autoimmune process. Clinical trials of immunosuppression to prevent complete destruction of the islets are underway. Untreated, type 1 diabetes is characterized by hyperglycemia, hypertriglyceridemia (chylomicrons and VLDL), and episodes of severe ketoacidosis. Thus, there is severe derangement of carbohydrate, lipid, and protein metabolism. The hyperglycemia results from the inability of the insulin-dependent tissues to take up glucose and from accelerated hepatic gluconeogenesis from amino acids derived from muscle protein. The ketoacidosis results from increased lipolysis in adipose tissue and accelerated fatty acid oxidation in liver. Hyperchylomicronemia results from low lipoprotein lipase activity in adipose tissue capillaries, an enzyme dependent on insulin for its synthesis.

Although insulin does not cure type 1 diabetes, it markedly alters the clinical course. Insulin promotes glucose uptake and inhibits gluconeogenesis, lipolysis, and proteolysis. It is a difficult job to adjust the insulin dose to variable dietary intake and physical activity, the other major determinant of glucose disposal by muscle. Tight control of blood sugar requires several injections of insulin per day and close blood sugar monitoring by the patient, but it has now been proven to reduce the microvascular complications of diabetes (renal and retinal disease). Increasingly, patients with type 1 diabetes and renal failure are being treated by combined transplantation of a kidney and pancreas to provide an endogenous source of insulin. Islet cell transplantation remains largely experimental.

plasma fatty acid levels and ketone body production by the liver. Ketoacidosis develops due to accumulation of ketone bodies and hydrogen ions. Fatty acid oxidation and ketogenesis cannot completely dispose of fatty acids taken up by liver, and the excess is esterified and directed into VLDL synthesis. Hypertriacylglycerolemia results because VLDL and chylomicrons cannot be cleared from the blood by lipoprotein lipase, whose expression is dependent upon insulin. Thus, in these patients every tissue plays the catabolic role that it was designed to play in starvation, in spite of delivery of adequate or even excess fuel from the gut. In effect, patients with type 1 diabetes are stuck in the starved state without benefit of the brake usually imposed during starvation by low but continuous production of insulin by the pancreas. This leads to severe wasting of body tissues and ultimately in death unless insulin is administered.

Exogenous insulin is the only effective medication in these patients. As noted above for type 2 diabetes, tight control by intensive therapy is desirable, but it increases the risk of hypoglycemia (see Clin. Corr. 21.7, p. 867).

Cancer

Tumors are composed of cancer cells that have to be fed like all cells, but unlike most normal tissues, tumors function independently of the starve–feed cycle (Clin. Corr. 21.9). Their demand for glucose as a source of energy and amino acids for protein synthesis is incessant. They usually prefer glucose and they rarely adapt in the fasting phase of the starve–feed cycle to use fatty acids and ketone bodies in order to minimize their use of glucose for the benefit of the rest of the body. Most tumors are unresponsive to the hormonal changes that alter the metabolic processes in normal tissues. They establish a Cori cycle with the liver but can still completely oxidize substantial amounts of glucose provided oxygen is available (Figure 21.27). Cells in the core of a tumor are often hypoxic because cancers often outgrow the development of blood vessels that supply oxygen. Lack of oxygen in any cell, normal or cancerous, leads to an increase in **hypoxia-inducible factor 1α (HIF-1α)**, a remarkably potent transcription factor for activation of genes encoding glucose transporters, the enzymes of glycolysis, and one of the kinases (pyruvate dehydrogenase kinase 1) responsible for phosphorylation and inactivation of the pyruvate dehydrogenase complex. HIF-1α also becomes constitutively active in some cancer cells because of mutations that activate certain oncogenes. As a consequence of the action of HIF-1α, most cancerous tumors have exceptional capacity for generation of ATP by glycolysis. Glycolysis is not

CLINICAL CORRELATION 21.9

Cancer Cachexia

Unexplained weight loss may be a sign of malignancy, and weight loss is common in advanced cancer. This is not completely accounted for by decreased appetite and food intake. The weight loss is largely from skeletal muscle and adipose tissue, with relative sparing of visceral protein (i.e., liver, kidney, and heart). Although tumors commonly have high rates of glycolysis, the energy requirement of the tumor probably does not explain weight loss as this can occur with even small tumors. Skeletal muscle protein degradation is mediated by lysosomes, cytosolic proteases, and the ubiquitin–proteosome pathway; the latter is considered the major pathway of protein degradation in infection, injury, and cancer. Endocrine abnormalities have been identified in cancer patients. Patients tend to be insulin-resistant, have higher cortisol levels, and have a higher basal metabolic rate. Some tumors synthesize and secrete biologically active peptides such as ACTH, nerve growth factor, and insulin-like growth factors, which can modify energy metabolism. The host response to a tumor, by analogy to chronic infection, includes release of interleukin-1 (IL-1), interleukin 6 (IL-6), interferon γ (IFN γ), and tumor necrosis factor α (TNFα) by immune cells. TNFα is also called cachexin because it produces wasting. TNFα and IL-1 may act in a paracrine fashion, as their plasma levels are not increased. IL-6 has been detected in cachectic patients' blood at increased levels. These cytokines stimulate fever, proteolysis, lipolysis, and secretion of acute phase reactants by the liver and can elevate resting energy expenditure by inducing uncoupling proteins. More recent studies have identified proteolysis-inducing factor (PIF) and lipid mobilizing factor (LMF) as products of tumors which stimulate skeletal protein catabolism and wasting of adipose tissue, respectively. Similar pathways can be activated in other wasting illness such as chronic inflammatory states and AIDS.

Catabolic response to stress and potential benefits of nutrition support. *Nutrition* 18:971, 2002; and Melstrom, L. G., Melstrom, K. A., Jr, Ding, X. Z., and Adrian, T. E. Mechanisms of skeletal muscle degradation and its therapy in cancer cachexia. *Histol. Histopathol.* 22:805, 2007.

an efficient process compared to complete oxidation of glucose, but efficient utilization of body resources is not characteristic of a cancer, and shutting off mitochondrial oxidative processes at the level of the pyruvate dehydrogenase complex may reduce production of toxic reactive oxygen species by the electron transport chain. Exceptional capacity for ATP generation by glycolysis enables cancer cells to survive and grow as they spread and metastasize into regions of low oxygen tension.

Aerobic and Anaerobic Exercise

Aerobic exercise is exemplified by long-distance running, anaerobic exercise by sprinting or weight lifting. During anaerobic exercise, there is very little interorgan cooperation. The blood vessels within the muscles are compressed during peak contraction; thus their cells are isolated from the rest of the body and largely rely on their own glycogen and

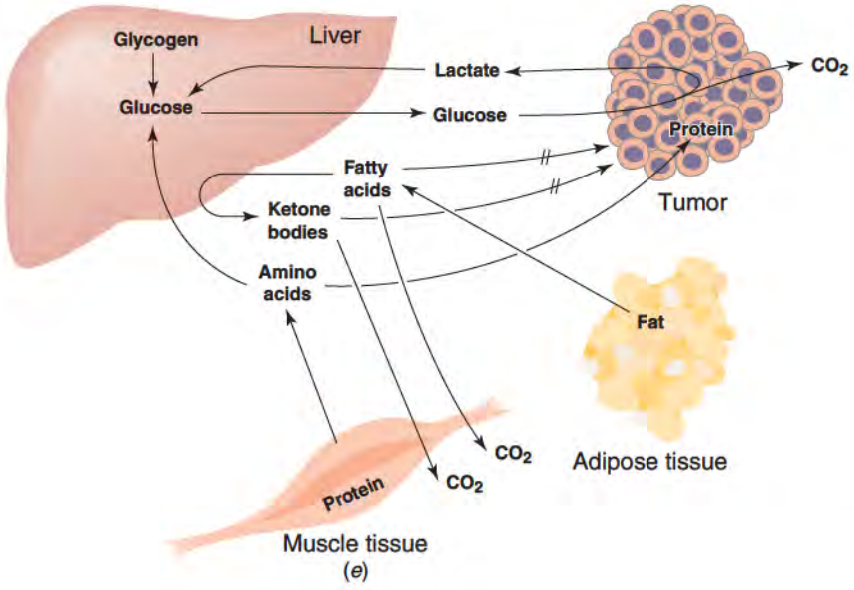

Figure 21.27 Metabolic interrelationships of tissues in cancer.

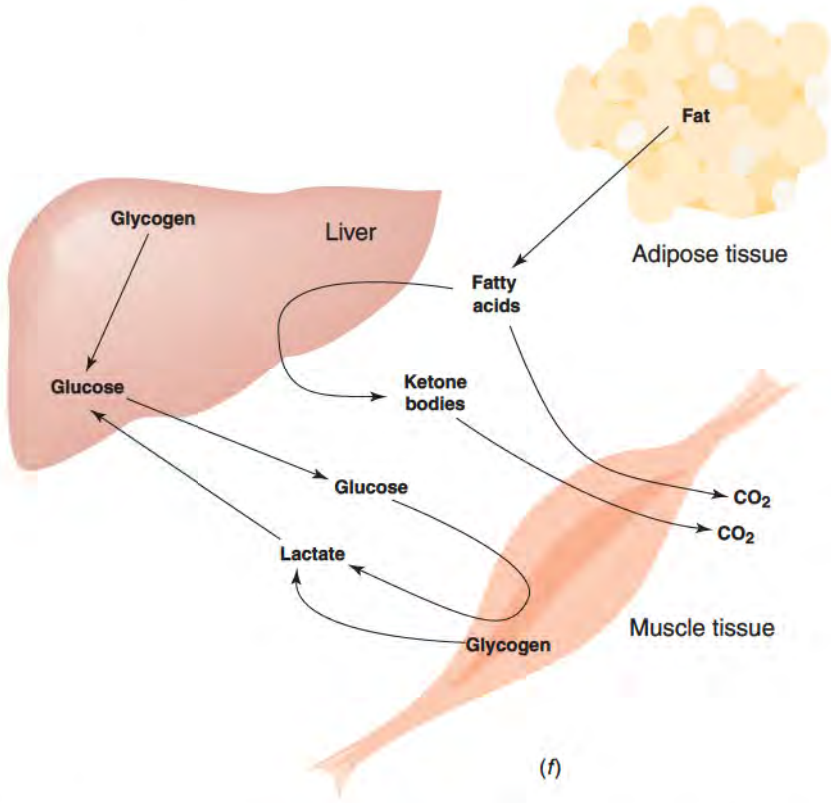

Figure 21.28 Metabolic interrelationships of tissues in exercise.

phosphocreatine. Phosphocreatine is a source of high-energy phosphate for ATP synthesis (see Figure 21.6, p. 866) until glycogenolysis and glycolysis are stimulated. For want of oxygen, glycolysis becomes the primary source of ATP. During moderate aerobic exercise (Figure 21.28), much energy is derived from glycolysis of muscle glycogen, which is the basis for carbohydrate loading. Muscle glycogen content can be increased by exhaustive exercise that depletes glycogen, followed by rest and a high-carbohydrate diet. Glucose uptake also increases due to insulin-independent translocation of GLUT4 to the plasma membrane, a process involving activation of AMPK. A decrease in ATP due to the demand of muscle contraction results in an increase in AMP, which allosterically activates glycogen phosphorylase, 6-phosphofructo-1-kinase, and AMPK. Increased glucose uptake, glycogen degradation, and glycolysis help provide the ATP needed for muscle contraction. There is also stimulation of branched-chain amino acid oxidation, ammonium production, and alanine release from the exercising muscle.

A well-fed individual does not store enough glycogen to meet the energy needs of running long distances. The respiratory quotient, the ratio of liters of carbon dioxide exhaled to oxygen consumed, falls during distance running. This indicates the progressive switch from glycogen to fatty acid oxidation during a race. Lipolysis gradually increases as glucose stores are exhausted, and, as in the fasted state, muscles oxidize fatty acids in preference to glucose. The increase in AMP due to the demand for ATP also activates AMPK, which phosphorylates and inactivates acetyl-CoA carboxylase. This, along with an increase in long chain acyl CoA esters, which are negative allosteric effectors of acetyl-CoA carboxylase, reduces synthesis of malonyl CoA. AMPK also activates malonyl-CoA decarboxylase, removing malonyl-CoA. This allows greater carnitine palmitoyltransferase I activity and fatty acid oxidation to provide ATP for the contracting muscle. Interestingly, exercise also has effects on the liver mediated by activation of AMPK. Phosphorylation of acetyl-CoA carboxylase, malonyl-CoA decarboxylase, and glycerol-3-phosphate acyltransferase by AMPK directs fatty acids into oxidation and away from esterification to triacylglycerol (p. 688). Unlike fasting, however, there is little increase in blood ketone body concentration during exercise because hepatic ketone body production is balanced by the muscle oxidation of ketone bodies for energy.

In contrast, blood lactate levels can increase greatly during exhaustive exercise, particularly when anaerobic glycolysis is stimulated. Lactate accumulates in the blood in this situ-

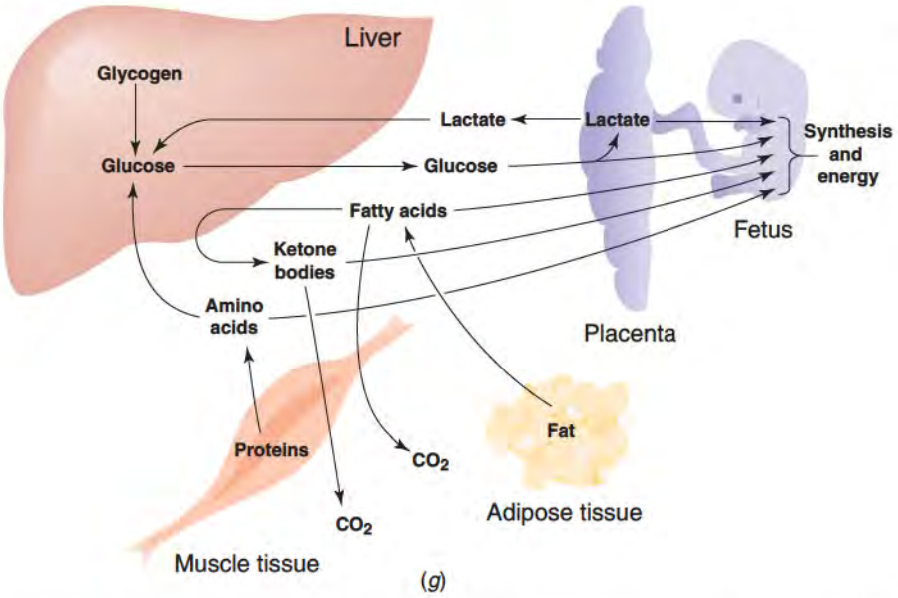

Figure 21.29 Metabolic interrelationships of tissues in pregnancy.

ation because the rate of lactate production by muscle exceeds the rate of lactate utilization for glucose synthesis by the liver (Figure 21.28). Normally the brain does not use blood lactate as a fuel because blood lactate concentration (normally about 1 mM) is much lower than the K_m of the lactate transport system across the blood brain barrier. However, when blood lactate levels increase into the range of 10–20 mM during exhaustive exercise, lactate penetrates the blood brain barrier to become an important fuel for the brain. That this helps clear both lactate and acid from the blood can be seen from the balanced equation for complete oxidation of lactate: $\text{lactate}^- + H^+ + 3\ O_2 \rightarrow 3\ CO_2 + 3\ H_2O$. It is also more efficient since direct utilization of lactate by the brain avoids the energy requirement for the conversion of lactate to glucose in the liver (6 mol of ATP per mole of glucose).

Pregnancy

The fetus is a nutrient-requiring organism (Figure 21.29). It mainly uses glucose for energy, but may also use amino acids, lactate, fatty acids, and ketone bodies. Lactate produced in the placenta by glycolysis is partly directed to the fetus, and the rest enters the maternal circulation to establish a Cori cycle with the liver. Maternal LDL cholesterol is an important precursor of placental steroids (estradiol and progesterone). During pregnancy, the starve–feed cycle is perturbed. The placenta secretes placental lactogen and two steroid hormones, estradiol and progesterone. Placental lactogen stimulates lipolysis in adipose tissue, and the steroid hormones induce insulin resistance. After meals, pregnant women enter the starved state more rapidly because of increased consumption of glucose and amino acids by the fetus. Plasma glucose, amino acids, and insulin levels fall rapidly, and glucagon and placental lactogen levels rise and stimulate lipolysis and ketogenesis. Consumption of glucose and amino acids by the fetus may be great enough to cause **maternal hypoglycemia.** In the fed state, pregnant women have increased levels of insulin and glucose and demonstrate resistance to exogenous insulin. These swings of plasma hormones and fuels are even more exaggerated in pregnant diabetic women and make control of their blood glucose difficult. This is important, as hyperglycemia adversely affects fetal development.

Lactation

In late pregnancy placental (progesterone) and maternal (prolactin) hormones induce lipoprotein lipase in the mammary gland and promote the development of milk-secreting cells and ducts. During lactation (Figure 21.30), the breast uses glucose for lactose and triacylglycerol synthesis and as its major energy source. Amino acids are taken up for protein synthesis, and chylomicrons and VLDL provide fatty acids for triacylglycerol synthesis. If these compounds are not supplied by the diet, proteolysis, gluconeogenesis, and lipolysis must supply them, eventually resulting in maternal malnutrition and poor-quality milk. The

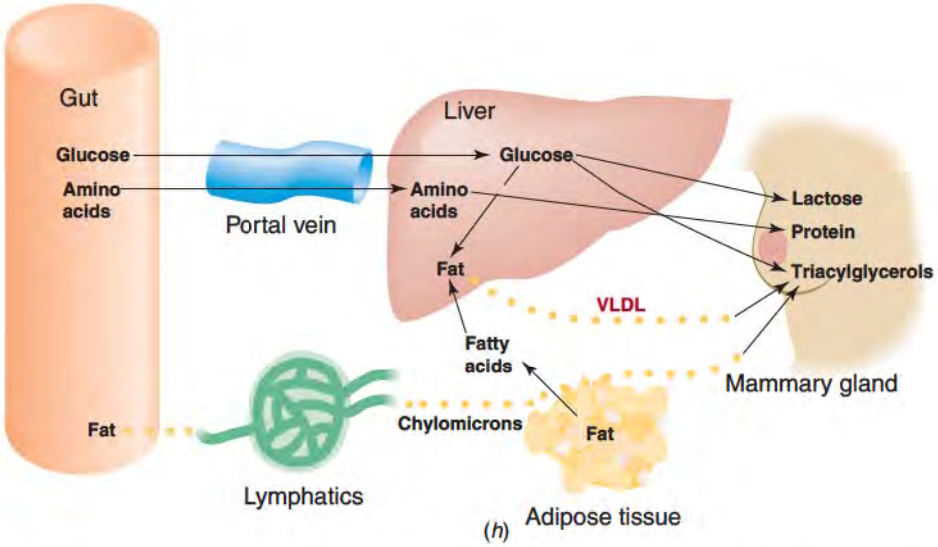

Figure 21.30 Metabolic interrelationships of tissues in lactation.

lactating breast secretes **parathyroid hormone-related protein (PTHrP,** p. 891), which mimics the effects of **parathyroid hormone (PTH)** in stimulating absorption of calcium and phosphorus from the gut and bone. The release of PTH from the parathyroid and PTHrP from the breast is under the control of the calcium-sensing receptor, a G protein coupled receptor that senses extracellular calcium and thus may serve to coordinate release of calcium mobilizing hormone with plasma calcium levels.

Stress and Injury

Physiological stresses include injury, surgery, renal failure, burns, and infections (Figure 21.31). Characteristically, blood cortisol, glucagon, catecholamines, and growth hormone levels increase and there is resistance to insulin. Basal metabolic rate and blood

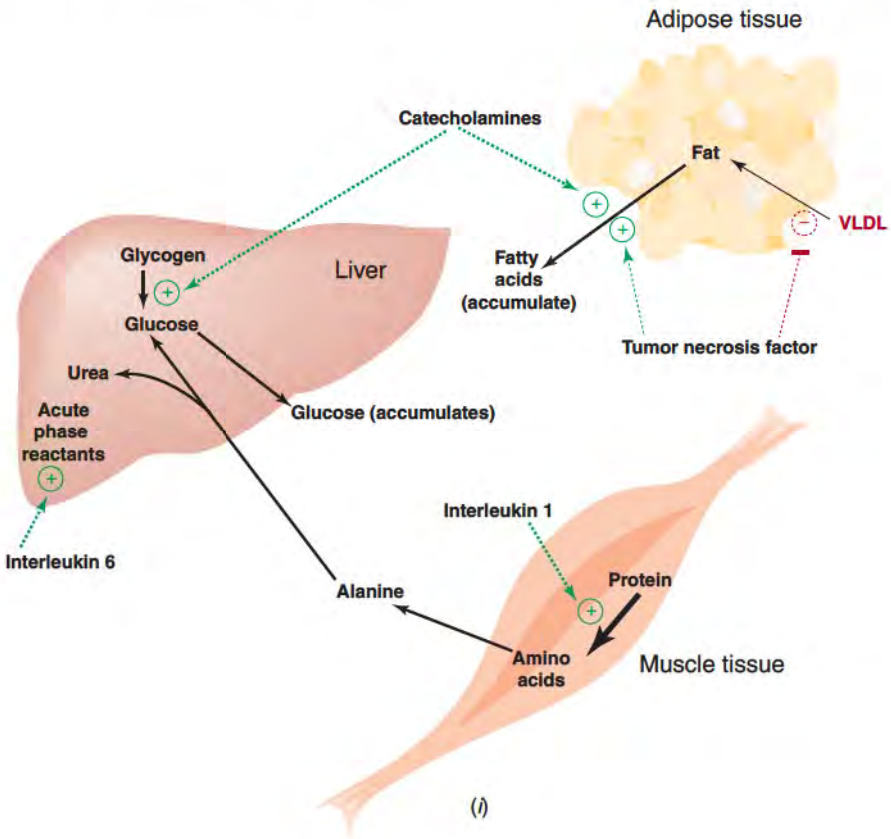

Figure 21.31 Metabolic interrelationships of tissues in stress and injury.

glucose and free fatty acid levels are elevated. However, for poorly understood reasons, ketogenesis is not accelerated, as it is in fasting where it provides a good fuel (ketone bodies) that can substitute for glucose in many tissues, especially the brain, thereby reducing the need for gluconeogenesis and conserving body protein. The muscle glutamine and branched-chain amino acid pools are reduced, resulting in reduced protein synthesis and increased protein breakdown. It can be very difficult to reverse this protein breakdown, despite intravenous administration of solutions containing amino acids, glucose, and triacylglycerol. However, solutions used to feed patients intravenously lack glutamine, tyrosine, and cysteine because of stability and solubility constraints. Supplementation of these amino acids, perhaps by the use of more stable dipeptides, may help to reverse the catabolic state better than now possible. In fact, there is growing recognition that enteral feeding (via tubes in the stomach or intestine) is superior to intravenous feeding in reducing or reversing catabolism.

Negative nitrogen balance of injured or infected patients is mediated by **interleukin 1, interleukin 6,** and **tumor necrosis factor** α (TNFα) produced by monocytes and lymphocytes (Clin. Corr. 21.9, p. 869). These cytokines induce fever and other metabolic changes. Interleukin 1 activates proteolysis in skeletal muscle. Interleukin 6 stimulates the liver synthesis of acute phase reactants, such as fibrinogen, complement proteins, some clotting factors, and α2 macroglobulin, which may defend against injury and infection. TNFα suppresses adipocyte triacylglycerol synthesis, inhibits lipoprotein lipase, stimulates lipolysis, inhibits release of insulin, and promotes insulin resistance. These cytokines may be responsible for the wasting seen in chronic infections. Sick patients in intensive care units are increasingly recognized as developing an acute myopathy that may virtually paralyze them. This has been attributed to the use of paralyzing drugs (to assist in use of ventilators), malnutrition, and increased cytokines and sympathetic nervous system activity.

Liver Disease

Advanced **liver disease** is associated with major metabolic derangements (Figure 21.32), especially for amino acids. In patients with **cirrhosis,** the liver cannot convert ammonia into urea and glutamine rapidly enough, and the blood ammonia level rises. Shunting of blood around the liver and interference with the intercellular glutamine cycle (p. 759) contribute to the problem. Ammonia arises from the action of glutaminase, glutamate dehydrogenase, and adenosine deaminase in intestine and liver and from the intestinal lumen, where bacterial **urease** splits urea into ammonia and carbon dioxide. Ammonia levels rise particularly after upper GI bleeding (i.e., bleeding from the esophagus,

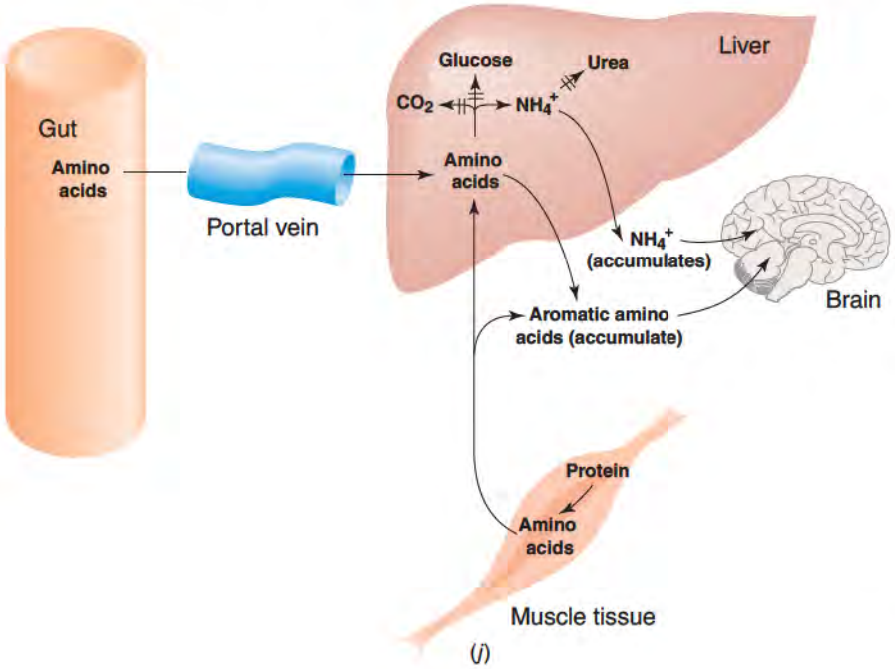

Figure 21.32 Metabolic interrelationships of tissues in liver disease.

stomach, or duodenum). In the past this was simply ascribed to the high protein content of blood, but recently it has been suggested that the unusual amino acid composition of hemoglobin is to blame. Hemoglobin totally lacks isoleucine, and thus absorption of amino acids derived from hemoglobin results in a reduction in plasma isoleucine, with impairment of protein synthesis and thus increased net rates of protein degradation and ammonia production. Ammonia toxicity for the central nervous system leads to coma that sometimes occurs in patients with liver failure. In advanced liver disease, plasma branched-chain amino acids are reduced while aromatic amino acids are elevated, resulting in a reduced Fischer ratio, defined as the molar ratio of the branched-chain amino acids to the aromatic amino acids. These two groups of amino acids are transported into the brain by the same carrier system. Because of less competition by the branched-chain amino acids, increased brain uptake of aromatic amino acids may increase synthesis of neurotransmitters such as serotonin, which may be responsible for some of the neurological abnormalities of liver disease. The liver is a major source of insulin-like growth factor I (IGF-1). Patients with cirrhosis suffer muscle wasting because of deficient IGF-1 synthesis in response to growth hormone. They also often have insulin resistance and may have diabetes mellitus. Finally, in outright liver failure, patients sometimes die of hypoglycemia because the liver is unable to maintain the blood glucose level by gluconeogenesis.

Renal Disease

In chronic renal disease, levels of amino acids normally metabolized by kidney (glutamine, glycine, proline, and citrulline) increase and nitrogen end products, for example, urea, uric acid, and creatinine, also accumulate (Figure 21.33). This is worsened by high dietary protein intake or accelerated proteolysis. Since gut bacteria can split urea into ammonia and liver uses ammonia and α-keto acids to form nonessential amino acids, a diet high in carbohydrate and an amino acid intake limited as much as possible to essential amino acids ensures that the liver synthesizes nonessential amino acids from TCA cycle intermediates. This type of diet therapy may delay the need for dialysis, but this therapy has largely been supplanted by earlier institution of dialysis. An additional abnormality in dialysis patients is carnitine deficiency, resulting from reduced intake of dietary carnitine (in meat) and

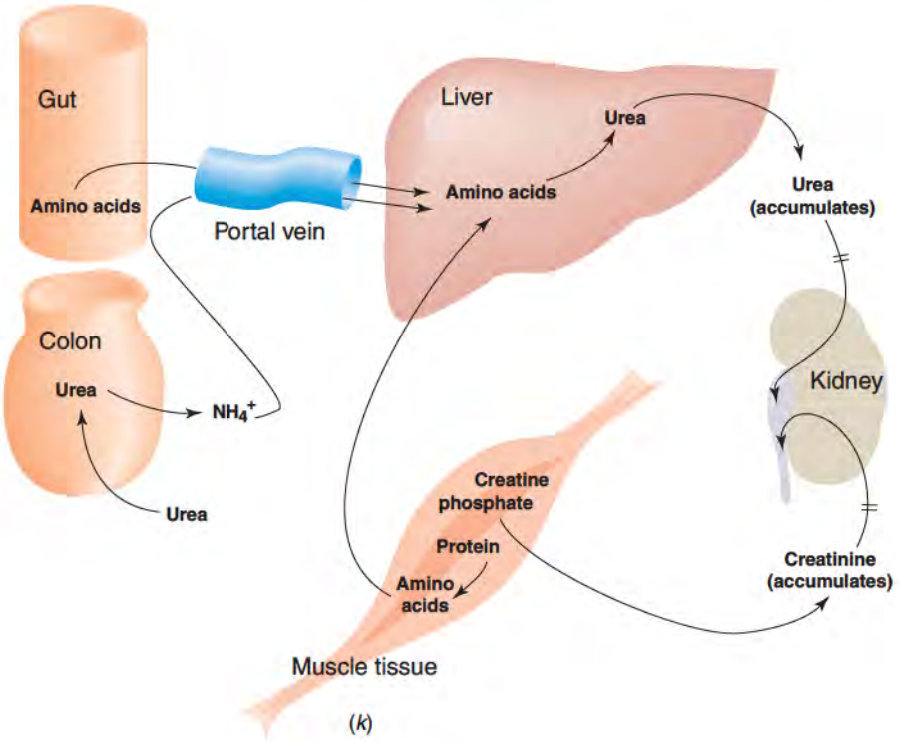

Figure 21.33 Metabolic interrelationships of tissues in kidney failure.

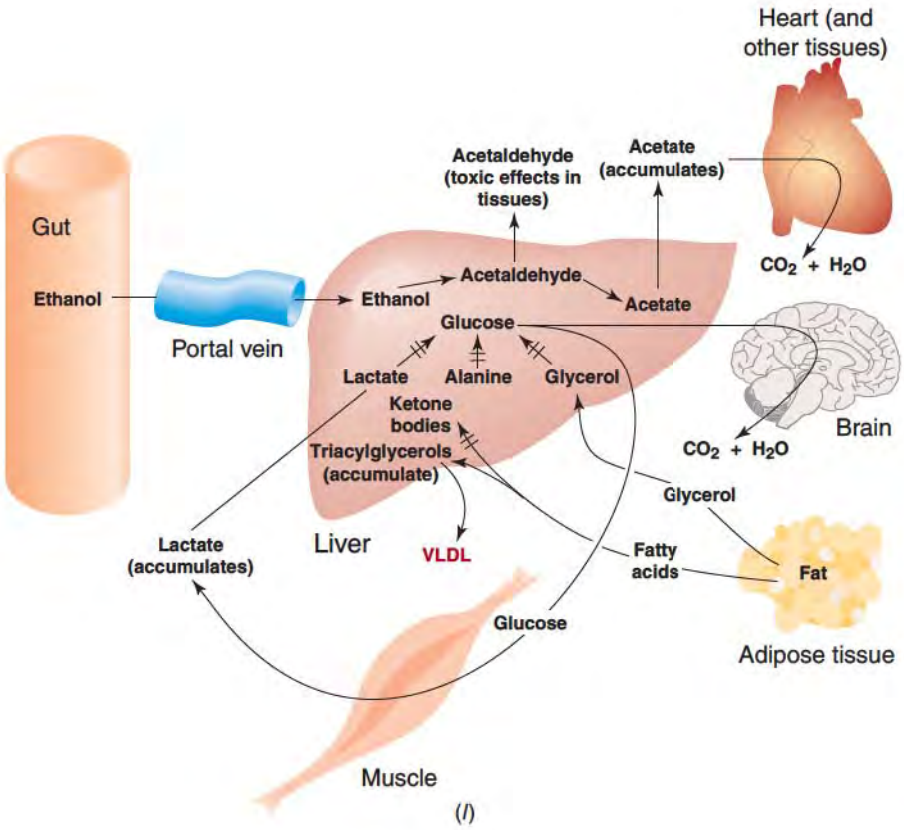

Figure 21.34 Metabolic interrelationships of tissues in consumption of alcohol.

reduced functional renal mass. Carnitine may also be lost from the bloodstream during hemodialysis. This may lead to cardiac and skeletal myopathy due to reduced ability of these tissues to oxidize fatty acids.

Consumption of Alcohol

The liver is primarily responsible for the first steps of **ethanol** catabolism.

$$\text{Ethanol } (CH_3CH_2OH) + NAD^+ \rightarrow \text{acetaldehyde } (CH_3CHO) + NADH + H^+$$
$$\text{Acetaldehyde } (CH_3CHO) + NAD^+ + H_2O \rightarrow \text{acetate } (CH_3COO^-) + NADH + 2H^+$$

The first, catalyzed by **alcohol dehydrogenases,** generates NADH in the cytosol; the second, catalyzed by aldehyde dehydrogenase, also generates NADH, but in the mitochondrial matrix space. Liver disposes of the NADH generated through the mitochondrial electron transport chain. Intake of even moderate amounts of ethanol generates too much NADH. Enzymes involved in gluconeogenesis (lactate dehydrogenase and malate dehydrogenase) and fatty acid oxidation (β-hydroxyacyl-CoA dehydrogenase) require NAD^+ as a substrate. Thus, these pathways are inhibited by alcohol intake (Figure 21.34), and fasting hypoglycemia and the accumulation of hepatic triacylglycerols (fatty liver) may develop. Lactate may accumulate from inhibition of the conversion of lactate to glucose but rarely causes overt metabolic acidosis.

Liver mitochondria have a limited capacity to oxidize **acetate** to CO_2 because the TCA cycle is inhibited by high NADH and ATP levels during ethanol oxidation. Much of the acetate derived from ethanol escapes the liver to the blood. Virtually every other tissue can oxidize it to CO_2 by way of the TCA cycle.

Acetaldehyde can also escape from the liver and readily forms covalent bonds with functional groups of biologically important compounds. Formation of acetaldehyde adducts with proteins in liver and blood of animals and humans drinking alcohol has been demonstrated. Such adducts may provide a marker for past drinking activity of an individual, just as hemoglobin A_{1c} is an index of blood glucose control in diabetic patients.

Acid–Base Balance

Regulation of acid–base balance, like that of nitrogen excretion, is shared between the liver and kidney. Although complete catabolism of most amino acids yields neutral products (CO_2, H_2O, and urea), the oxidation of positively charged arginine, lysine, and histidine and sulfur-containing amino acids methionine and cysteine result in net formation of protons (acid). For example,

$$\text{Arginine}^+ + 5.5\ O_2 \longrightarrow 4\ CO_2 + 2\ \text{urea}\ (NH_2\overset{\overset{O}{\|}}{C}NH_2) + 3\ H_2O + H^+$$

Complete catabolism of negatively charged glutamate and aspartate consumes some of these protons but does not completely compensate.

$$\text{Glutamate}^- + 4.5\ O_2 + H^+ \longrightarrow 4.5\ CO_2 + 0.5\ \text{Urea}\ (NH_2\overset{\overset{O}{\|}}{C}NH_2) + 3.5\ H_2O$$

Therefore, for acid–base balance, the excess protons must be matched by an equivalent amount of base. In the kidney glutamine is readily taken up, deaminated by glutaminase to give glutamate, oxidatively deaminated by glutamate dehydrogenase to give α-ketoglutarate, and converted by enzymes of the TCA cycle to malate, which is converted to glucose.

Summation of all steps reveals net production of glucose, and more importantly the production of ammonium and bicarbonate ions.

$$\text{Glutamine} + 1.5\ O_2 + 3\ H_2O \rightarrow 0.5\ \text{glucose} + 2\ HCO_3^- + 2\ NH_4^+$$

The ammonium ions are excreted into the glomerular filtrate destined to become urine while the bicarbonate ions enter the blood to neutralize protons.

$$HCO_3^- + H^+ \rightleftharpoons H_2CO_3 \rightleftharpoons CO_2 + H_2O$$

CO_2 is released in the lungs, thereby effectively eliminating excess protons (acid) produced by amino acid oxidation. In metabolic acidosis (Figure 21.35), more acid than normal is produced in the body because some metabolic process is out of control, for example, lactic acid formation by anaerobic glycolysis or β-hydroxybutyric acid production by ketogenesis.

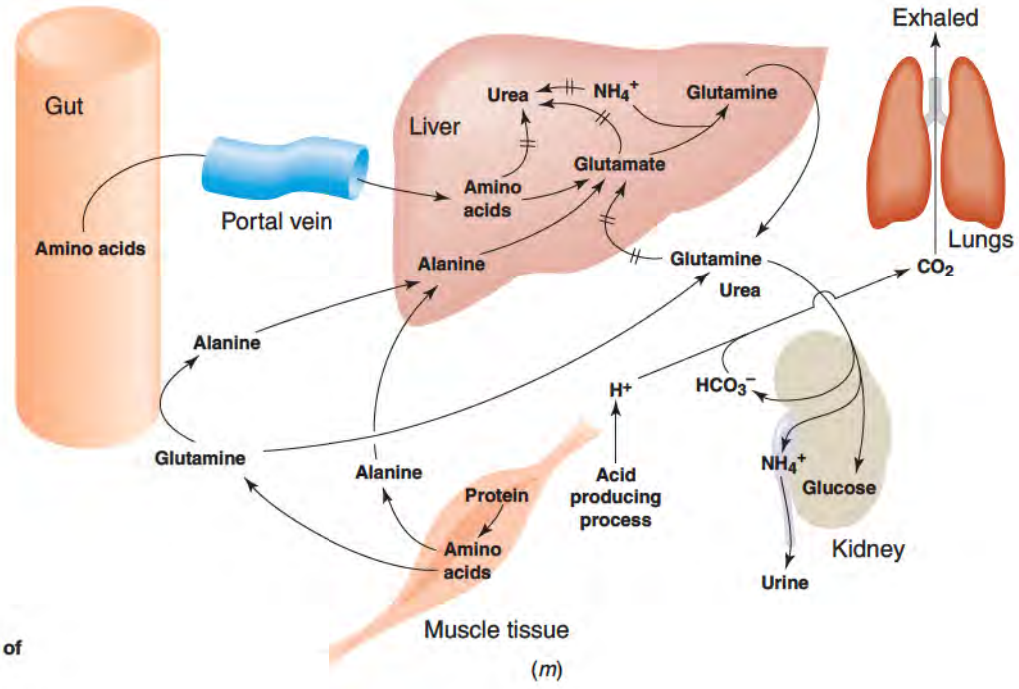

Figure 21.35 Metabolic interrelationships of tissues in acidosis.

In these conditions, renal glutaminase, glutamate dehydrogenase, phosphoenolpyruvate carboxykinase, and the mitochondrial glutamine transporter are induced to promote glucose synthesis from glutamine by the reactions given above. The consequence is increased urinary excretion of ammonium ions and greater generation of bicarbonate ion for neutralization of acid. The liver adapts in metabolic acidosis to synthesize less urea, making more glutamine available to the kidney. The opposite occurs in alkalosis. Urea synthesis increases in liver while glucose synthesis, ammonium ion excretion, and bicarbonate generation by kidney decrease.

Liver regulates the fate of glutamine by an intercellular cycle involving periportal hepatocytes near the hepatic arteriole and portal venule and perivenous scavenger hepatocytes located near the central venule (Figure 21.36). Blood enters the liver by way of the hepatic artery and portal vein and leaves by way of the central vein. Glutaminase and urea cycle enzymes are concentrated in the periportal hepatocytes while glutamine synthetase is found exclusively in perivenous scavenger hepatocytes (p. 756). Glutamine entering the periportal cells is hydrolyzed to ammonium ion for urea synthesis; hence, the bulk of glutamine and ammonium nitrogen that enters the liver leaves as urea. The ammonium ion that escapes conversion to urea is converted to glutamine by glutamine synthetase in the perivenous hepatocytes.

Glutamine is released to circulate in the blood before reentering the glutamine cycle in the periportal hepatocytes. Thus, in liver, release of ammonium ion by glutaminase for urea synthesis and its consumption in the synthesis of glutamine are important in maintaining low blood ammonium levels. In acidosis, some of the blood glutamine escapes hydrolysis in the liver because glutamine uptake by hepatocytes and glutaminase activity are partially inhibited by a fall in blood pH. Carbamoyl phosphate synthetase I of periportal hepatocytes is also less active when the blood pH decreases, thereby limiting urea synthesis. This permits perivenous cells to convert more ammonium ion to glutamine, and makes more glutamine available for production of bicarbonate ion by the kidneys.

Colon

The small intestine uses glutamine as its major energy source, but the colon uses the short-chain fatty acids butyrate, propionate, isobutyrate, and acetate (Figure 21.37) derived from bacterial fermentation of unabsorbed dietary components, predominantly carbohydrates such as fiber and pectin, in the lumen. Since they would otherwise be lost in stool, their

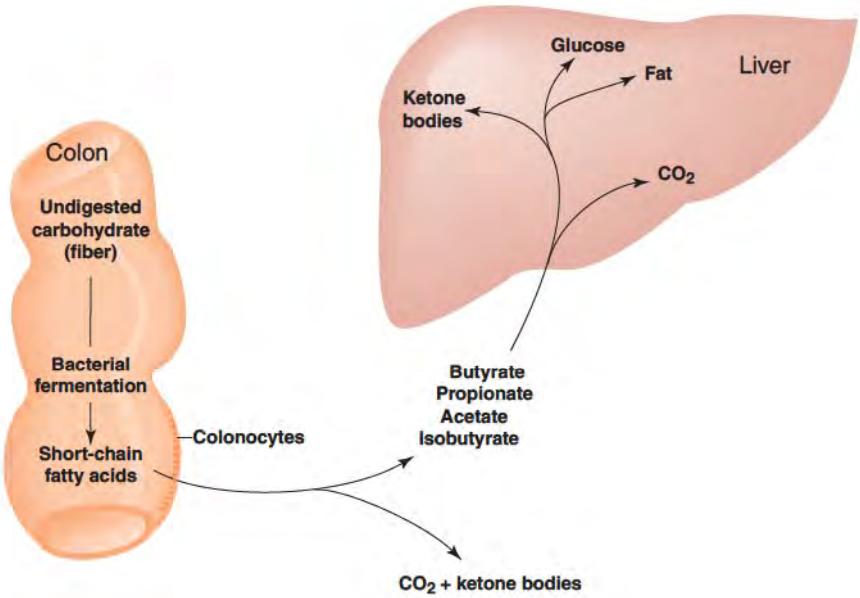

Figure 21.37 Bacterial fermentation generates fuel for colonocytes.

use by colonocytes is a way to salvage additional energy from dietary sources. Short-chain fatty acids produced in excess of the energy needs of colonocytes pass into the portal blood for use by the liver. Interestingly, colonocytes produce ketone bodies from butyrate and release them into the portal blood for use as fuel by extrahepatic tissues. When surgery is performed that bypasses the colon, for example, an ileostomy, some patients develop diversion colitis. In some cases, enemas that contain short-chain fatty acids have healed the colitis.

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. Since the K_m of aminotransferases for amino acids is much higher than that of aminoacyl-tRNA synthetases,
   - **A.** at low amino acid concentrations, protein synthesis takes precedence over amino acid catabolism.
   - **B.** liver cannot accumulate amino acids.
   - **C.** amino acids will undergo transamination as rapidly as they are delivered to the liver.
   - **D.** any amino acids in excess of immediate needs for energy must be converted to protein.
   - **E.** amino acids can be catabolized only if they are present in the diet.

2. Carnitine
   - **A.** is formed in all cells for their own use.
   - **B.** is synthesized directly from free lysine.
   - **C.** formation requires that lysyl residues in protein be methylated by *S*-adenosylmethionine.
   - **D.** is important in the detoxification of peroxides.
   - **E.** is cleaved to γ-butyrobetaine.

3. All of the following represent control of a metabolic process by substrate availability except
   - **A.** increased urea synthesis after a high protein meal.
   - **B.** rate of ketogenesis.
   - **C.** hypoglycemia of advanced starvation.
   - **D.** response of glycolysis to fructose 2,6-bisphosphate.
   - **E.** gluconeogenesis in diabetes.

4. Conversion of hepatic enzymes from nonphosphorylated to their phosphorylated form
   - **A.** always activates the enzyme.
   - **B.** is more likely to occur in the fasted than in the well-fed state.
   - **C.** is signaled by insulin.
   - **D.** is always catalyzed by a cAMP-dependent protein kinase.
   - **E.** usually occurs at threonine residues of the protein.

5. Long-term adaptation to changes in the nutritional state can be regulated by the change in synthesis of enzymes, regulated by the rate of gene transcription. All of the following statements concerning transcription are correct except
   - **A.** insulin increases a sterol-response-element-binding protein (SREBP), which increases transcription of lipogenic genes.
   - **B.** glucose increases a carbohydrate-response-element-binding protein (ChREBP), which decreases the transcription of lipogenic genes.
   - **C.** glucagon promotes the transcription of genes encoding gluconeogenic enzymes via activation of adenylate cyclase.
   - **D.** a SRBEP regulates cholesterol synthesis.
   - **E.** energy deficiency activates AMPK and reduces the ability of SREBP to transcribe genes for fat and cholesterol synthesis.

6. Arginine and ornithine are intermediates in the utilization of ammonia and in other processes. All of the following statements are correct except
   - **A.** ornithine for the urea cycle is synthesized from glutamate in the kidney.
   - **B.** citrulline is a precursor for arginine synthesis by the kidney.
   - **C.** kidney uses arginine in the synthesis of creatine for distribution to muscle.
   - **D.** arginine is the source of nitric oxide.
   - **E.** creatinine cleared by the kidney is generated from creatine phosphate in muscle.

Questions 7 and 8: Protein and calorie malnutrition are important nutritional problems, especially among children. Both often occur in developing countries when the child is weaned from breast milk. Protein malnutrition, kwashiorkor, occurs when the child is fed a diet adequate in calories (mostly carbohydrate) but deficient in protein. Inadequate caloric intake is called marasmus. In kwashiorkor, insulin levels are high and there is subcutaneous fat. Children with low weight for height can make a good recovery when properly fed although those with the reverse situation do not. Children with marasmus lack subcutaneous fat.

7. Adipose tissue responds to low insulin:glucagon ratio by
   - **A.** dephosphorylating the interconvertible enzymes.
   - **B.** stimulating the deposition of fat.
   - **C.** increasing the amount of pyruvate kinase.
   - **D.** activation of hormone-sensitive lipase.
   - **E.** releasing glutamine.

8. Which of the following would favor gluconeogenesis in the fasted state?
   - **A.** Fructose 1,6-bisphosphate stimulation of pyruvate kinase
   - **B.** Acetyl CoA activation of pyruvate carboxylase
   - **C.** Citrate activation of acetyl-CoA carboxylase
   - **D.** Malonyl CoA inhibition of carnitine palmitoyltransferase I
   - **E.** Fructose 2,6-bisphosphate stimulation of 6-phosphofructo-1-kinase

Questions 9 and 10: Advanced liver disease, cirrhosis, leads to a number of metabolic problems, especially of amino acids. Patients suffer from muscle wasting, with an impairment of protein synthesis and an increased rate of protein degradation and ammonia production. The liver cannot convert ammonia into urea and glutamine rapidly enough and blood ammonia level rises; this may lead to coma. Patients also often have insulin resistance. With outright liver failure, patients sometimes die of hypoglycemia because liver is unable to maintain the blood glucose level by gluconeogenesis.

9. Normally the liver helps to maintain low blood ammonia levels by the glutamine cycle of which glutaminase is an important component. Glutaminase
   - **A.** is found in the same liver compartment as the urea cycle enzymes.
   - **B.** requires ATP for the reaction it catalyzes.
   - **C.** is the sole source of ammonia for urea synthesis.
   - **D.** is more active in liver in acidosis.
   - **E.** provides the product that combines with ornithine in the urea cycle.

10. Muscle proteolysis releases branched-chain amino acids which
    - **A.** can also be synthesized from alanine.
    - **B.** can be catabolized by muscle but not liver.
    - **C.** are the main amino acids metabolized by intestine.
    - **D.** are the amino acids released in largest amounts by muscle.
    - **E.** are a major source of nitrogen for alanine and glutamine produced in muscle.

Questions 11 and 12: Diabetes mellitus is a disease in which glucose metabolism is impaired. Type 2 occurs primarily in middle-aged to older obese individuals whereas type 1 usually appears in childhood or in the teens. Insulin's ability to control blood glucose levels is affected either because of lack (or very low levels) of insulin or inadequate function of insulin (or both).

11. In type 2 (noninsulin-dependent) diabetes mellitus,
- **A.** hypertriglyceridemia does not occur.
- **B.** ketoacidosis in the untreated state is always present.
- **C.** β-cells of the pancreas are no longer able to make any insulin.
- **D.** may be accompanied by high levels of insulin in the blood.
- **E.** severe weight loss always occurs.

12. Insulin normally does all of the following except
- **A.** recruit glucose transporters 4 (GLUT4) from intracellular sites to the plasma membrane.
- **B.** activates protein kinase A and AMP-dependent protein kinase (AMPK).
- **C.** activates phosphoprotein phosphatases.
- **D.** signals an increase in sterol-response-element-binding proteins (SREBP-1).
- **E.** inhibits ketogenesis at levels lower than required to inhibit gluconeogenesis.

Problems

13. What metabolic and hormonal changes account for decreased gluconeogenesis in phase IV (2 to 24 days of starvation) of glucose homeostasis in humans?

14. How does the activation of AMP-dependent protein kinase (AMPK) during aerobic exercise foster the switch to fatty acid oxidation for long-distance running?

Answers

1. A High K_m means a reaction will proceed slowly at low concentrations, whereas a low K_m means the reaction can be rapid under the same circumstances. Protein synthesis requires only that all amino acids be present.

2. C These trimethyllysines are released when protein is hydrolyzed. A: Only liver and kidney have the complete synthetic pathway. B: Lysine must first be present in cellular protein. D: This is glutathione. E: This is a precursor.

3. D Fructose 2,6-bisphosphate is an allosteric effector (activates the kinase and inhibits the phosphatase) of the enzyme controlling glycolysis. A: After a high-protein meal, the intestine produces ammonia and precursors of ornithine for urea synthesis. B: Ketogenesis is dependent on the availability of fatty acids. C: This represents lack of gluconeogenic substrates. E: Amino acids from excess muscle breakdown provide gluconeogenic substrates to the liver.

4. B In the well-fed state, insulin:glucagon is high and cAMP levels are low. A: Some enzymes are active when phosphorylated; for others the reverse is true. C: Glucagon signals the phosphorylation of hepatic enzymes by elevating cAMP. D: This is the most common, though not only, mechanism of phosphorylation. E: The most common site for phosphorylation in metabolic enzymes is serine.

5. B ChREBP increases the transcription of lipogenic genes. A: This occurs in the well-fed state. C: Glucagon is released in response to low blood glucose so would be expected to increase gluconeogenic enzymes. D: The cytosolic HMGCoA synthase is increased which leads to cholesterol synthesis. E: These activities are energy requiring so need to be inhibited when energy is deficient.

6. A Kidney lacks the enzyme needed to convert glutamate to glutamate semialdehyde. B: This is true in both kidney and liver. C: The reaction requires *S*-adenosylmethionine. E: Creatinine is thus a measure of both muscle mass and renal function.

7. D Phosphorylation activates hormone-sensitive lipase to mobilize fat. A: Low insulin:glucagon means high cAMP and high activity of cAMP-dependent protein kinase and protein phosphorylation. C: cAMP works by stimulating covalent modification of enzymes. E: This occurs in muscle.

8. B Pyruvate carboxylase is a key gluconeogenic enzyme. A and E: Stimulation of these enzymes stimulates glycolysis. C and D: Malonyl CoA inhibits transport of fatty acids into mitochondria for β-oxidation, a necessary source of energy for gluconeogenesis.

9. A This is the periportal hepatocytes. B: Glutamine synthetase requires ATP; glutaminase catalyzes hydrolysis of glutamine to glutamate and ammonia. C: Glutamate dehydrogenase and bacterial urease in the intestine also provide ammonia. D: Less flux through liver glutaminase during acidosis permits glutamine to escape liver for use by the kidney. E: Ammonia reacts with bicarbonate to form carbamoyl phosphate, which combines with ornithine.

10. E Transamination of branched-chain amino acids transfers the nitrogen to alanine or glutamine. A: Branched-chain amino acids are essential amino acids and cannot be synthesized from other amino acids. B: Muscle transaminates them, and then the branched-chain α-ketoacids are catabolized by liver. C: Intestine metabolizes primarily glutamine. D: Alanine and glutamine are.

11. D The problem is insulin resistance, not complete failure to produce insulin. A: Hypertriglyceridemia is characteristic. B: Ketoacidosis is common only in the insulin-dependent type. C: See correct answer. E: Most patients are obese and remain so.

12. B These enzymes are active in their phosphorylated states and insulin promotes dephosphorylation. A: This promotes uptake of glucose. D: This increases transcription of genes encoding lipogenic enzymes. E: This may account in part for the lack of ketoacidosis in type 2 diabetics.

13. In phase IV, most tissues are using primarily fatty acids and ketone bodies. Ketone bodies are now sufficiently high that they can enter the brain and reduce the glucose requirement. Low insulin:glucagon stimulates lipolysis and gluconeogenesis. Increased fatty acid oxidation increases acetyl CoA and NADH. High NADH allosterically inhibits the tricarboxylic acid cycle and the accumulating acetyl CoA is converted to ketone bodies. Low insulin:glucagon also decreases catabolism of muscle protein. Decreased gluconeogenesis conserves protein for a longer period of time.

14. AMP is increased as ATP is used for contraction, so AMPK is activated. AMPK phosphorylates and activates enzymes that foster glycogenolysis and glycolysis and glycogen is used until it is exhausted. AMPK also phosphorylates and inactivates acetyl-CoA carboxylase and activates malonyl-CoA decarboxylase reducing malonyl CoA. This allows greater carnitine palmitoyltransferase I activity to move long-chain acyl CoA esters into the mitochondria for fatty acid oxidation.

Key Concepts

- The hormonal cascade refers to (1) synthesis and secretion by hypothalamic neurons of specific releasing hormones, (2) releasing hormones stimulate the synthesis and secretion of tropic hormones by specific cells of the pituitary anterior lobe, and (3) tropic hormones increase the synthesis and secretion of specific hormones by target endocrine glands.
- Some genes for hormones code for large proteins that serve as precursors for a number of smaller proteins with distinctive hormonal activities. Other genes code for multiple copies of the same hormone.
- Norepinephrine and epinephrine are synthesized from tyrosine in the adrenal medulla. Thyroid hormone is synthesized by incorporation of iodine into tyrosine residues of thyroglobulin stored in the lumen of thyroid gland follicles.
- Protein hormones transmit their signals to target cells by binding to specific, high affinity membrane receptors; this leads to an increase in intracellular second messengers including cyclic AMP, cyclic GMP, inositol 1,4,5, trisphosphate, diacylglycerol, and phosphatidylinositol 3,4,5-trisphosphate.
- The female ovarian cycle is controlled by the pulsatile and cyclic secretion of gonadotropin-releasing hormone from the hypothalamus, which stimulates synthesis and secretion of both follicle stimulating and luteinizing hormone in the anterior pituitary. These hormones stimulate ovarian synthesis of estradiol and progesterone.
- Many second messengers activate specific protein kinases. Binding of insulin to its receptor activates auto-tyrosine kinase.
- Steroid hormones are derived from cholesterol and are synthesized in the adrenal cortex (aldosterone, cortisol, androgens), the Leydig cells of the male testes (testosterone, estrogen), and the female ovaries (estrogen, progesterone, androgens).
- Steroid hormone binding to specific plasma proteins protects them from degradation.

- Intracellular receptors for steroid and thyroid hormones, as well as vitamin D are members of the same superfamily and function as ligand-activated transcription factors, increasing gene transcription by binding to hormone response elements.
- Receptor proteins of this superfamily have three major functional domains: a carboxy-terminal ligand-binding domain; a DNA-binding domain; and a highly variable amino-terminal domain containing an antigenic region and a region that modulates transcriptional activation.

22.1 • INTRODUCTION

The hormones that will be discussed in this chapter fall into three major categories: **peptide and protein hormones**, hormones derived from the amino acid tyrosine (**thyroid hormones** and the **catecholamine hormones**), and **steroid hormones**. Taken collectively, these hormones regulate the growth, differentiation, and function of a wide variety of target cells that express receptors specific for these hormones. The peptide hormones and the catecholamine hormones interact with **cell surface receptors** (Figure 22.1) and transmit their signals through **second messengers** that are generated intracellularly. The binding of insulin to its cell surface receptor activates an intrinsic tyrosine kinase activity. Steroid hormones are derived from cholesterol and include glucocorticoid hormones, mineralocorticoid hormones, and the sex hormones. Steroid hormones diffuse freely across the plasma membrane and bind to **intracellular receptors** that function as **ligand-activated transcription factors**. The intracellular receptors for all of the steroid hormones and for nonsteroid hormones, including thyroid hormone, the active metabolite of vitamin D3, and retinoic acid, belong to the **steroid receptor super family** and share sequence homologies. The three major domains of steroid receptor are a C-terminal ligand-binding domain, a DNA-binding domain and an N-terminal immunogenic domain.

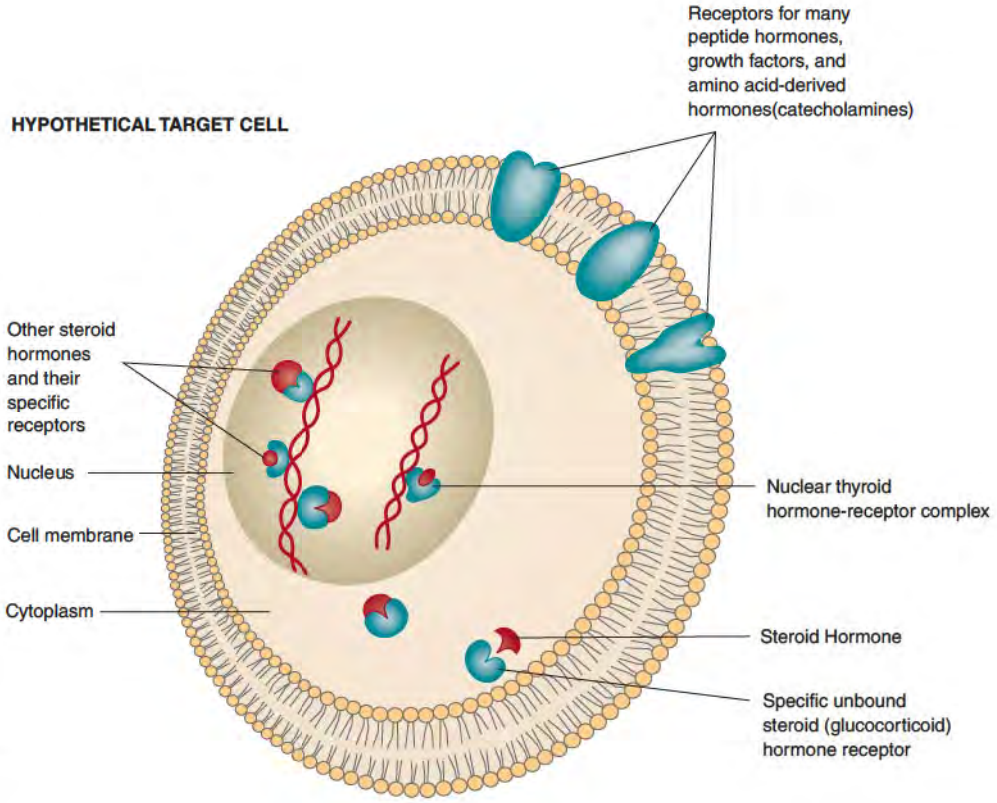

Figure 22.1 Diagram showing the different locations of classes of hormone receptors expressed by a target cell.

22.2 • HORMONES AND THE HORMONAL CASCADE SYSTEM

The definition of a hormone has expanded over the past several decades. Hormones secreted by endocrine glands were considered for many years to represent all of the physiologically relevant hormones. The term **hormone** now refers to any substance in an organism that carries a "signal" to generate some alteration at the cellular level. **Endocrine hormones** are synthesized in one tissue or gland and travel through the general circulation to reach distant target cells that express cognate receptors. **Paracrine hormones** are secreted by a cell and travel a relatively short distance to interact with cognate receptors on a neighboring cell. **Autocrine hormones** are produced by a cell that is also the target for that hormone (neighboring cells may also be targets). Endocrine hormones are frequently more stable than autocrine hormones that exert their effects over very short distances.

Hormonal Cascade Systems Amplify Specific Signals

Before we focus on details concerning each hormone, we need to look more broadly at the organization of the endocrine system and the hormonal hierarchy. For many hormonal systems in higher animals the signal pathway originates in the brain and culminates within the target cell. Figure 22.2 outlines the sequence of events in this cascade. A stimulus may originate in the external environment or within the organism and can be transmitted as action potentials, chemical signals, or both. In many cases, such signals are forwarded to the limbic system and subsequently to the hypothalamus, the anterior pituitary, and the target gland that secretes the ultimate hormone that then affects various target cells, frequently in proportion to the number of cognate receptors expressed by those cells. This may be a true **cascade** in the sense that increasing amounts of hormone are generated at successive levels (hypothalamus, anterior pituitary, and target gland) and in the sense that the half-lives ($t_{1/2}$) of blood-borne hormones tend to become longer the further they are down the cascade.

Consider a specific hormone secreted via one of these cascades. An environmental stress such as change in temperature, noise, or trauma results in a signal to the hippocampal structure

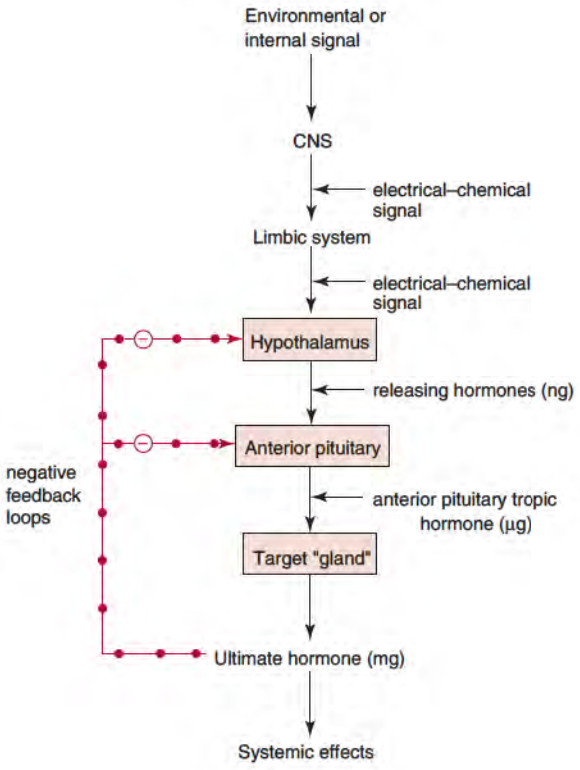

Figure 22.2 Hormonal cascade of signals from CNS to ultimate hormone. The target gland is the last hormone-producing tissue in the cascade, which is stimulated by an appropriate anterior pituitary hormone. Examples are thyroid gland, adrenal cortex, ovary, and testes. Ultimate hormone feeds back negatively on sites producing intermediate hormones in the cascade. Amounts (nanogram [ng], microgram [μg], and milligram [mg]) represent approximate quantities of hormone released.
Redrawn from Norman, A. W., and Litwack, G. *Hormones*. New York: Academic Press, 1987, 38.

from the limbic system for release of nanogram amounts of a hypothalamic-releasing hormone, corticotropin-releasing hormone (CRH), which has a $t_{1/2}$ in the bloodstream of several minutes. CRH travels down a closed portal system to the **anterior pituitary**, where it binds its cognate receptor in the membrane of corticotropic cells and initiates intracellular events that result in release of adrenocorticotropic hormone (ACTH) and β-lipotropin. ACTH is released in microgram amounts and has a longer $t_{1/2}$ than CRH. ACTH circulates until it binds to its cognate receptors expressed on the membranes of cells in the zona fasciculata of the adrenal cortex (target gland). Here it increases the synthesis and release of the steroid hormone cortisol in milligram amounts. Circulating cortisol has a longer $t_{1/2}$ than ACTH. Cortisol then interacts with target cells throughout the body that express intracellular glucocorticoid receptors. The ultimate hormone, cortisol, feeds back negatively on cells of the anterior pituitary and hypothalamus and reduces its own rate of synthesis and secretion from the adrenal cortex. At the level of the **target cell**, cortisol–receptor complexes mediate specific transcriptional responses, which collectively produce the systemic effects of cortisol. Other systems operate through similar cascades although through different specific **releasing hormones**, **anterior pituitary tropic hormones**, and ultimate hormones. Clearly, the number of target cells affected depends on their expression of receptor for ultimate hormones.

A distant but related system involves the **posterior pituitary hormones**, oxytocin and vasopressin (antidiuretic hormone), which are stored in and secreted by the posterior pituitary but are synthesized in neuronal cell bodies in the hypothalamus. This system is represented in Figure 22.3, which is an extended version of Figure 22.2. The posterior pituitary system branches to the right from the hypothalamus. Oxytocin and vasopressin are synthesized in separate cell bodies of hypothalamic neurons. Synthesis of vasopressin occurs largely in the supraoptic nucleus and synthesis of oxytocin occurs largely in the paraventricular nucleus. Their release from the posterior pituitary is independent and occurs in response to separate stimuli.

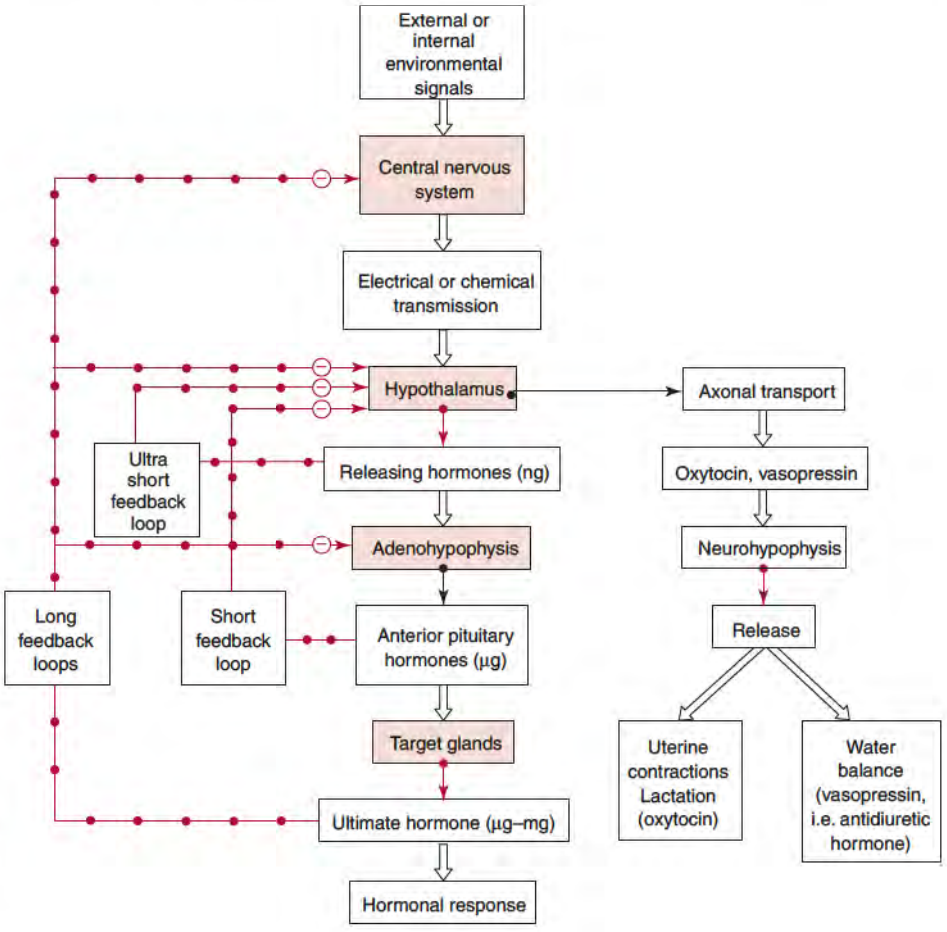

Figure 22.3 Many hormonal systems involve hypothalamus. Cascade of hormonal responses starting with an external or internal signal. This signal is transmitted first to the CNS and may involve the limbic system, including the hippocampus and amygdala. These components innervate the hypothalamus in a specific region, which responds by secreting (nanogram amounts) a specific releasing hormone. Releasing hormones are transported down a closed portal system to the anterior pituitary, where they cause secretion of microgram amounts of specific anterior pituitary hormones. These access the general circulation through fenestrated local capillaries and trigger release of an ultimate hormone in microgram to milligram daily amounts. The ultimate hormone generates its response by binding to receptors in target tissues. Overall, this system is an amplifying cascade. Consequently, the organism is in intimate association with the external environment. Solid arrows indicate a secretory process. Long arrows studded with open or closed circles indicate negative feedback pathways (ultrashort, short and long feedback loops).

TABLE 22.1 • Hypothalamic Releasing Hormones[a]

Releasing Hormone	*Number of Amino Acids in Structure*	*Anterior Pituitary Hormone Released or Inhibited*
Thyrotropin-releasing hormone (TRH)	3	Thyrotropin (TSH)
Gonadotropin-releasing hormone (GnRH)	10	Luteinizing and follicle-stimulating hormones (LH and FSH) from the same cell type; leukotriene C_4 (LTC_4) can also release LH and FSH by a different mechanism
Gonadotropin release-inhibiting factor (GnRIF)	Not established	
Corticotropin-releasing hormone (CRH)	41	ACTH, β-lipotropin (β-LPH), and some β-endorphin
Arginine vasopressin (AVP)	9	Stimulates CRH action on ACTH release
Angiotensin II (AII)	8	Stimulates CRH action on ACTH release; releases ACTH weakly
Growth hormone releasing hormone (GHRH)	49	Growth hormone (GH) release
Somatostation (growth hormone release-inhibiting hormone, GHIH)	14	GH release inhibited
Hypothalamic gastrin-releasing peptide		Inhibits release of GH and PRL
Prolactin-releasing factor (PRF)	Not established	Releases prolactin (PRL)
Prolactin release-inhibiting factor (PIF)		Evidence that a new peptide may inhibit PRL release; dopamine also inhibits PRL release and may be a secondary PIF: oxytocin may inhibit PRL release

[a] Melanocyte-stimulating hormone (MSH) is a major product of the pars intermedia (Figure 23.5) in the rat and is under the control of aminergic neurons. Humans may also secrete α-MSH from pars intermedia-like cells, although this structure is anatomically indistinct in the human.

Highly specific signals dictate release of polypeptide hormones along the cascade. Thus, **aminergic neurons** that secrete dopamine and/or serotonin relay to neurons involved in the synthesis and secretion of **releasing hormones** from the hypothalamus. Releasing hormones are summarized in Table 22.1. Aminergic neurons respond to various types of internal or external signals. Their activities account for the **pulsatile release** of hormones such as gonadotropin-releasing hormone (GnRH), and the **rhythmic cyclic release** of hormones like cortisol.

A prominent feature of the hormonal cascade (Figure 22.3) is the **negative feedback** that operates when sufficiently high levels of an ultimate hormone have been secreted. In long-loop feedback, the final hormone binds a cognate receptor in/on cells of the anterior pituitary, hypothalamus, and CNS to prevent further synthesis/secretion of releasing hormones. Short-loop feedback is exemplified by the pituitary tropic hormone that feeds back negatively on the hypothalamus and operates through a cognate receptor. In ultrashort feedback loops the hypothalamic releasing factor feeds back on the hypothalamus to inhibit its own further secretion.

Major Polypeptide Hormones and Their Actions

Since cellular communication is so specific, it is not surprising that there are numerous hormones in the body and new hormones continue to be discovered. Table 22.2 presents some major polypeptide hormones and their actions and shows that many hormones cause release of other hormones. This is particularly the case for hormonal cascade systems like that presented in Figures 22.2 and 22.3.

Polypeptide Hormones of Anterior Pituitary

Polypeptide hormones of the anterior pituitary are shown in Figure 22.4 along with their release-controlling hormones from the hypothalamus. The major hormones are growth hormone (GH), thyrotropin or thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), β-lipotropin (β-LTH), β-endorphin (from pars intermedia-like cells), α-MSH (from pars intermedia-like cells), β-MSH (from pars intermedia-like cells),

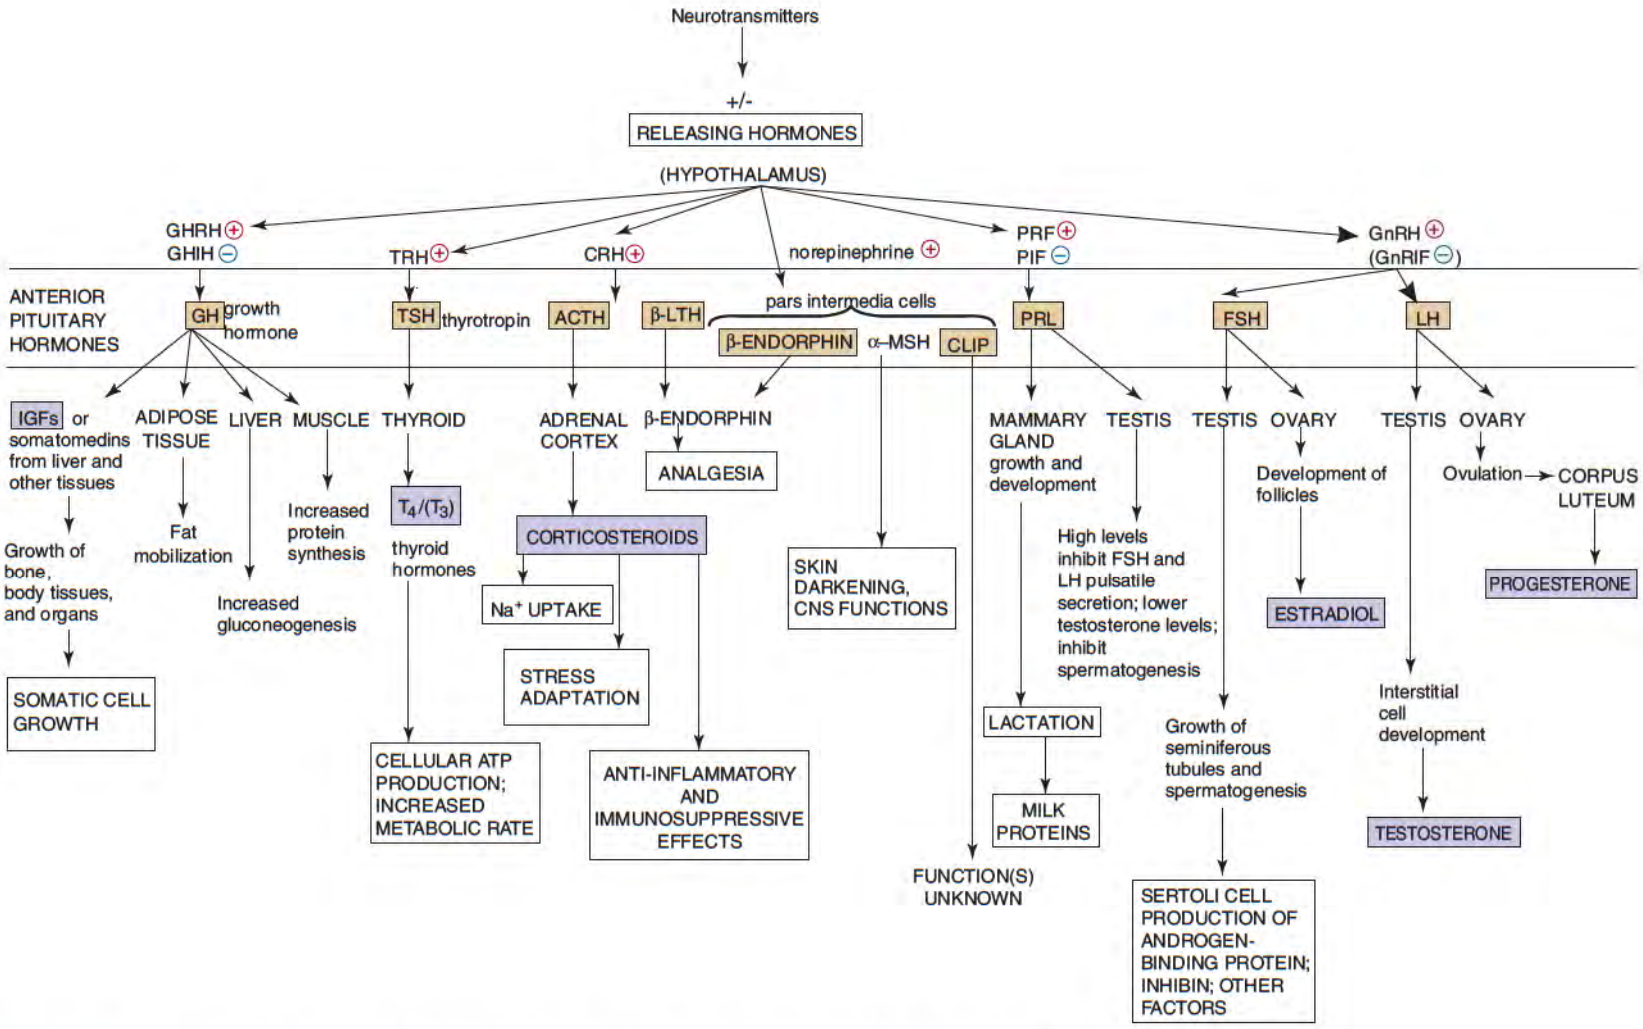

Figure 22.4 Overview of anterior pituitary hormones with hypothalamic releasing hormones and their actions.

TABLE 22.2 • Important Polypeptide Hormones in the Body and Their Actions[a]

Source	*Hormone*	*Action*
Hypothalamus	Thyrotropin-releasing hormone (TRH) Gonadotropin-releasing hormone (GnRH)	Acts on thyrotrope to release TSH Acts on gonadotrope to release LH and FSH from the same cell
	Growth hormone-releasing hormone or somatocrinin (GRH)	Acts on somatotrope to release GH
	Growth hormone release inhibiting hormone or somatostatin (GIH)	Acts on somatotrope to prevent release of GH
	Corticotropin-releasing hormone (CRH)	Acts on corticotrope to release ACTH and β-lipotropin
	Angiotensin II and vasopressin stimulate CRH action in releasing ACTH	
	Prolactin-releasing factor (PRF) (not well established)	Acts on lactotrope to release PRL
	Prolactin release-inhibiting factor (PIF) (not well established; may be a peptide hormone under control of dopamine or may be dopamine itself)	Acts on lactotrope to inhibit release of PRL
Anterior pituitary	Thyrotropin (TSH)	Acts on thyroid follicle cells to bring about release of $T_4(T_3)$
	Luteinizing hormone (LH) (human chorionic gonadotropin, hCG, is a similar hormone from the placenta)	Acts on Leydig cells of testes to increase testosterone synthesis and release; acts on corpus luteum of ovary to increase progesterone production and release
	Follicle-stimulating hormone (FSH)	Acts on Sertoli cells of seminiferous tubule to increase secretion of androgen-binding protein (ABP) and increase estradiol production from testosterone; acts on ovarian follicles to stimulate maturation of ovum and production of estradiol
	Growth hormone (GH)	Acts on a variety of cells to produce IGFs (or somatomedins), cell growth, and bone growth
	Adrenocorticotropic hormone (ACTH)	Acts on cells in the adrenal cortex to increase cortisol production and secretion
	β-Endorphin	Acts on cells and neurons to produce analgesic and other effects
	Prolactin (PRL)	Acts on mammary gland to cause differentiation of secretory cells (with other hormones) and to stimulate synthesis of components of milk
	Melanocyte-stimulating hormone (MSH)	Acts on skin cells to cause the dispersion of melanin (skin darkening)
Ultimate gland hormones	Insulin-like growth factors (IGF)	Respond to GH and produce growth effects by stimulating cell mitosis
	Thyroid hormone (T_4/T_3) (amino acid-derived hormone)	Responds to TSH and stimulates oxidation in many cells
	Opioid peptides	May arise as breakdown products of γ-lipotropin or β-endorphin or from specific gene products; can respond to CRH or dopamine and may produce analgesia and other effects

(continued)

TABLE 22.2 • *(continued)*

Source	*Hormone*	*Action*
Ovarian granulosa cells; testicular Sertoli cells.	Inhibin	Stimulates steroidogenesis in ovaries and testes; regulates secretion of FSH from anterior pituitary. Second form of inhibin (activin) may stimulate FSH secretion
Intermediate lobe of pituitary gland	Corticotropin-like intermediary peptide (CLIP)	Derives from intermediate pituitary by degradation of ACTH; may be an endogenous modulator of pancreatic exocrine function.
Peptide hormones responding to other signals than anterior pituitary hormones	Arginine vasopressin (AVP; antidiuretic hormone, ADH)	Responds to increased activity in osmoreceptor, which senses extracellular [Na^+]; increases water reabsorption from distal kidney tubule
	Oxytocin	Responds to suckling reflex and estradiol; causes milk "let down" or ejection in lactating female, involved in uterine contractions of labor; luteolytic factor produced by corpus luteum; decreases steroid synthesis in testis
β Cells of pancreas respond to glucose and other blood constituents	Insulin	Increases tissue utilization of glucose
α Cells of pancreas respond to low levels of glucose and falling serum calcium	Glucagon	Decreases tissue utilization of glucose to elevate blood glucose
Derived from angiotensinogen by actions of renin and converting enzyme	Angiotensin II and III (AII and AIII)	Renin initially responds to decreased blood volume or decreased [Na^+] in the macula densa of the kidney. AII/AIII stimulate outer layer of adrenal cortex to synthesize and release aldosterone
Released from heart atria in response to hypovolemia; regulated by other hormones	Atrial natriuretic factor (ANF) or atriopeptin	Acts on adrenal cortex cells to decrease aldosterone release; has other effects also
Generated from plasma, gut, or other tissues	Bradykinin	Modulates extensive vasodilation resulting in hypotension
Hypothalamus and intestinal mucosa	Neurotensin	Effects on gut; may have neurotransmitter actions
Hypothalamus, CNS, and intestine	Substance P	Pain transmitter, increases smooth muscle contractions of the GI tract
Nerves and endocrine cells of gut	Bombesin (mammalian equivalent is gastrin-releasing peptide)	Increases gastric acid secretion
	Cholecystokinin (CCK)	Stimulates gallbladder contraction and bile flow; increases secretion of pancreatic enzymes
Stomach antrum	Gastrin	Increases secretion of gastric acid and pepsin
Duodenum at pH values below 4.5	Secretin	Stimulates pancreatic acinar cells to release bicarbonate and water to elevate duodenal pH
Hypothalamus and GI tract	Vasointestinal peptide (VIP)	Acts as a neurotransmitter in peripheral autonomic nervous system; relaxes vascular smooth muscles; increases secretion of water and electrolytes from pancreas and gut
Kidney	Erythropoietin	Acts on bone marrow for terminal differentiation and initiates hemoglobin synthesis
Ovarian corpus luteum	Relaxin	Inhibits myometrial contractions; relaxes pelvic ligaments and increases dilation of cervix.
	Human placental lactogen (hPL)	Acts like PRL and GH.

TABLE 22.2 • *(continued)*

Source	*Hormone*	*Action*
Salivary gland	Epidermal growth factor	Mitogenic; stimulates proliferation of various epidermal and epithelial cell types
Thymus	Thymopoietin (α-thymosin)	Stimulates phagocytes; stimulates differentiation of precursors into immune competent T cells
Parafollicular C cells of thyroid gland	Calcitonin (CT)	Lowers serum calcium
Parathyroid glands	Parathyroid hormone (PTH)	Stimulates bone resorption; stimulates phosphate excretion by kidney; raises serum calcium levels
Endothelial cells of blood vessels	Endothelin	Vasoconstriction

Source: Part of this table is reproduced from Norman, A. W. and Litwack, G. Hormones. Orlando, FL: Academic Press, 1987.

[a] This is only a partial list of polypeptide hormones in humans. TSH, thyroid-stimulating hormone or thyrotropin; LH, luteinizing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; ACTH, adrenocorticotropic hormone; PRL, prolactin; T_4, thyroid hormone (also T_3); IGF, insulin-like growth factor. For the releasing hormones and for some hormones in other categories, the abbreviation may contain "H" at the end when the hormone has been well characterized, and "F" in place of H to refer to "Factor" when the hormone has not been well characterized. Names of hormones may contain "tropic" or "trophic" endings; tropic is mainly used here. Tropic refers to a hormone generating a change, whereas trophic refers to growth promotion. Both terms can refer to the same hormone at different stages of development. Many of these hormones have effects in addition to those listed here.

corticotropin-like intermediary peptide (CLIP; from pars intermedia-like cells), prolactin (PRL), follicle-stimulating hormone (FSH), and luteinizing hormone (LH). All of these hormones are single polypeptide chains, except TSH, FSH, and LH, all of which are dimers that share a similar or identical α-subunit. Since the intermediate lobe in humans is rudimentary, the circulating levels of free α- and β-MSH are relatively low. It is of interest, particularly in the human, that MSH receptors recognize and are activated by ACTH, because the first 13 amino acids of ACTH contain the α-MSH sequence. For this reason, ACTH may be an important contributing factor to skin pigmentation and may exceed the importance of MSH, especially in conditions where the circulating level of ACTH is high. The clinical consequences of hypopituitarism are presented in Clin. Corr. 22.1.

CLINICAL CORRELATION 22.1

Hypopituitarism

The hypothalamus is connected to the anterior pituitary by a delicate stalk that contains the portal system through which releasing hormones, secreted from the hypothalamus, gain access to the anterior pituitary cells. Located in the cell membranes of these cells are specific receptors for releasing hormones. In most cases, different cells express different releasing hormone receptors. The connection between the hypothalamus and anterior pituitary can be disrupted by trauma or tumors. Trauma can occur in an automobile accident or other local damaging events that may result in severing of the stalk and preventing the releasing hormones from reaching their target anterior pituitary cells. When this happens, the anterior pituitary cells no longer receive the appropriate signals for the release of anterior pituitary hormones. *Panhypopituitarism* is a term used to describe this overall deficiency of anterior pituitary hormones. In the case of tumors of the pituitary gland, all of the anterior pituitary hormones may not be shut off to the same degree, or the secretion of some may disappear sooner than others. Thus the symptoms of hypopituitarism sometimes develop slowly. In any case, if hypopituitarism occurs, this condition may result in a life-threatening situation in which the clinician must determine the extent of loss of each of the pituitary hormones, especially ACTH. Posterior pituitary hormones—oxytocin and vasopressin—may also be lost, resulting in excessive urination (vasopressin deficiency) which must be addressed. Panhypopituitarism can also result in an increased sensitivity to the actions of insulin because of the decreased secretion of the insulin antagonists, growth hormone and cortisol, leading to hypoglycemia. The usual therapy involves administration of the end organ hormones, such as thyroid hormone, cortisol, sex hormones, and progestin; with female patients it is also necessary to maintain the ovarian cycle. These hormones can be easily administered in oral form. Growth hormone deficiency is not a problem in the adult but would be a serious problem in a growing child. The patient suffering from panhypopituitarism must learn to anticipate needed increases of cortisol in the face of stressful situations. Fortunately, these patients are usually maintained in reasonably good condition.

22.3 • SYNTHESIS OF POLYPEPTIDE AND AMINO-ACID-DERIVED HORMONES

Polypeptide Hormones: Gene Coding

Genes for polypeptide hormones contain the coding sequence for the hormone and the control elements upstream of the structural gene. In some cases, more than one hormone is encoded in a gene. For example, proopiomelanocortin generates at least nine peptide hormones from a single gene product. As is seen with many other protein hormones, both antidiuretic hormone (ADH, vasopressin) and oxytocin are synthesized as prepro-hormones. The prohormones that are generated contain segments called **neurophysin**, which are cleaved during transport to the posterior pituitary. When secretion occurs equal amounts of the hormone and its neurophysin enter the circulation. These neurophysins have no known physiological function.

Proopiomelanocortin Is Precursor for Numerous Hormones

Proopiomelanocortin is a precursor for several hormones including: ACTH, β-lipotropin, and γ-lipotropin, γ-MSH, α-MSH, CLIP, and β-endorphin, and potentially β-MSH and enkephalins (Figure 22.5). All of these are not expressed simultaneously in a single cell type but are produced in separate cells depending on their content of specific proteases, metabolic controls, and regulators. Thus, while proopiomelanocortin is expressed in both corticotropes of the anterior pituitary and pars intermedia cells, the stimuli and products are different (Table 22.3). The pars intermedia is a discrete anatomical structure located between the anterior and posterior pituitary (Figure 22.6) in some species including the rat. In the human, however, pars intermedia are not a discrete anatomical structure, although some residual pars intermedia-like cells may be present in the equivalent location.

Genes of Polypeptide Hormones May Encode Additional Peptides

Other genes that encode more than one peptide are those for vasopressin and oxytocin and their accompanying neurophysins. Vasopressin, neurophysin II, and a glycoprotein of unknown function are released from the vasopressin precursor. A similar situation exists for

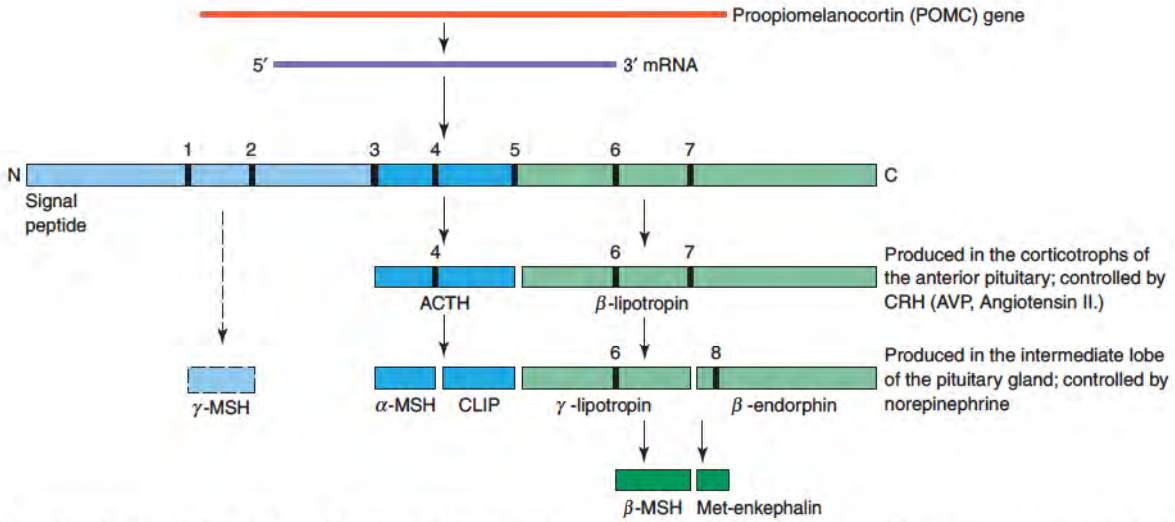

Figure 22.5 Proopiomelanocortin is a polypeptide encoded by one gene. The dark vertical bars represent proteolytic cleavage sites for specific enzymes. The cleavage sites are Arg-Lys, Lys-Arg, or Lys-Lys. Some specificity also may be conferred by neighboring amino acid residues. In the anterior pituitary, enzymes cleave at sites 3 and 5, releasing the major products, ACTH and β-lipotropin. In the pars intermedia, especially in vertebrates below humans, these products are further cleaved at major sites 4, 6, and 7 to release α-MSH, CLIP, γ-lipotropin, and β-endorphin. Some β-lipotropin may be further degraded to form β-endorphin. The anterior pituitary is under the positive control of the CRH and its stimulators, arginine vasopressin (AVP), and Angiotensin II. AVP by itself does not release ACTH but enhances the action of CRH in this process. The intermediary pituitary is under the positive control of norepinephrine. β-Endorphin also contains a pentapeptide, enkephalin, which potentially could be released at some point (hydrolysis at 8).

TABLE 22.3 • Summary of Stimuli and Products of Proopiomelanocortina[a]

Cell type	Corticotroph	Pars intermedia
Stimulus	CRH (+) (Cortisol (−))	Dopamine (−) Norepinephrine (+)
Auxiliary stimulus	AVP, AII	
Major products	ACTH, β-lipotropin (β-endorphin)	α-MSH, CLIP, γ-lipotropin, β-endorphin

[a]CRH, corticotropin-releasing hormone; AVP, arginine vasopressin; AII, angiotensin II; ACTH, adrenocorticotropin; α-MSH, α melanocyte-stimulating hormone; CLIP, corticotropin-like intermediary peptide.

Note: Although there are *pars intermedia cells* in the human pituitary gland, they do not represent a distinct lobe.

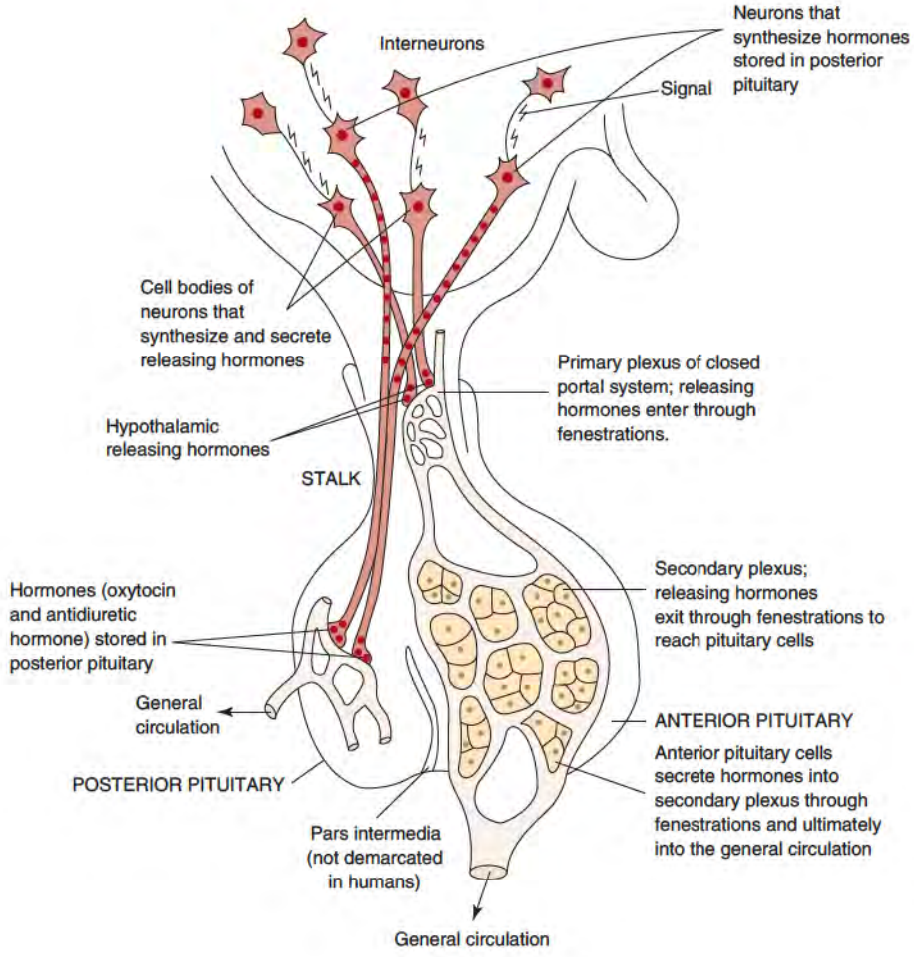

Figure 22.6 Anatomical relationship between hypothalamus and pituitary gland. The major vascular network is a primary plexus which releasing hormones enter through fenestrations. The secondary plexus is in the anterior pituitary where the releasing hormones are transported out of fenestrations to interact with the anterior pituitary target cells. Hypothalamic releasing hormones cause secretion of the anterior pituitary hormones, which enter the general circulation. Adapted from Norman, A. W., and Litwack, G. *Hormones.* New York: Academic Press, 1987, 104.

oxytocin and neurophysin I, except that no glycoprotein is released (Figure 22.7). **Vasopressin** and **neurophysin II** are co-released in response to stimuli from baroreceptors and osmoreceptors, which sense a fall in blood pressure or a rise in extracellular sodium ion concentration, respectively. **Oxytocin** and **neurophysin I** are coreleased by the suckling response in lactating females or as part of a conditioned reflex, such as a mother hearing her infant cry. Oxytocin is well known for its milk "let-down" action in the lactating female. Although oxytocin from the mother is probably not involved in initiating labor in humans, it may help maintain labor. Oxytocin from the fetus could be involved in the onset of labor.

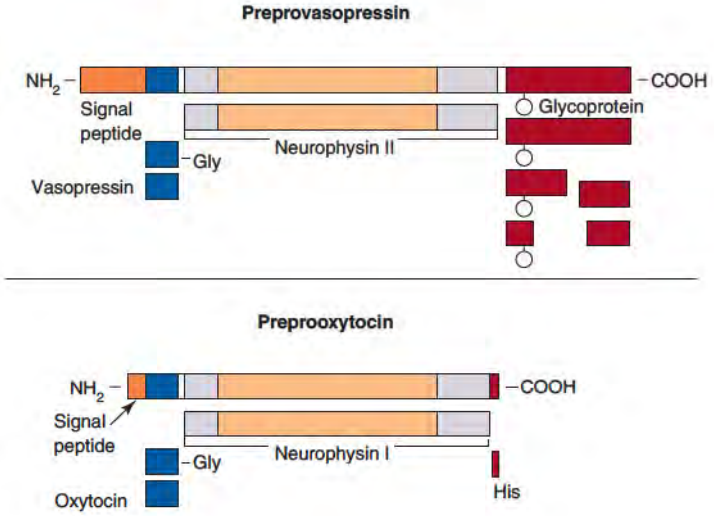

Figure 22.7 Preprovasopressin and preprooxytocin. Proteolytic maturation proceeds from top to bottom for each precursor. The organization of the gene translation products is similar except that a glycopeptide is included on the vasopressin precursor in the C-terminal region. Orange bars of the neurophysin represent conserved amino acid regions; gray bars represent variable C- and N-termini.

Other polypeptide hormones are encoded by a single gene that does not encode another protein or hormone. An example is the gene encoding the decapeptide GnRH. This gene appears to reside to the left of a gene for the GnRH-associated peptide (GAP), which may be capable of inhibiting prolactin release. Thus, GnRH and the prolactin release-inhibiting factor (GAP) appear to be cosecreted by the same hypothalamic cells, but are not co-encoded. Many genes for hormones encode only one copy of the hormone and this may be the more common situation. An example is shown in Figure 22.8. Information encoding CRH is contained in the second axon.

One Gene Can Code for Multiple Copies of a Hormone

An example of multiple copies of a single hormone encoded on a single gene is the enkephalins secreted by chromaffin cells of the adrenal medulla. **Enkephalins** are pentapeptides with opioid activity; methionine-enkephalin (Met-ENK) and leucine-enkephalin (Leu-ENK) have the structures

Tyr-Gly-Gly-Phe-Met (Met-ENK)

Tyr-Gly-Gly-Phe-Leu (Leu-ENK)

A model of the enkephalin precursor which encodes several Met-ENK (M) molecules and a molecule of Leu-ENK (L) is presented in Figure 22.9. The processing sites for release of

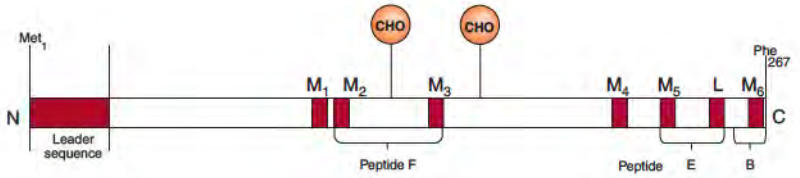

Figure 22.9 Model of enkephalin precursor. Distribution of Met-enkephalin sequences (M_1–M_6) and Leu-enkephalin (L) sequences within the precursor of bovine adrenal medulla. CHO, potential carbohydrate attachment sites.

enkephalin molecules from the protein precursor contain Lys-Arg, Arg-Arg, and Lys-Lys bonds. Another example is the gene for the tripeptide hormone TRH. The TRH peptide sequence is present six times within the human TRH pre-prohormone.

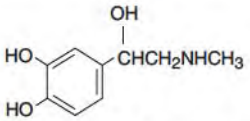

Figure 22.10 Structure of catecholamine hormone epinephrine.

Amino-Acid-Derived Hormones

Epinephrine Is Synthesized from Phenylalanine/Tyrosine

Epinephrine (Figure 22.10) is synthesized from phenylalanine/tyrosine in the adrenal medulla (p. 895). This catecholamine hormone is secreted along with some norepinephrine, enkephalins, and dopamine-β-hydroxylase by medullary chromaffin cells. Its secretion is signaled by the neuronal response to stress, which is transmitted by way of preganglionic acetylcholinergic neurons (Figure 22.11*a*). This signal increases intracellular Ca^{2+}, which in turn stimulates exocytosis and release of hormone stored in the **chromaffin granules** (Figure 22.11*b*). Once secreted, epinephrine and norepinephrine mediate their specific effects by interacting with receptors located on the plasma membranes of target cells. These receptors are generically grouped as α and β; each group has several subtypes. Epinephrine has a greater affinity for β-receptors than α-receptors, while norepinephrine acts primarily via α receptors.

In contast to the catecholamine hormones, the steroid hormones including aldosterone, cortisol, and dehydroepiandrosterone are synthesized and secreted by cells in the adrenal cortex (p. 885). Like epinephrine, the secretion of cortisol by the adrenal cortex is increased in response to stress. This secreted cortisol perfuses the adrenal medulla where it induces **phenylethanolamine *N*-methyltransferase (PNMT)** that converts norepinephrine to epinephrine. Thus, in biochemical terms, the stress response at the level of the adrenal cortex ensures the production of epinephrine from the adrenal medulla (Figure 22.12).

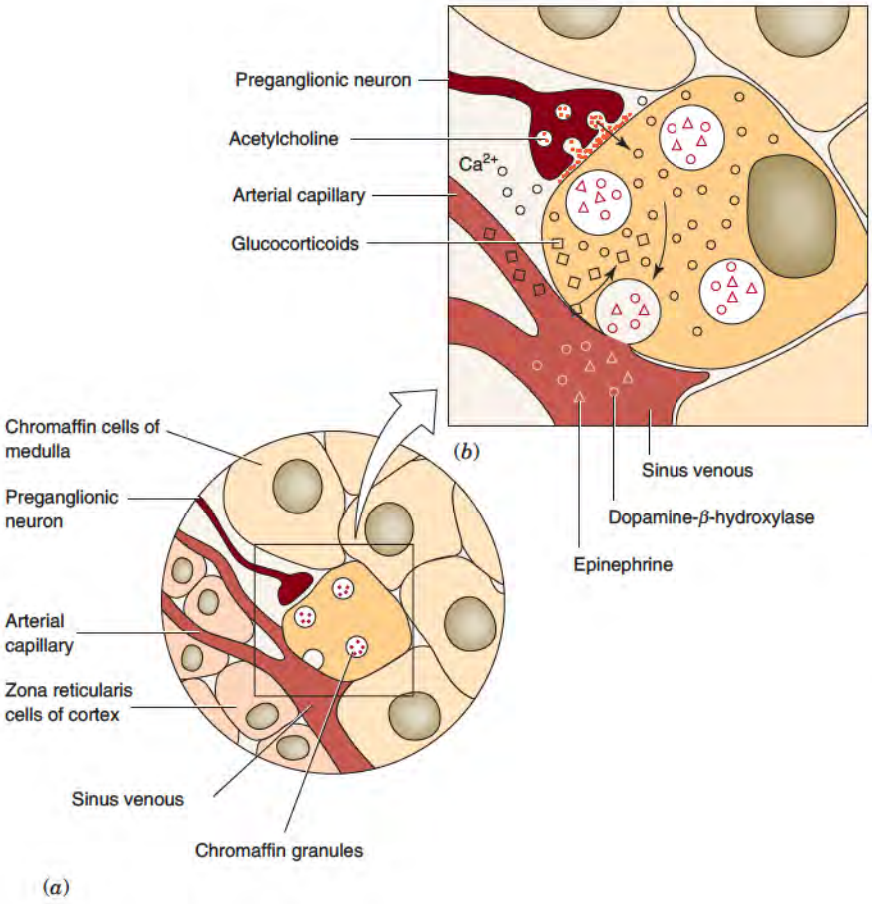

Figure 22.11 Relationship of adrenal medulla chromaffin cells to preganglionic neuron innervation and the structural elements involved in synthesis of epinephrine and discharge of catecholamines in response to acetylcholine. (*a*) Functional relationship between cortex and medulla for control of synthesis of adrenal catecholamines. Glucocorticoids that induce the PNMT enzyme reach the chromaffin cells from capillaries shown in (*b*). Discharge of catecholamines from storage granules in chromaffin cells after release of acetylcholine from nerve fiber stimulation. Calcium enters the cells, causing the fusion of granules and plasma membranes and exocytosis of the contents.

Synthesis of Thyroid Hormone Requires Incorporation of Iodine into Tyrosines of Thyroglobulin

An outline of the biosynthesis and secretion of thyroid hormone, **tetraiodo-L-thyronine (T_4)**, or **thyroxine**, and its more active metabolite, **triiodo-L-thyronine (T_3)**, is presented in Figures 22.13 and 22.14. The thyroid gland is specialized to concentrate iodide from the blood, and through the reactions shown in Figures 22.13 and 22.14, monoiodotyrosine (MIT), diiodotyrosine (DIT), T_4, and T_3 and reverse T3 are produced via iodination of tyrosyl residues within the **thyroglobulin** (TG) molecule. **Thyroglobulin** is a large glycoprotein that is synthesized and secreted by the thyroid epithelial cells and is stored in the lumen of the thyroid follicles. The coupling of an MIT and DIT or two DIT molecules can occur within the same thyroglobulin molecule or between two adjacent thyroglobulin molecules. Secretion of T_3 and larger amounts of T_4 into the bloodstream requires endocytosis (Figure 22.14) of the thyroglobulin by follicular epithelial cells and its proteolysis by lysosomal enzymes. The DIT and MIT released within the epithelial cell are then deiodinated and the released iodide ions are recycled and reutilized for thyroid hormone synthesis. This recycling of iodine ions is extremely important, and mutations resulting in inactivation of the deiodinase enzyme can result in an iodide deficiency.

Inactivation and Degradation of Amino-Acid-Derived Hormones

Most polypeptide hormones are degraded by proteases, presumably in lysosomes. Some hormones contain modified amino acids; for example, the N-terminal amino acid may be **cycloglutamic acid** (**pyroglutamic acid**), and there may be a C-terminal amino acid amide (Table 22.4). Breakage of the cyclic glutamate ring or cleavage of the C-terminal amide inactivates many of these hormones. Such reactions have been reported to occur in blood and may account for the short half-life of some hormones in plasma.

Some hormones contain cystine disulfide bonds (Table 22.5), and these may be degraded by **cystine aminopeptidase** and **glutathione transhydrogenase** (Figure 22.15). Alternatively, the peptide may undergo partial proteolysis to shorter peptides, some of which may have hormonal actions. Maturation or processing of **prohormones** into mature hormones involves selective proteolysis (see Figure 22.5, p. 892).

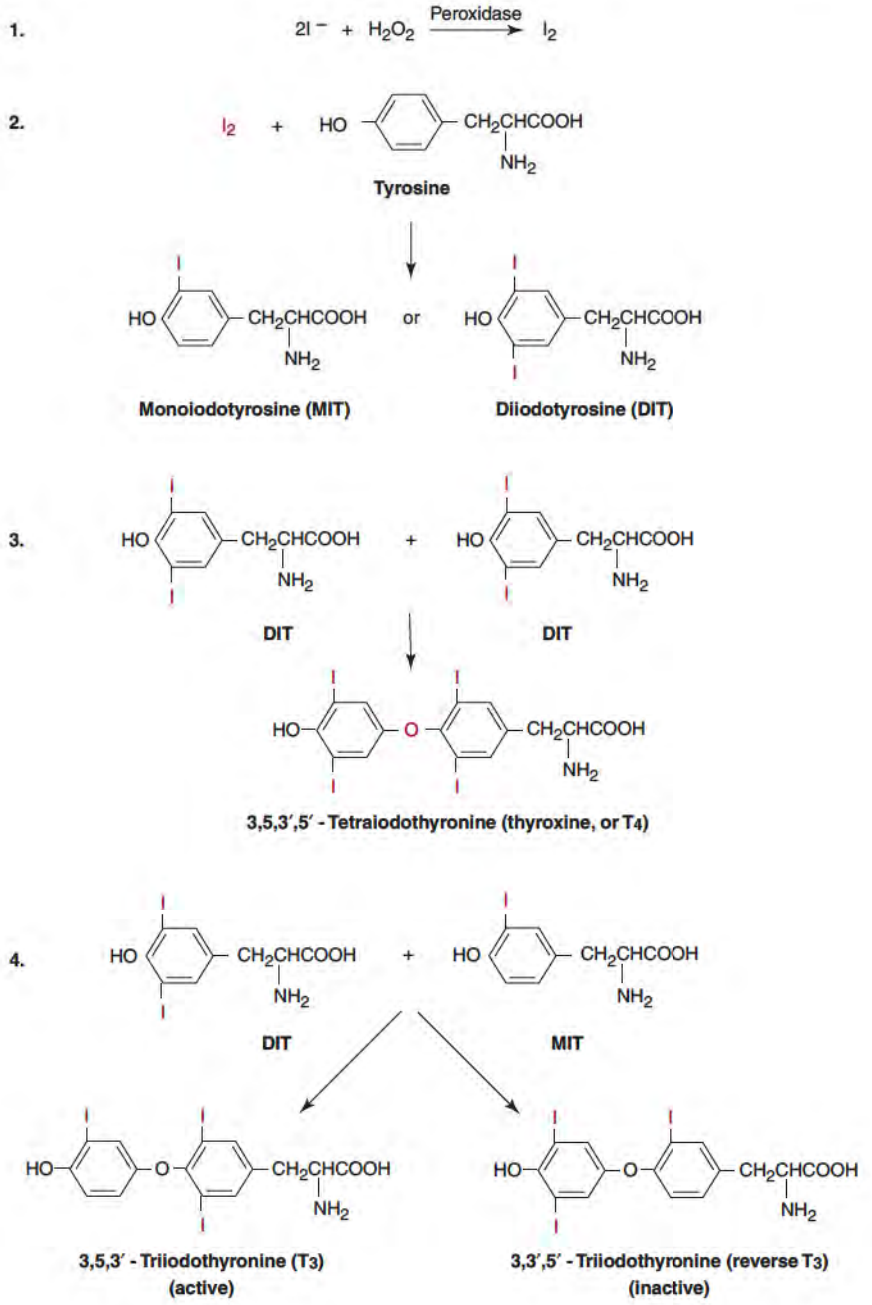

Figure 22.13 Synthesis and structures of thyroid hormones T_4 and T_3 and reverse T_3. Step 1, oxidation of iodide; step 2, iodination of tyrosine residues; step 3, coupling of DIT to DIT; and step 4, coupling of DIT to MIT (coupling may be intramolecular or intermolecular).

22.4 • PROTEIN HORMONE SIGNALING

Overview of Signaling

Membrane Receptors

In the cascade system displayed in Figures 22.2 and 22.3 (pp. 885 and 886), hormones emanate from one source, cause hormonal release from the next step, and so on, down the cascade. Correct responses follow each specific stimulus. Polypeptide hormones generally bind to membrane receptors expressed specifically on target cells. The receptor recognizes structural features of the hormone with an affinity constant for the interaction of 10^9–10^{11}/M. This activates or inactivates an effector protein in or on the membrane (p. 474). Some receptors undergo **internalization** to the cell interior and others open a membrane ion channel (p. 478).

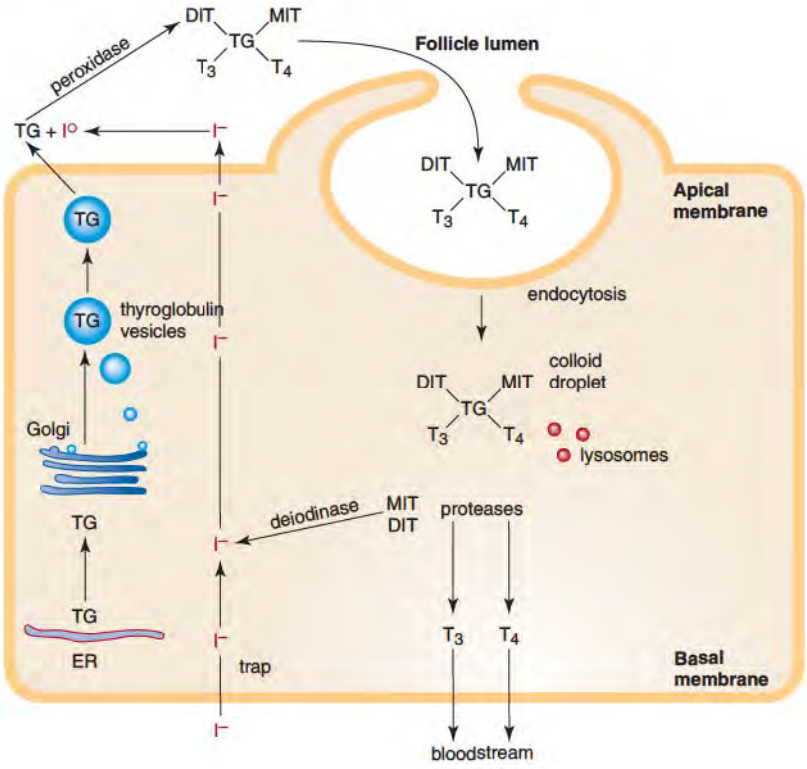

Figure 22.14 Cellular mechanisms for T_3 and T_4 release into bloodstream. Iodide trapping by basal membrane concentrates iodide approximately 30-fold. Secretion requires endocytosis of thyroglobulin and subsequent proteolysis. DIT and MIT are deiodinated and the released iodide ions are reutilized for hormone synthesis. Redrawn from Berne, R. M., and Levy, M. L. (Eds.). *Physiology*, 2d ed. New York: Mosby, 1990, 938.

Intracellular Signal Cascade: Second Messengers

After binding to their cognate membrane receptors, many peptide and protein hormones transmit their signal intracellularly via second messengers, which transmit and amplify the hormonal signal (p. 509). Some hormones transmit their signal by increasing the intracellular concentration of one second messenger, while others increase the concentration of several second messengers, either simultaneously or sequentially. Second messengers include cyclic AMP (cAMP), cyclic GMP (cGMP), inositol trisphosphate (IP_3), diacylglycerol

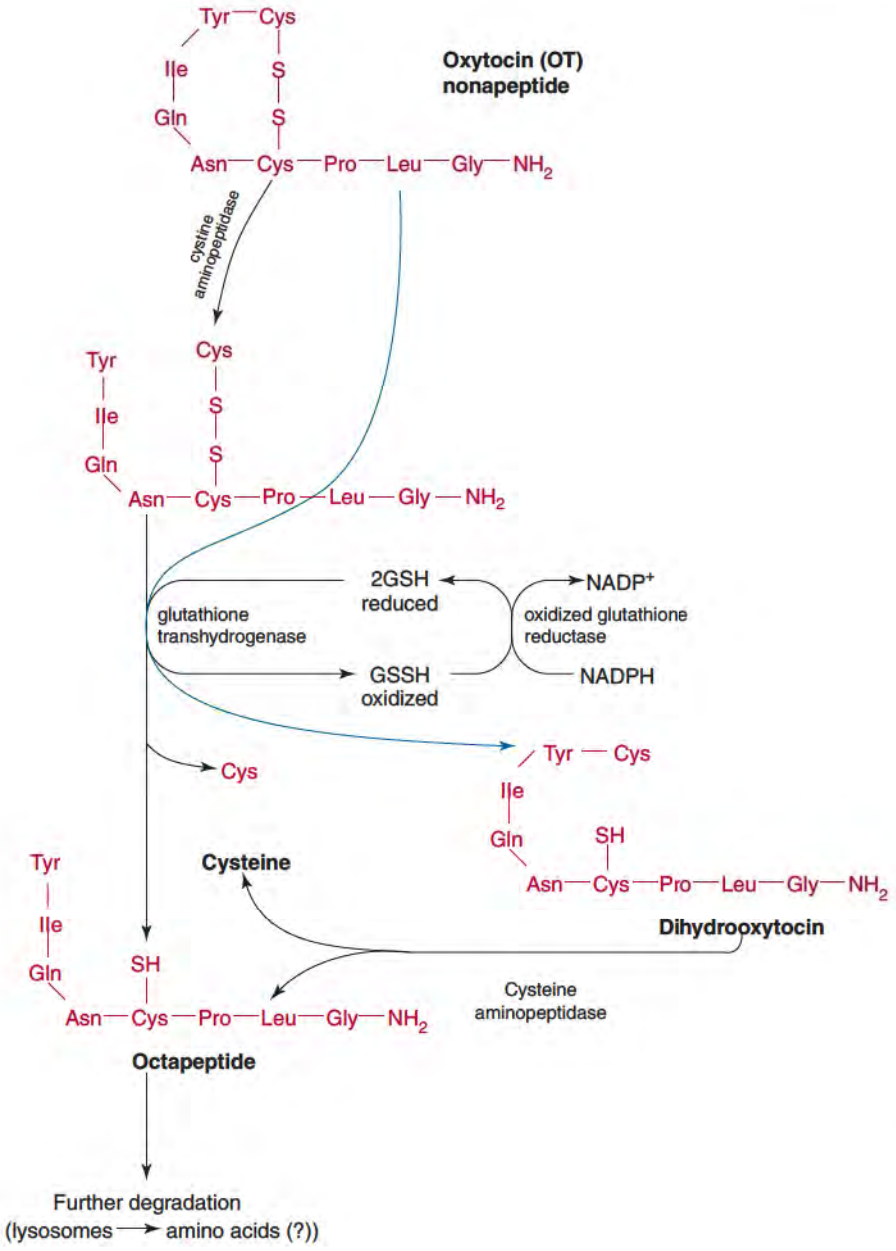

Figure 22.15 Degradation of posterior pituitary hormones. Oxytocin transhydrogenase is similar to degrading enzymes for insulin; presumably, these enzymes also degrade vasopressin. Redrawn from Norman, A. W., and Litwack, G. *Hormones*. New York: Academic Press, 1987, 167.

(DG), and phosphatidylinositol 3,4,5-trisphosphate (PIP_3). Different hormones bind to receptors that activate either a stimulatory or an inhibitory G protein subunit (G_s or G_i, respectively) and result in activation or inhibition of an effector enzyme and, thus, an increase or decrease in the corresponding intracellular second messenger. The intracellular second messengers activate specific kinases that initiate a cascade of phosphorylation/dephosphorylation reactions and result in activation of some, and inactivation of other, enzymes (p. 510). Stimulation of adenylate cyclase by G protein-coupled receptors generates cAMP, which activates **protein kinase A**, whereas stimulation of guanylate cyclase by different G protein-coupled receptors generates cGMP, which activates **protein kinase G**. Stimulation of phospholipase C with generation of DG and IP_3 results in the mobilization of Ca^{2+} stores and activation of **protein kinase C**.

An example of a hormone that transduces a signal via the generation of a second messenger is depicted in Figure 22.16. Thyrotropin-releasing hormone synthesized by hypothalamic neurons reaches the thyrotropes in the anterior pituitary and stimulates them to synthesize and secrete thyroid-hormone-stimulating hormone (TSH). TSH binds to its G

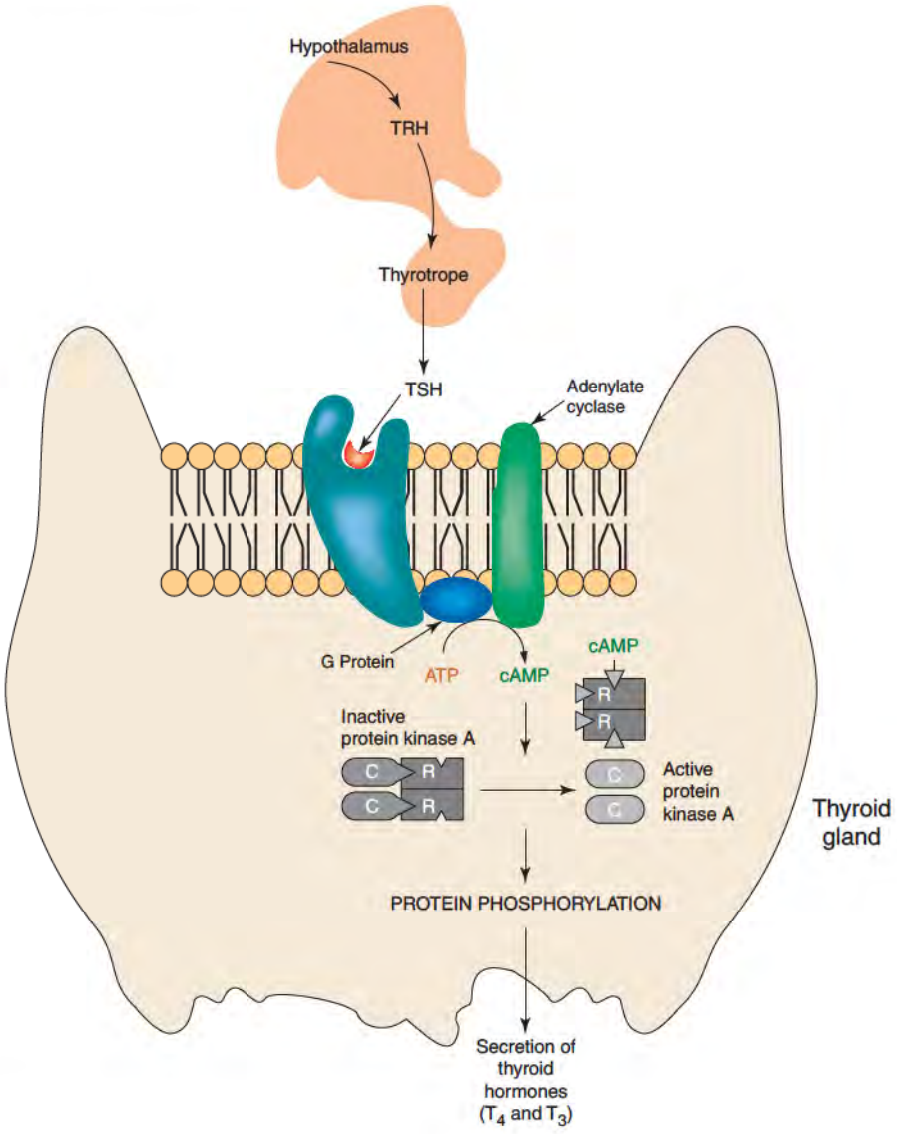

Figure 22.16 Effect of TSH on secretion of thyroid hormone. TSH stimulates all steps in synthesis and secretion of T_3 and T_4. These are mediated by its binding to TSH receptors located on basal membrane of thyroid epithelial cells, elevation of cAMP levels, and subsequent cascade of phosphorylation reactions.

protein-coupled membrane receptors in the thyroid gland and activates adenylate cyclase with generation of cAMP. cAMP in turn binds to the regulatory subunits in the inactive form of protein kinase A leading to their dissociation from the catalytic subunits, which are fully active (p. 510) and initiate a cascade of protein phosphorylations that results in secretion of thyroid hormone.

Amplification occurs at each step of this signal transduction pathway. For example, activation of one molecule of adenylate cyclase may result in the generation of ~100 molecules of cAMP and the ultimate phosphorylation of ~10,000 enzyme molecules. The effects of cAMP are terminated when it is hydrolyzed by **phosphodiesterase**. Since phosphodiesterase is also modulated by hormones via a G protein, the level of cAMP is actually under dual regulation. Two different hormones can have antagonistic effects as one stimulates adenylate cyclase and the other stimulates phosphodiesterase. Hormonal activation of protein kinase A can also alter the rate of transcription of genes (p. 529). After activation by cAMP, the catalytic subunit of PKA diffuses into the nucleus where it catalyzes phosphorylation of a serine residue in **CREB (cAMP-response element binding protein)**, a ubiquitously expressed transcription factor. The activated CREB then binds as a dimer to the conserved consensus **cAMP response element (CRE)**. A conserved palindromic CRE has been identified in the promoter of various genes regulated by cAMP. Two other transcription factors, CREM (CRE modulator) and ATF-1 (Activating Transcription

Factor), are also phosphorylated by protein kinase A. While CREB and ATF-1 stimulate transcription, some isoforms of CREM inhibit CRE activity. Thus hormonal activation of a protein kinase can increase or decrease gene transcription.

Cyclic Hormonal Systems

The **diurnal variation** in the secretion of cortisol from the adrenal cortex is regulated by the sleep/wake transition whereas secretion of **melatonin** from the pineal gland is dictated by daylight and darkness. The female ovarian cycle also operates on a cyclic basis dictated by the central nervous system. These are all examples of **chronotropic control** of hormone secretion.

Melatonin and Serotonin Synthesis Are Controlled by Light/Dark Cycles

In the release of melatonin from the pineal gland (Figure 22.17*a*, p. 902), the internal signal is provided by norepinephrine released by an adrenergic neuron. Control is exerted by light entering the eyes, which inhibits the pineal gland and hence the release of melatonin. Norepinephrine released in the dark stimulates cAMP formation through a β receptor in the pinealocyte membrane. Increased activity of PKA enhances synthesis of ***N*-acetyltransferase** and conversion of **serotonin**, synthesized from tryptophan (p. 785), to ***N*-acetylserotonin**, and this is the rate-limiting step that dictates the circadian rhythm of melatonin. **Hydroxyindole-*O*-methyltransferase (HIOMT)** then converts *N*-acetylserotonin to **melatonin** (Figure 22.17*b*), which is secreted during the dark hours. Relatively small doses of melatonin can induce sleep and basically reset the daily rhythm. This physiological response could benefit workers whose shifts alternate between daylight and nighttime hours. Melatonin is also a potent antioxidant and may provide some protection against damaging oxygen free radicals. Although melatonin inhibits reproductive functions in animals that breed during specific seasons, there is no proof that it influences human reproductive functions.

Ovarian Cycle Is Controlled by Pulsatile and Cyclic Secretion of Gonadotropin-Releasing Hormone

GnRH is secreted from hypothalamic neuroendocrine cells in pulses about 1 h apart in response to norepinephrinergic neurons in both adult males and females. In females the frequency of pulses, and therefore the total amount of GnRH secreted during a 24-h period, changes over the course of the monthly menstrual cycle. Figure 22.18 (p. 903) summarizes this important role of pulsatile GnRH secretion in terms of FSH and LH secretion from the female anterior pituitary. Entry of GnRH into the portal system is through fenestrations in the blood vessels to reach the **gonadotropes** located in the anterior pituitary. Here GnRH binds to its membrane receptors and mediates its effects via the phosphatidylinositol second messenger system (p. 534), with release of FSH and LH from the same gonadotrope. Clin. Corr. 22.2 describes how the premature secretion of large amounts of GnRH can result in precocious puberty in a young child. **FSH** operating through protein kinase A via cAMP elevation, stimulates synthesis and secretion of 17β-estradiol, and matures the ovarian follicle and ovum. **Inhibin**, a disulfide-linked dimeric glycoprotein hormone, is also synthesized and secreted by the granulosa cells of the ovarian follicle. These hormones are feedback inhibitors of FSH production by gonadotropes. **Activins** are dimeric proteins closely related to the inhibins. These hormones are produced by the same tissue that secretes inhibins, but stimulate, rather than inhibit, FSH secretions by the gonadotropes. When a follicle reaches maturity, a surge of LH and prostaglandin $F_{2\alpha}$ triggers ovulation. The residual follicle under primary control by LH (Figure 22.18) becomes the functional corpus luteum. LH binds to its cognate receptors in the corpus luteum and through stimulation of protein kinase A increases synthesis of progesterone. **Estradiol** and **progesterone** bind to specific intracellular receptors in the uterine endometrium and promote thickening of the wall, vascularization, and increased secretory activity in preparation for implantation of the fertilized egg. Estradiol is synthesized in large amounts prior to production of progesterone and induces expression of progesterone receptors. This induction of progesterone receptors primes the uterus for subsequent stimulation by progesterone.

CLINICAL CORRELATION 22.2

Precocious Puberty

Children with brain tumors or other hypothalamic lesions may undergo what is called precocious puberty. In this endocrine disorder, sexual maturation occurs at a very early age due to premature secretion of large amounts of GnRH. As an extreme example, the youngest recorded mother to give birth to a full-term, healthy infant by cesarean section was only 5 years, 8 mon of age. Of course such pregnancies are in fact the result of sexual abuse of a child with true precocious puberty.

In young boys the testes usually enlarge under gonadotropin stimulation before any other signs of puberty are seen. In young girls an increased growth rate, breast development, an increase in the size of ovaries and uterus, and changes in the vaginal mucosa are the usual presenting features. The rapid growth in these young girls is associated with a rise in estrogen synthesis and secretion, and this leads to increased growth hormone secretion. Spermatogenesis in males and ovulation in females may occur, and fertility is certainly possible.

Three major drugs that have been used successfully to treat this disorder include medroxyprogesterone, cyproterone acetate, and superactive GnRH agonists, which are the most effective. Medroxyprogesterone inhibits gonadotropin secretion and also functions as a competitive inhibitor of a specific enzyme involved in steroidogenesis. Cyproterone acetate has antiandrogenic (androgen receptor antagonist), antigonadotropic, and progestational properties. GnRH agonists are synthetic analogues of the amino acid sequence of the endogenous decapeptide. Somewhat paradoxically, when given chronically, these agents suppress pulsatile LH and FSH release, steroid production by the gonads, and gametogenesis in both males and females.

Absence of Fertilization

If fertilization does not occur, the corpus luteum involutes or degenerates because of diminished LH supply, and progesterone and estrogen levels fall sharply. The hormonal stimuli for a thickened and vascularized uterine endometrial wall are thus lost and menstruation occurs as a consequence of cellular necrosis. The fall in blood steroid levels releases the feedback inhibition on the gonadotropes and hypothalamus and the cycle starts again. The time course for the ovarian menstrual cycle in humans is shown in Figure 22.19 (p. 904).The first monthly cycle occurs at the time of puberty when GnRH secretion begins to increase (day 1 of Figure 22.19). GnRH is released in a pulsatile fashion, causing the gonadotrope to release FSH and LH, and the blood concentrations of these hormones gradually increase in

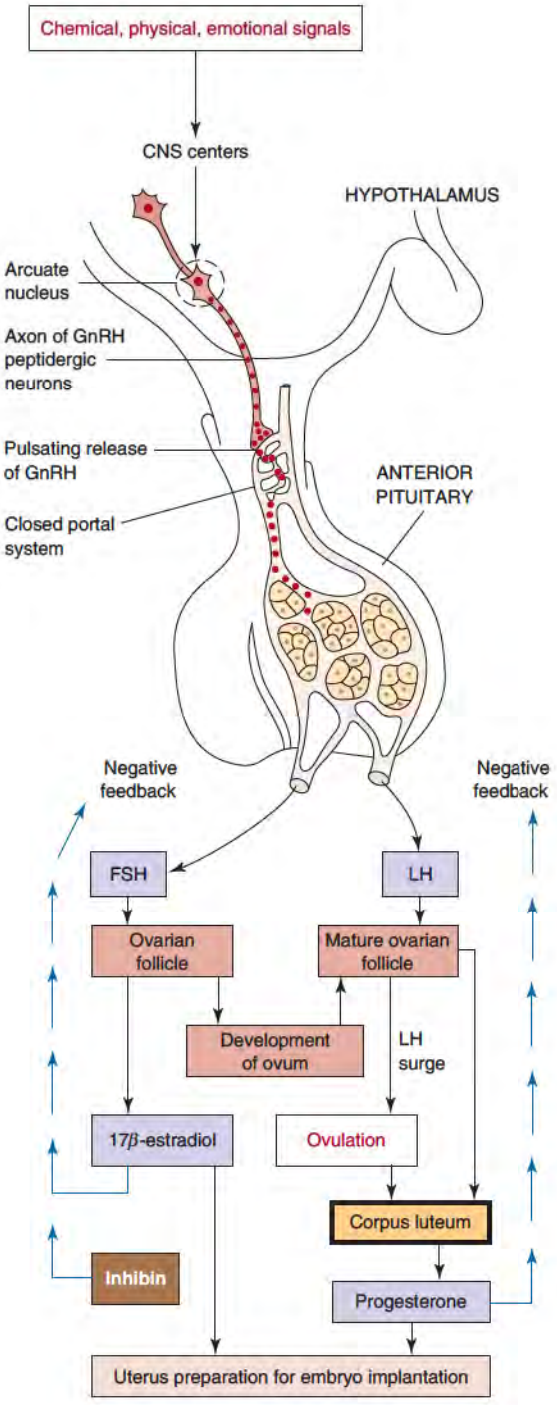

Figure 22.18 Ovarian cycle in terms of generation of hypothalamic releasing hormone, pituitary gonadotropic hormones, and sex hormones. At puberty, several centers in CNS coordinate with hypothalamus so that GnRH is released in a pulsatile fashion. This causes release of LH and FSH, which affects the ovarian follicle, ovulation, and corpus luteum. Inhibin B selectively inhibits FSH secretion. Products of the follicle and corpus luteum, respectively, are β-estradiol and progesterone; GnRH, gonadotropin-releasing hormone; FSH, follicle-stimulating hormone; and LH, luteinizing hormone.

subsequent days. Under the stimulation of FSH, the follicle begins to mature (lower section of Figure 22.19) and 17β-estradiol (E_2) is produced, causing the uterine endometrium to thicken. Under the continued action of FSH, the follicle matures, and high concentrations of estradiol are produced (around day 13 of the cycle). This elevated level of estradiol now mediates **positive feedback** (rather than negative feedback mediated by lower estradiol levels) resulting in a surge of LH and a decreased release of FSH from the gonadotropes. The FSH response is smaller because this gonadotropic hormone stimulates the ovarian production of **inhibin B** that inhibits FSH, but not LH, secretion. The high midcycle peak of LH is referred to as the *LH spike*. Ovulation then occurs at about day 14 (midcycle) through the effects of high LH concentration and other factors, such as prostaglandin F_{2a} (PGF_{2a}). After ovulation, LH promotes differentiation at the ruptured follicle (Figure 22.19, bottom) into a corpus luteum that produces high levels of progesterone that further thicken the uterine

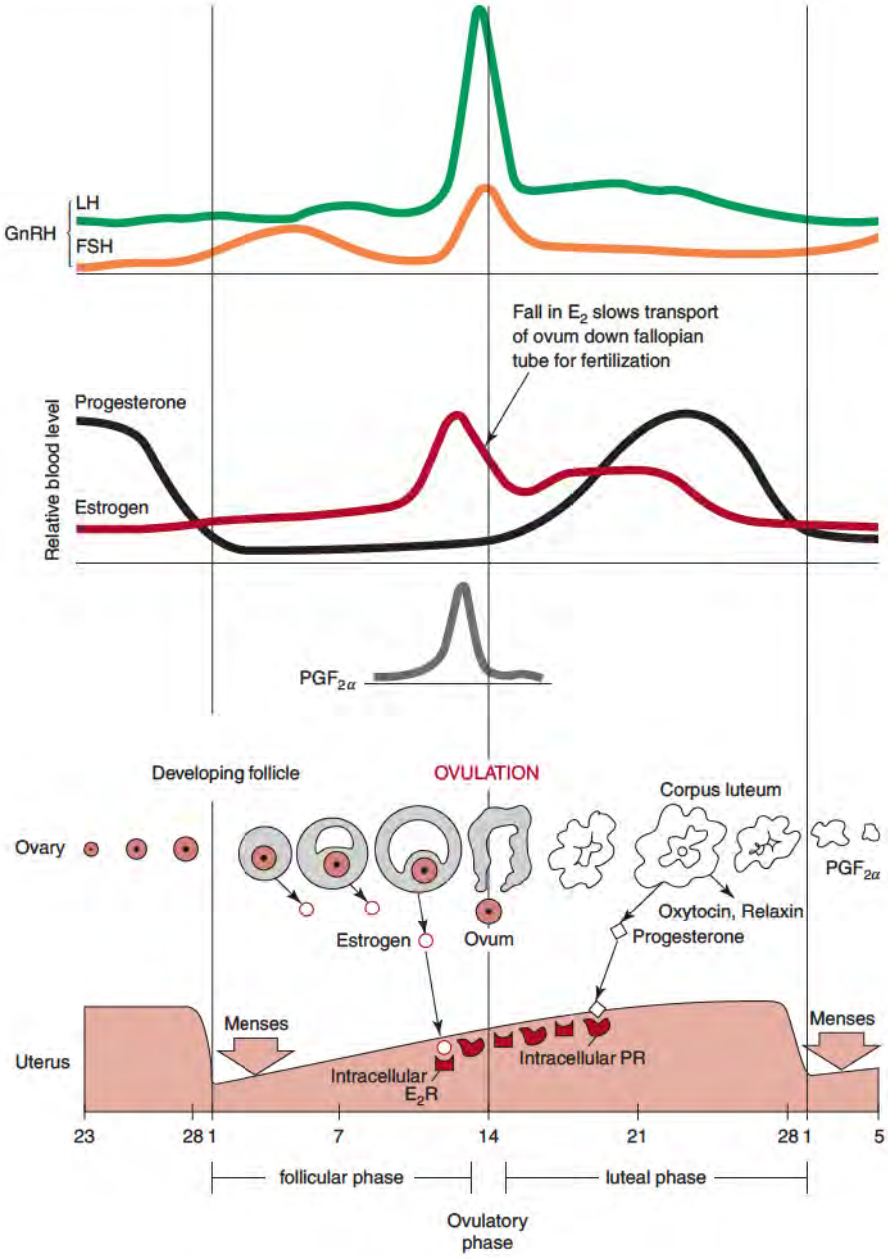

Figure 22.19 Ovarian cycle. In the upper diagram, relative blood levels of GnRH, LH, FSH, progesterone, estrogen, and $PGF_{2\alpha}$ are shown. In the lower diagram, events in ovarian follicle, corpus luteum, and uterine endometrium are diagrammed. Abbreviations: GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; $PGF_{2\alpha}$, prostaglandin $F2_{2\alpha1}$; E_2, estradiol; E_2R, intracellular estrogen receptor; and PR, intracellular progesterone receptor.

endometrial wall. The corpus luteum also secretes **inhibin A**, which along with estradiol and progesterone, suppresses FSH and LH secretion by the anterior pituitary during the luteal phase of the cycle. In the absence of fertilization, the corpus luteum remains functional for about 2 weeks. It then involutes or regresses due to the decline in LH levels and an age-related reduction in LH sensitivity. With the death of the corpus luteum, there is a profound decline in estradiol and progesterone levels. The endometrial wall can no longer be maintained and menstruation occurs, followed by the start of another menstrual cycle.

Fertilization

If fertilization occurs as shown in Figure 22.20, the corpus luteum remains viable because of production of **chorionic gonadotropin** (CG), which resembles and acts like LH, from the trophoblast cells. The secretion of CG reaches a peak about 80 days after the last menstrual period. It then declines very rapidly and is produced by the placenta at a relatively low level for the remainder of pregnancy. Once CG levels fall, the corpus luteum begins to involute, and by about 12 weeks of pregnancy, the placenta takes over production and secretion of progesterone and estrogens (primarily estriol). From the seventh month onward estrogen

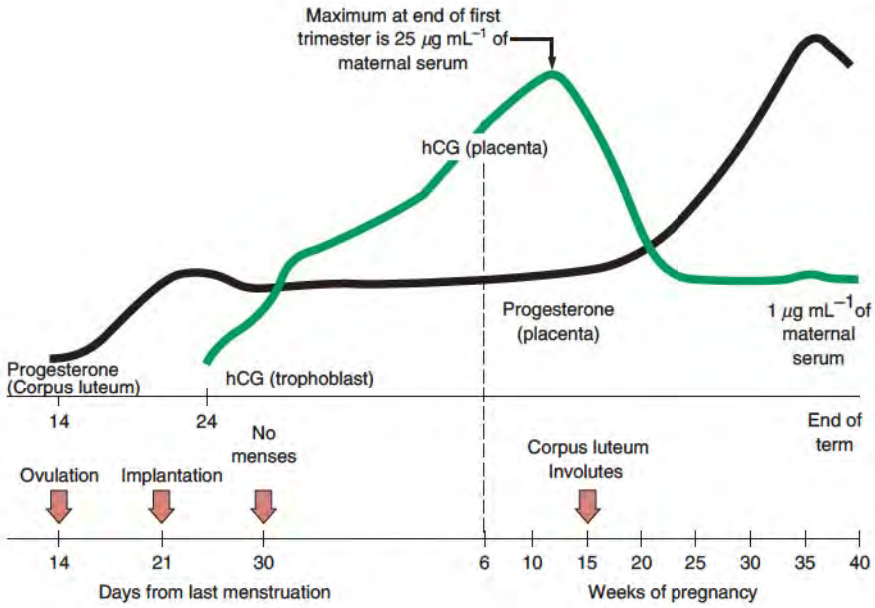

Figure 22.20 Effect of fertilization on ovarian cycle in terms of secretion of progesterone and human chorionic gonadotropin (hCG).

secretion continues to increase while progesterone secretion remains constant or may even decrease slightly. The estrogen/progesterone ratio increases toward the end of pregnancy and may be partly responsible for increased uterine contractions. Oxytocin from the posterior pituitary contributes to these uterine contractions. The fetal membranes release prostaglandins ($PGF_{2\alpha}$) at the time of parturition, which increases the intensity of uterine contractions. Finally, the fetal adrenal cortex secretes cortisol, which stimulates fetal lung maturation by inducing the synthesis of surfactant-associated proteins.

22.5 • MEMBRANE HORMONE RECEPTORS

Some Hormone-Receptor Interactions Involve Multiple Hormone Subunits

Thyrotropin (TSH), **luteinizing hormone (LH)**, and **follicle-stimulating hormone (FSH)** each contain an α- and a β-subunit. The α-subunits for all three hormones are similar or identical. The specificity of receptor recognition is imparted by the β-subunit, whose structure is unique for each hormone. A model of the interaction of LH with its receptor is shown in Figure 22.21. The LH receptor recognizes both subunits of the hormone, but the β-subunit is specifically recognized by the receptor to elicit a hormonal response. The TSH–receptor complex stimulates adenylate cyclase and the phosphatidylinositol pathway. The preferred model is one in which there is a single receptor whose interaction with hormone activates both the adenylate cyclase and the phospholipid second messenger systems, as shown in Figure 22.22 (p. 906).

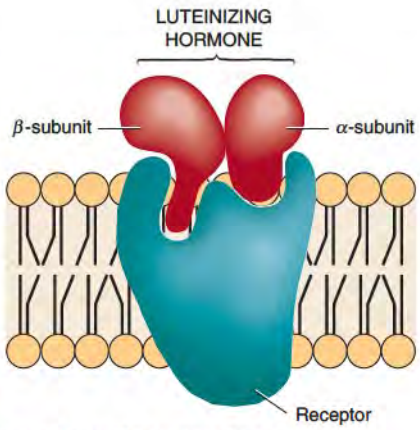

Figure 22.21 The interaction of α- and β-subunits of LH with LH receptor of rat Leydig cells. Both α- and β-subunits participate in LH receptor binding.

β-Adrenergic Receptor

Structures of receptors are conveniently discussed in terms of functional domains. For membrane receptors there are **ligand-binding domains**, **transmembrane domains**. and **intracellular domains**; this last domain may have intrinsic protein kinase activity. Specific **immunological domains** contain primary epitopes of antigenic regions. The β-adrenergic receptors (β_1 and β_2) recognize the catecholamines norepinephrine and epinephrine, and hormone binding stimulates adenylate cyclase. The subtypes differ in their affinity for norepinephrine and for synthetic antagonists. β_1 receptors bind norepinephrine with a higher affinity than epinephrine, whereas the reverse is the case for the β_2 receptors. Isoproterenol, an analog of epinephrine that is a β-receptor stimulator, has a greater affinity for both

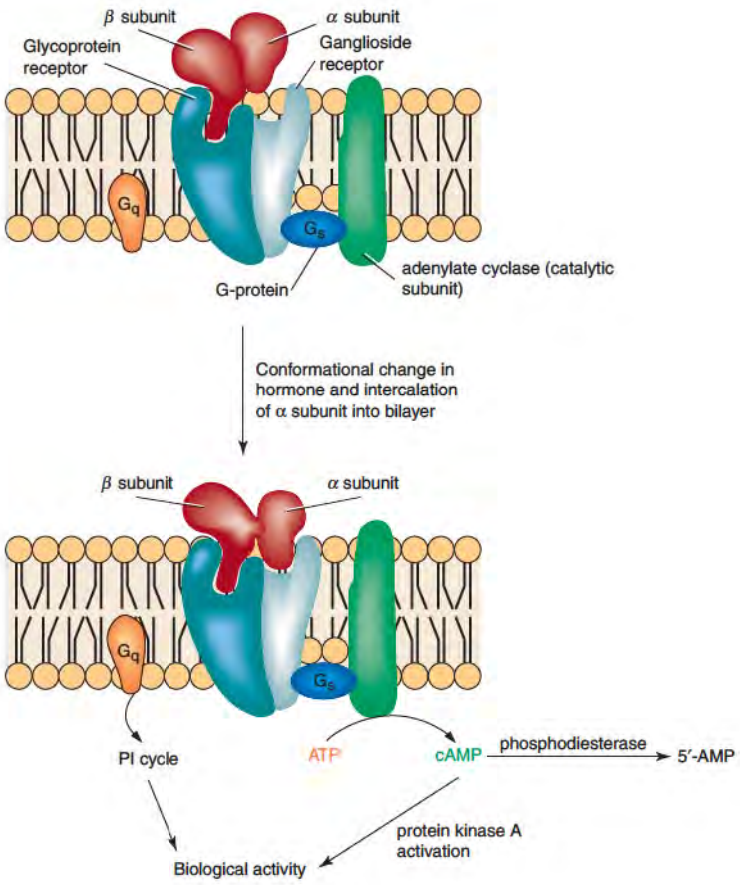

Figure 22.22 Model of TSH receptor. Receptor is composed of glycoprotein and ganglioside component. After TSH β-subunit interacts with receptor, hormone changes its conformation and α-subunit interacts with other membrane components. β-subunit of TSH may carry primary determinants recognized by glycoprotein receptor component. It is suggested that the TSH signal to adenylate cyclase is via the ganglioside; the glycoprotein component appears more directly linked to phospholipid signal system. PI, phosphatidylinositol; G_s, G protein linked to activation of adenylate cyclase; G_q, G protein linked to PI cycle.

receptors than either norepinephrine or epinephrine. Figure 22.23 shows the amino acid sequence for the β_2-adrenergic receptor (see p. 79 for single-letter abbreviations of amino acids). The N-terminal segment extends from α-helix I into the extracellular space, and there are seven membrane-spanning domains. The β_1 receptor shows extensive homology with the β_2 receptor. Intracellular loops join helices I and II, III and IV, and V and VI. The long chain extended from VII is the intracellular C-terminal region and contains phosphorylation sites (serine and threonine residues), which are important for receptor desensitization. Phosphorylation results in binding of an inhibitory protein, called **β arrestin**, which blocks the receptor's ability to activate G (p. 522). Extracellular loops join helices II and III, IV and V, and VI and VII, but mutational analysis suggests that these loops do not participate in ligand binding. Ligand binding may occur in a pocket formed by the clustering of these membrane-spanning α-helices, as shown from a top view in Figure 22.24, p. 908. Transmembrane domain VI may function in stimulation of adenylate cyclase. Substitution of a specific cysteine residue in this domain produces a mutant with normal ligand-binding properties but decreased ability to stimulate adenylate cyclase.

Internalization of Receptors

Many types of cell membrane hormone–receptor complexes are internalized by **endocytosis** (Figure 22.25, p. 908). For endocytosis to occur, the polypeptide–receptor complex enters **coated pits**, which are indentations of the plasma membrane into the cytoplasm. These coated pits pinch off from the membrane to form **coated vesicles**, which shed their coats, fuse with each other, and form vesicles called **receptosomes**. The receptors and ligands on the inside of these receptosomes have different fates. Receptors may be recycled to the cell surface following fusion with the Golgi apparatus. Alternatively, the coated vesicles fuse with lysosomes, which contain proteolytic enzymes that degrade both receptor and hormone. Some hormone–receptor complexes dissociate in the lysosome and only the hormone is degraded; the receptor is then returned intact to the plasma membrane. The

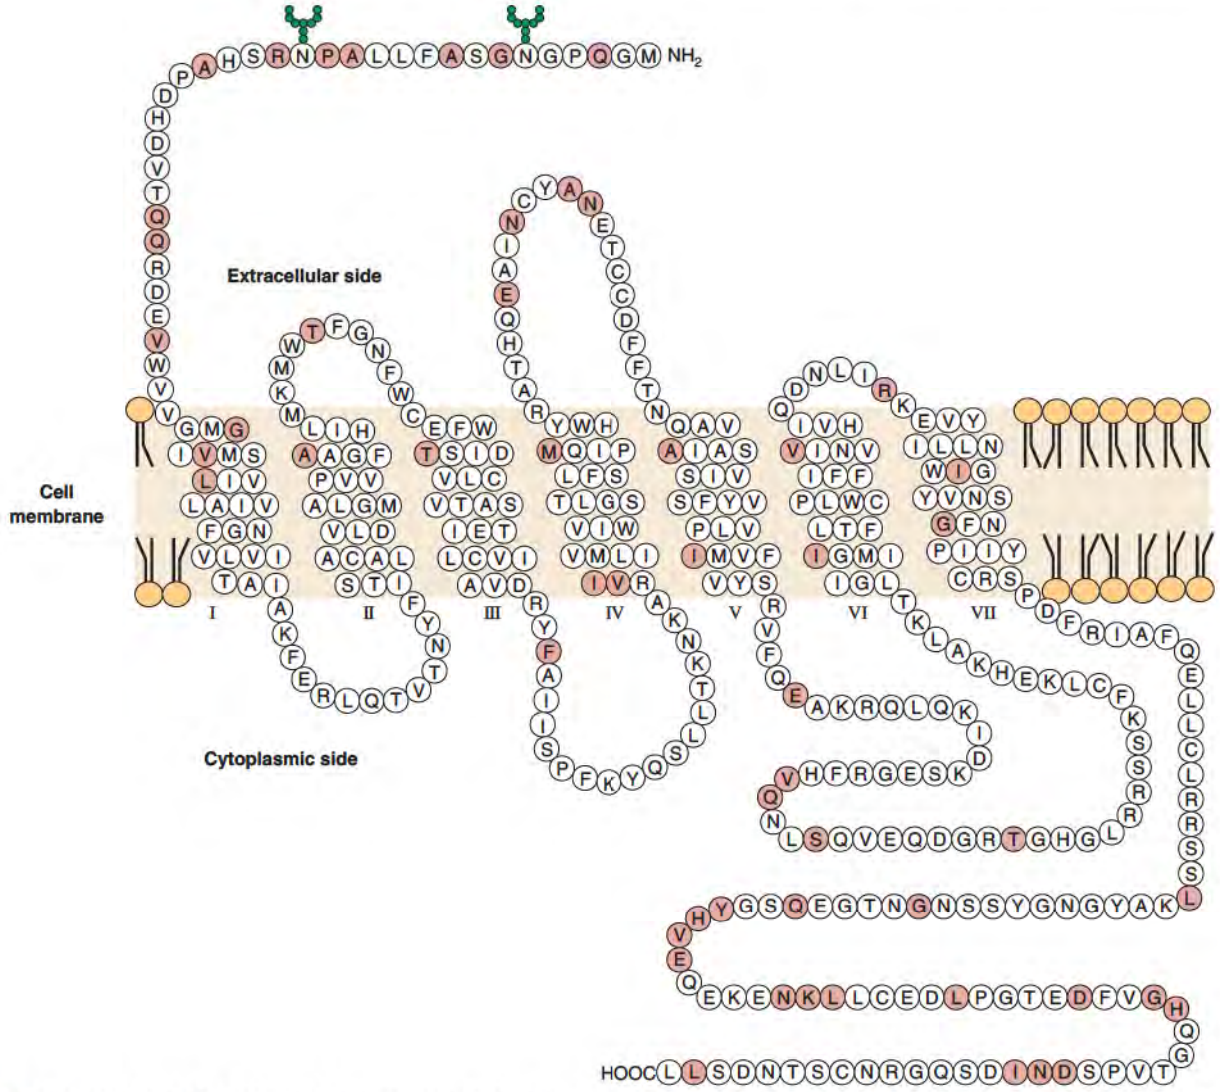

Figure 22.23 Proposed model for insertion of β_2-adrenergic receptor (AR) in cell membrane. The model is based on hydropathicity analysis of human β_2-AR. Standard one-letter codes for amino acid residues are used. Hydrophobic domains are represented as transmembrane helices. Pink circles with black letters indicate residues in the human sequence that differ from those in hamster. Also noted are the potential sites of N-linked glycosylation. Redrawn from Kobilka, B. K., Dixon, R. A., Frielle, T., Doblman, H.G., et al. *Proc. Natl. Acad. Sci. USA* 84:46, 1987.

receptor may also be concentrated in coated pits in the absence of exogenous ligand and cycle in and out of the cell in a constitutive, non-ligand-dependent manner.

Clathrin Directs Internalization of Hormone–Receptor Complexes from Plasma Membrane

The major protein component of a coated vesicle is **clathrin**, a nonglycosylated protein (180 kDa) whose amino acid sequence is highly conserved. The coated vesicle contains 70% clathrin, 5% polypeptides of about 35 kDa, and 25% polypeptides of 50–100 kDa. Coated vesicles have a lattice-like surface structure composed of hexagons and pentagons (Figure 22.26). Three clathrin molecules on the cytoplasmic side of the plasma membrane generate each polyhedral vertex and two clathrin molecules contribute to each edge. A 200-nm-diameter coated vesicle contains about 1000 clathrin molecules, which form flexible lattice structures or cages that act as scaffolds for vesicular budding. Completion of the budding process results in entry of the mature clathrin-coated vesicle into the cell by endocytosis.

Endocytosis introduces an intact receptor or ligand to the cell interior in cases where the nucleus may contain a receptor-binding site or a ligand-binding site. For example, growth factors bind to a cell membrane receptor but trigger events that lead to mitosis. Signal transmission may occur by an effect on a specific cytoplasmic protein (transcription factor), which translocates into the nucleus. Internalization of an intact ligand could allow

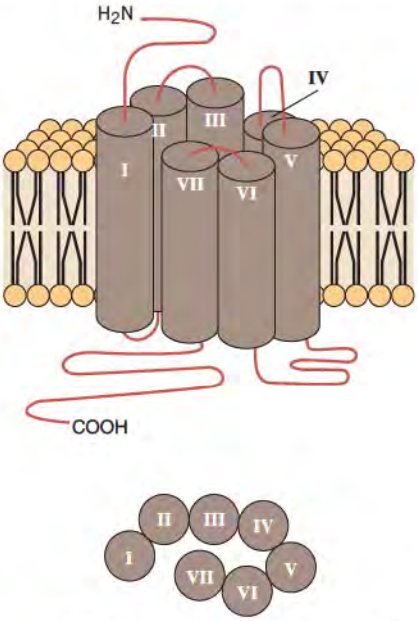

Figure 22.24 Proposed arrangement of the β-adrenergic receptor in membrane. Lower portion of figure is a view from above the plane of the plasma membrane. It is proposed that helices IV, VI, and VII form a ligand-binding pocket, with helix VII most centrally located.

it to interact with a nuclear receptor. Although such mechanisms are speculative, they constitute a rationale for the participation of endocytosis in signal transmission. Endocytosis renders a cell less responsive to hormone, since it reduces the number of cell surface receptors. Internalization of receptors by endocytosis thus leads to receptor **down-regulation** and a decrease in hormone sensitivity.

22.6 • INTRACELLULAR HORMONE CASCADES: PROTEIN KINASES

Many hormones that bind to cell membrane receptors transmit their signals through second messengers that activate specific protein kinases; cAMP activates protein kinase A, DAG activates protein kinase C, and cGMP activates protein kinase G (p. 522). Other less prevalent systems involve hydrolysis of membrane phosphatidylcholine or sphingomyelin. Some hormones such as TSH use more than one intracellular second messenger system to transmit their signal.

Specific proteins are phosphorylated by protein kinase A and others are phosphorylated by protein kinase C. Both PKA and PKC phosphorylate on **serine** or **threonine** residues. Protein kinases that phosphorylate **tyrosine** residues are found in the cytoplasmic domains of some membrane receptors, especially growth factor receptors. The insulin and IGF-1 receptors possess tyrosine kinase domains and activities. The location of these domains of some receptor tyrosine kinases with respect to the plasma membrane is presented in Figure 22.27. The protein kinase domains are similar in amino acid sequence, suggesting that they have all evolved from a common primordial gene. Several **tyrosine specific kinases** that function as transmembrane receptors are shown in Figure 22.27. The α (extracellular) and β (transmembrane) polypeptides of the insulin receptor are encoded by a single gene,

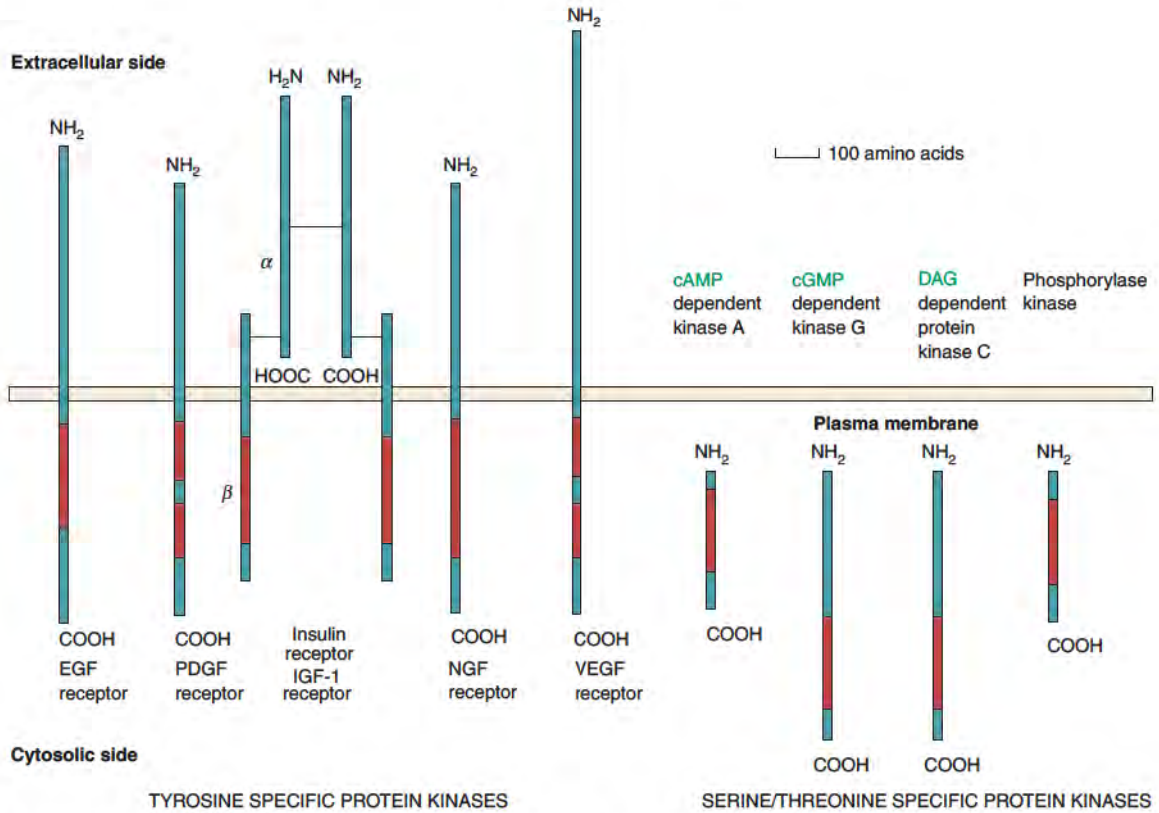

Figure 22.27 Protein kinases of plasma membrane or cytosol showing size and location of catalytic domains. In each case, the catalytic domain (red region) is about 250 amino acid residues long. Abbreviations: EGF, epidermal growth factor; PDGF, platelet derived growth factor; NGF, nerve growth factor; and VEGF, vascular endothelial growth factor.

which produces a precursor protein that is cleaved into the α and β disulfide-linked chains. In general, proteins regulated by phosphorylation-dephosphorylation usually have multiple phosphorylation sites and may be phosphorylated by more than one type of protein kinase.

Insulin Receptor: Transduction through Tyrosine Kinase

The α subunits of the **insulin receptor** are located extracellularly and are the insulin-binding sites (Figure 22.27). Ligand binding induces **autophosphorylation** of tyrosine residues located in the cytoplasmic portions of β-subunits. This autophosphorylation facilitates binding of cytoplasmic substrate proteins, such as **insulin receptor substrate-1 (IRS-1)**. IRS-1 when phosphorylated acts as a docking protein for proteins that mediate insulin action. It is not clear whether protein phosphorylation is the only mechanism for all actions of insulin. The net responses to this hormone include short-term metabolic effects, such as a rapid increase in the uptake of glucose, and longer-term effects on cellular differentiation and growth. Although the insulin receptor becomes auto-phosphorylated on tyrosines and phosphorylates tyrosines of IRS-1, other mediators are phosphorylated predominantly on serine and threonine residues, as indicated in Figure 22.28. Insulin stimulates phosphorylation of some proteins and dephosphorylation of others. Activation or inhibition of specific enzymes suggests that separate signal transduction pathways may originate from the insulin receptor. An insulin second messenger may be released at the cell membrane to account for the short-term metabolic effects of insulin. This may be a glycoinositol derivative that stimulates phosphoprotein phosphatase. A detailed diagram of the signal transduction pathways for insulin is presented Figure 22.29. Many proteins that are activated or inactivated subsequent to insulin binding have now been identified. This diagram shows that binding of insulin to the α-subunit of the receptor promotes autophosphorylation of a β-subunit on several tyrosine residues. The activated β-subunit then catalyzes the phosphorylation of cellular proteins such as members of the IRS family, including Shc and Cbl (members of IRS family) (Figure 22.29). On tyrosine phosphorylation, these proteins interact with other signaling molecules through their SH2 (Src-homolog-2) domains, which bind to a distinct amino acid sequence neighboring a phosphotyrosine residue. Several pathways that are

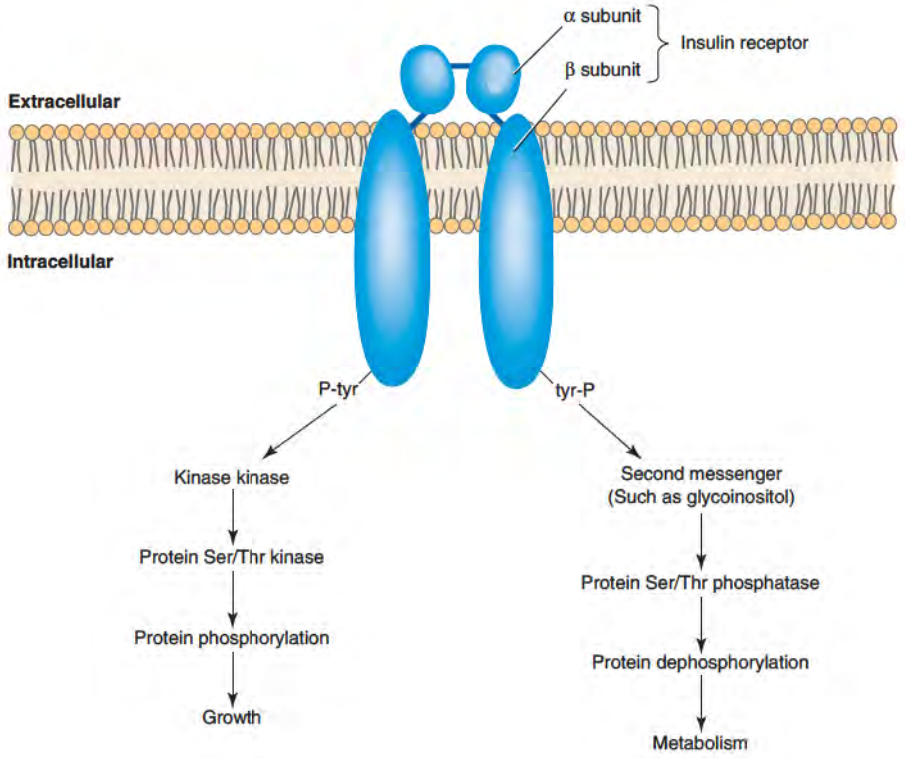

Figure 22.28 Hypothetical model depicting two pathways to explain paradoxical effects of insulin on protein phosphorylation. Insulin simultaneously produces increases in the serine/threonine phosphorylation of some proteins and decreases in others. This paradoxical effect may result from the activation of both kinases and phosphatases. Model explains (1) the generation of a soluble second messenger that directly or indirectly activates serine/threonine phosphatase, and (2) the stimulation of a cascade of protein kinases, resulting in the phosphorylation of cellular proteins.

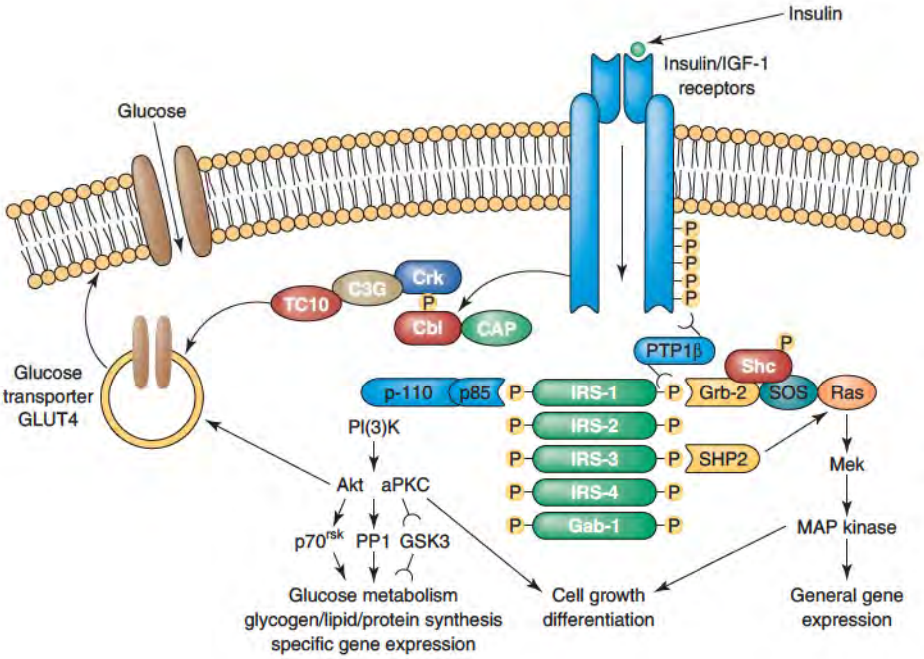

Figure 22.29 Hypothetical scheme for signal transduction in insulin action. The insulin receptor undergoes tyrosine autophosphorylation and kinase activation on hormone binding. It phosphorylates intracellular substrates including IRS-1, Shc, and Cbl, which associate with SH2-containing proteins like p85 and Grb2. Formation of the IRS-1/p85 complex activates PI (3-) kinase; the IRS-1/Grb2 complex activates MAP kinase. Abbreviations: IRS-1, insulin receptor substrate-1; SH, src homology; MAP kinase, mitogen-activated protein kinase; MeK, MAP kinase kinase; GPI, glycosyl-phosphatidylinositol; PLC, phospholipase; and SOS, son of sevenless. activated include PI_3 kinase (phosphatidylinositol 3′-kinase), Ras (small GTP binding protein), the MAP kinase (mitogen-activated protein kinase), and TC10 (small GTP binding protein). Once activated via an exchange of GTP for GDP, TC10 promotes translocation of the glucose transporter GLUT4 vesicles to the plasma membrane, perhaps by stabilizing microfilaments. These pathways act in a concerted fashion to coordinate the regulation of vesicle trafficking (incorporation of GLUT4 into plasma membrane), protein synthesis, enzyme activation and inactivation, and gene expression. The net result of these pathways is regulation of glucose, lipid, and protein metabolism as well as cell growth and differentiation. The importance of the activity of the insulin receptor kinase in the overall signal transduction pathway of insulin is emphasized in Clin. Corr. 22.3.

CLINICAL CORRELATION 22.3

Decreased Insulin Receptor Kinase Activity in Gestational Diabetes Mellitus

During pregnancy, an important maternal metabolic adaptation is a decrease in insulin sensitivity. This adaptation helps provide adequate glucose for the developing fetus. However, in some pregnant women glucose intolerance develops. Gestational diabetes mellitus (GDM) is a serious pregnancy associated disorder affecting up to 14% of all pregnant women. This disease is characterized by an additional decrease in insulin sensitivity and an inability to compensate with increased insulin secretion. Although both pregnancy-induced insulin resistance and GDM are generally reversible after pregnancy, approximately 30%–50% of women with a history of GDM go on to develop type 2 diabetes later in life, particularly if they are obese. Although the cellular mechanisms responsible for the insulin resistance in GDM are not fully understood, the resistance to insulin-mediated glucose transport appears to be greater in skeletal muscle from GDM subjects than in women who are pregnant but do not have GDM. Recent data indicate that defects in insulin action, rather than a decrease in insulin receptor binding affinity, may contribute to the pathogenesis of GDM. More specifically, skeletal muscle cells of GDM subjects appear to over-express plasma cell membrane glycoprotein-1 (PC-1), which has been reported to inhibit the tyrosine kinase activity of the insulin receptor by directly interacting with the α-subunits and blocking the insulin-induced conformational change. Additionally, excessive phosphorylation of serine/threonine residues located within muscle insulin receptors appears to down-regulate tyrosine kinase activity in GDM. There also appears to be a decreased expression and phosphorylation (tyrosine residues) of the insulin receptor substrate-1 (IRS-1; see Figure. 22.39, p. 920) in skeletal muscle cells from GDM subjects. These postreceptor defects in insulin signaling may thus contribute to the pathogenesis of GDM and the increased risk for type 2 diabetes later in life.

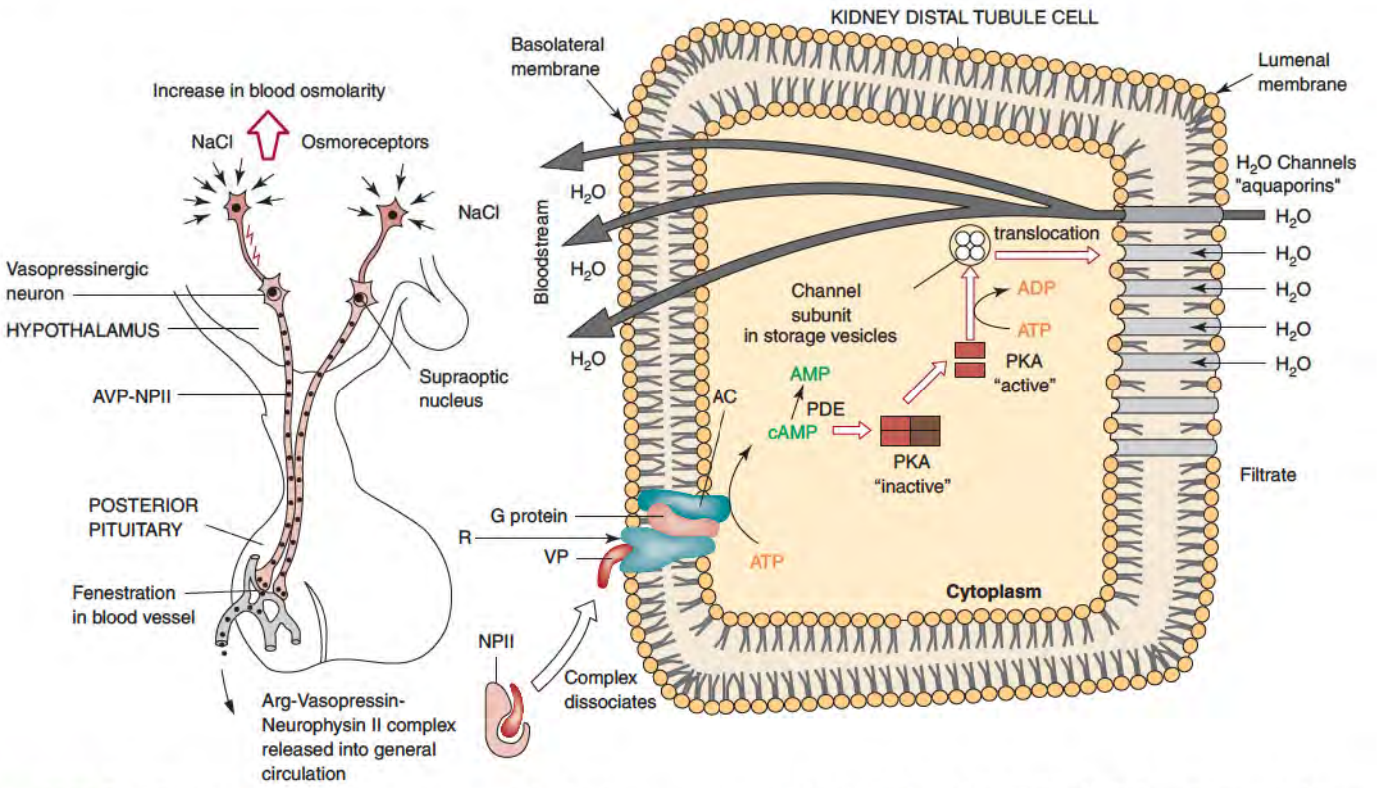

Figure 22.30 Secretion and action of arginine vasopressin in distal kidney tubules. Release of arginine vasopressin (AVP or VP) from the posterior pituitary is triggered by osmoreceptors or baroreceptors (not shown). This signal is transmitted down a vasopressinergic neuron and promotes the release of a VP–neurophysin complex from the posterior pituitary gland, where the hormone is normally stored. The neurophysin bound to the VP eventually dissociates, and the posterior pituitary hormone binds to cognate membrane receptors on the kidney distal tubule cell. Through this G protein-coupled receptor, adenylate cyclase is stimulated to increase levels of cAMP from ATP. Cyclic-AMP-dependent protein kinase A is then activated and it phosphorylates various proteins including subunits of the aquaporin channels. The phosphorylated subunits aggregate and functional water channels (aquaporins) are inserted in the lumenal plasma membrane, thus increasing the reabsorption of water. Abbreviations: NPII, neurophysin II; VP, vasopressin; R, receptor; AC, adenylate cyclase; and PDE, phosphodiesterase.
Redrawn in part from Dousa, T. P., and Valtin, H. Cellular actions of vasopressin in the mammalian kidney. *Kidney Int.* 10:45, 1975.

Activity of Vasopressin: Protein Kinase A

Arginine vasopressin (AVP), the antidiuretic hormone, causes increased water reabsorption from the urine in the distal kidney. A mechanism of action of this system is shown in Figure 22.30. Neurons that synthesize and secrete AVP (vasopressinergic neurons) release this hormone in response to stimuli from **baroreceptors** that respond to a fall in blood pressure or from **osmoreceptors** that respond to an increase in extracellular salt concentration. VP binds to its cognate membrane receptors in the distal kidney, anterior pituitary, hepatocytes, and perhaps other cell types. In the kidney, AVP binding to its G protein-coupled receptor stimulates adenylate cyclase activity and activates protein kinase A, which phosphorylates subunits that aggregate to form specific water channels, or aquaporins (p. 479). Water crosses the kidney cell to the basolateral side and then enters the general circulation, where it dilutes the salt concentration. Specific mutations in the intracellular and extracellular loop sequences of the aquaporin channels result in loss of function and in development of nephrogenic diabetes insipidus, which is characterized by increased thirst and production of a large volume of urine. Other examples of hormones that activate protein kinase A are listed in Table 22.6.

Gonadotropin-Releasing Hormone (GnRH): Protein Kinase C

Table 22.7 lists polypeptide hormones that stimulate the phosphatidylinositol pathway and activate **protein kinase C** (p. 535). Although AVP activates protein kinase A in

TABLE 22.6 • Examples of Hormones that Operate through the Protein Kinase A Pathway

Hormone	*Location of Action*
CRH	Corticotrope of anterior pituitary
TSH	Thyroid follicle
LH	Leydig cell of testis Mature follicle at ovulation and corpus luteum
FSH	Sertoli cell of seminiferous tubule and ovarian follicle
ACTH	Inner layer of cells of adrenal cortex
Opioid peptides	Some in CNS function on inhibitory pathway through G_i
AVP	Kidney distal tubular cell
PGI_2 (prostacyclin)	Blood platelet membrane
Norepinephrine/ epinephrine	β-Receptor: expressed in various tissues and cell types

TABLE 22.7 • Examples of Polypeptide Hormones that Stimulate the Phosphatidylinositol Pathway and Activate Protein Kinase C

Hormone	*Location of Action*
TRH	Thyrotrope of the anterior pituitary releasing TSH
GnRH	Gonadotrope of the anterior pituitary releasing LH and FSH
AVP	Corticotrope of the anterior pituitary; assists CRH in releasing ACTH: hepatocyte; causes increase in intracellular Ca^{2+}
TSH	Thyroid follicle: releasing thyroid hormones; causes increase in phosphatidylinositol cycle as well as increase in protein kinase A activity
Angiotensin II/III	Zona glomerulosa cell of adrenal cortex: releases aldosterone
Epinephrine	Smooth muscle cells that express α_1-receptors

renal cells, this hormone activates protein kinase C in other target cells. **GnRH** mediates its effects through activation of protein kinase C and the action of this hypothalamic releasing hormone is summarized in Figure 22.31. An aminergic nerve fiber most likely stimulates the appropriate neurons to secrete GnRH, which then enters the closed portal system, which connects the hypothalamus and anterior pituitary through fenestrations. GnRH binds to cognate membrane receptors in the gonadotrope (enlarged view in Figure 22.31) and activates phospholipase C. Hydrolysis of PIP_2 forms diacylglycerol (DAG) and IP_3, and DAG activates protein kinase C, which phosphorylates specific proteins. IP_3 binds to a receptor on the membrane of the endoplasmic reticulum and releases Ca^{2+} stored therein. The released Ca^{2+} also activates protein kinase C, which ultimately results in the secretion of LH and FSH from the same cell. There are at least 11 isoforms of protein kinase C, nine being activated by DAG. The isoforms of protein kinase C normally exist as monomeric proteins in the cytoplasm. The free enzyme is folded in such a way that the binding site for substrate proteins is blocked. When DAG binds to the enzyme it translocates it to the inner surface of the plasma membrane, where it can also bind to acidic phospholipids. The increased Ca^{2+} concentration also increases the binding of the enzyme to the membrane. When protein kinase C is bound, the protein unfolds and exposes binding sites for protein substrates. This results in phosphorylation of the bound proteins that then mediate a variety of intracellular effects.

Activity of Atrial Natriuretic Factor (ANF): Protein Kinase G

The receptor for atrial natriuretic factor (ANF) is a transmembrane protein whose cytoplasmic C-terminal domain has guanylate cyclase activity and whose extracellular

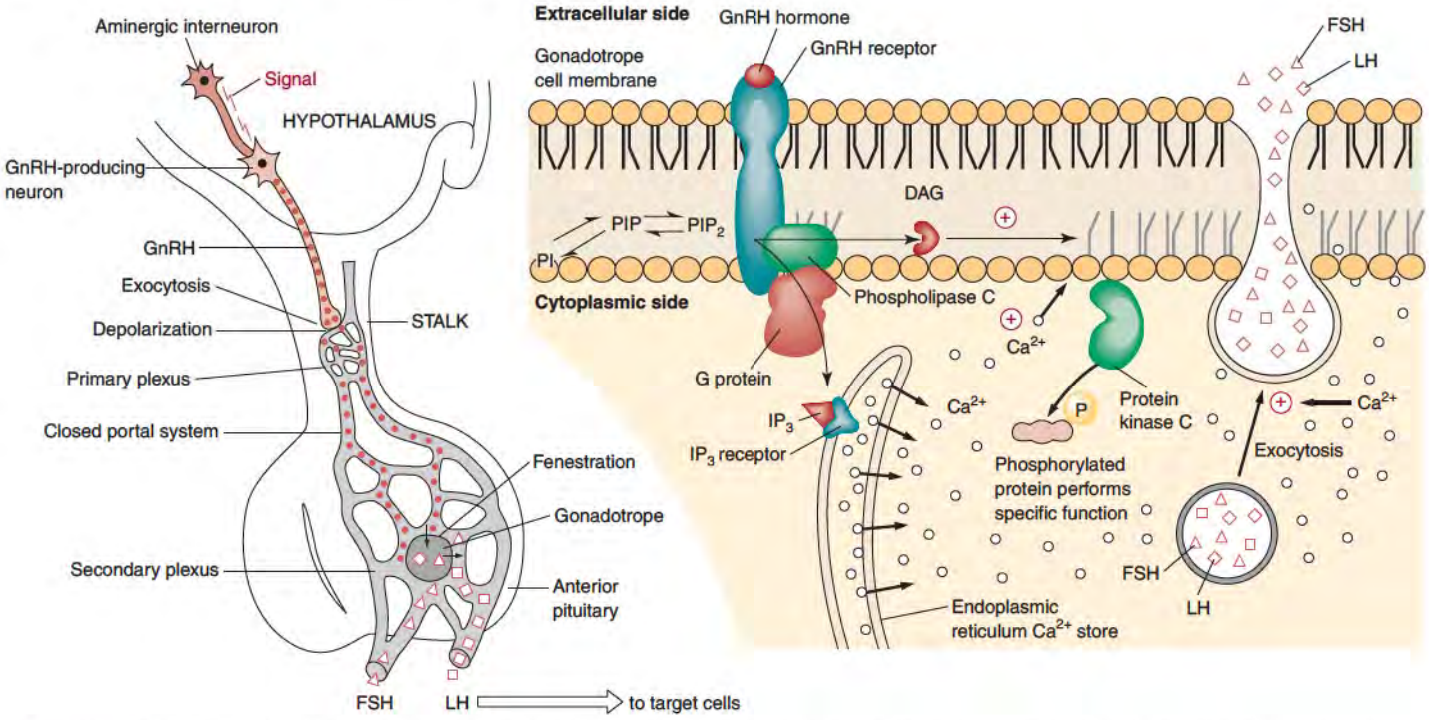

Figure 22.31 Regulation of secretion of LH and FSH by protein kinase C. A general mode of action of GnRH to release the gonadotropins from the gonadotropes of the anterior pituitary is presented. N-terminal domain binds ANF (Figure 22.32). A model for signal transduction by ANF is presented in Figure 22.33. ANF is a member of a family of peptides (Figure 22.34). This hormone is secreted by cardiac myocytes in response to signals such as blood volume expansion, high salt intake, increased right atrial pressure, and increased heart rate. Its secretion is stimulated by activators of cardiac protein kinase C and decreased by activators of protein kinase A. These opposing actions may be mediated by α- and β-adrenergic receptors, respectively. An overview of the secretion of ANF and its general effects is shown in Figure 22.35, p. 916. ANF is secreted as a dimer but only the monomeric form binds the receptor. ANF increases the glomerular filtration rate, leading to increased urine volume and excretion of sodium ion. Renin and aldosterone secretion are reduced, and the vasoconstriction produced by angiotensin II is inhibited, causing relaxation of the renal vessels and of other vascular beds and large arteries. ANF mediates these effects via its membrane receptor, whose intracellular domain has guanylate cyclase activity (see Figure 22.33, p. 915). The cGMP that is produced activates protein kinase G, which then phosphorylates cellular proteins involved in this pathway. Many analogs of ANF bind to receptors in the kidney but fail to elicit a physiological response. This suggests that these receptors may serve as specific peripheral storage-clearance binding sites for ANF and modulate its plasma levels.

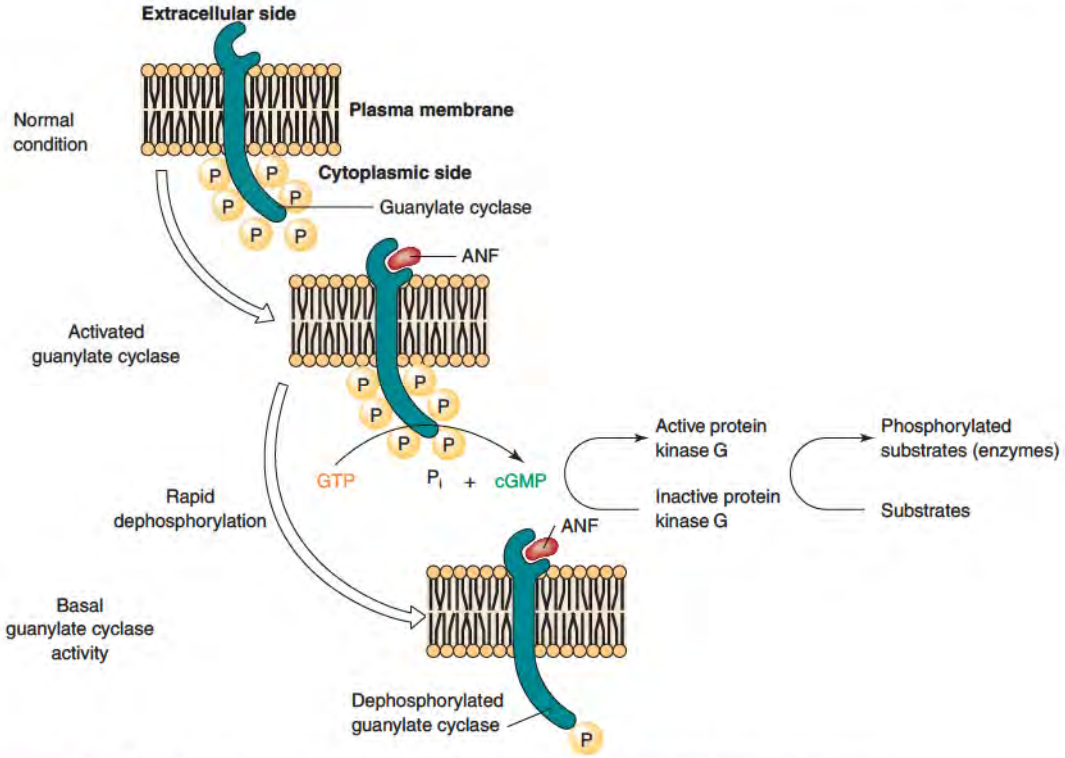

Figure 22.33 Model for signal transduction by ANF receptor. The guanylate cyclase domain is in a highly phosphorylated state under normal conditions. Binding of hormone markedly enhances enzyme activity and dephosphorylation of the guanylate cyclase domain.

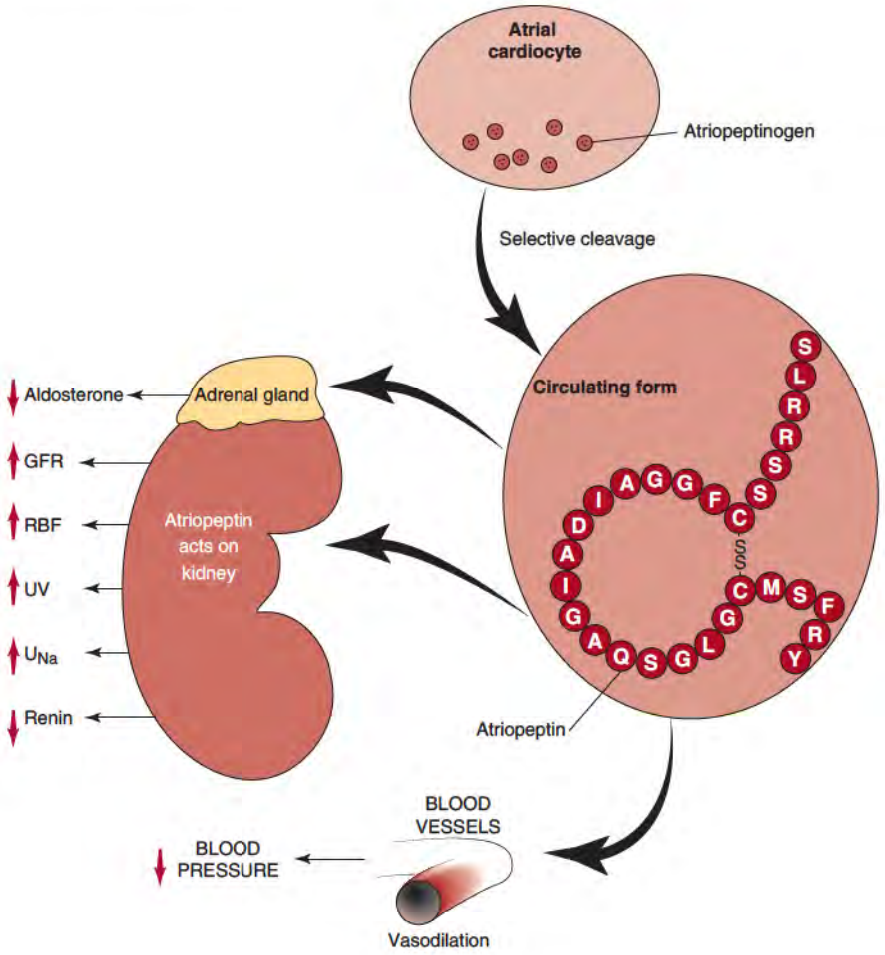

Figure 22.35 Schematic diagram of atrial natriuretic factor–atriopeptin hormonal system. Prohormone is stored in perinuclear granules in atrial cardiocytes. An elevated vascular volume results in cleavage of atriopeptinogen and release of atriopeptin, which increases the glomerular filtration rate (GFR), renal blood flow (RBF), urine volume (UV), and sodium excretion (U_{Na}), and decreases plasma renin activity and the secretion of aldosterone and arginine vasopressin. Vasodilation lowers blood pressure (BP). In contrast, diminution of vascular volume suppresses circulating levels of atriopeptin.

22.7 • STEROID HORMONES

Structures and Functions of Steroid Hormones

Steroid hormones are divided into the **sex** and **progestational hormones**, and the **adrenocortical hormones**. They are synthesized in the gonads (ovaries and testes) and adrenal cortex from cholesterol (p. 719) through Δ^5-pregnenolone as an intermediate. Their structure is based on the **cyclopentanoperhydrophenanthrene** nucleus; the numbering of this ring system and the lettering of the rings is presented in Figure 22.36. Conversion of steroid hormones to less active or inactive forms involves alteration of ring substituents rather than the ring structure itself. The major steroid hormones and their important functions in humans are summarized in Table 22.8. Many are similar in overall structure, although their receptors can be highly specific. Receptors for cortisol and aldosterone can bind either ligand, although the glucocorticoid receptor binds aldosterone with low affinity. Steroid hormones are classified on the basis of the number of carbons they contain. Thus **progesterone**, **cortisol**, and **aldosterone** are C_{21} steroids; **testosterone** and **dehydroepiandrosterone** are C_{19} steroids; and **17β-estradiol** is a C_{18} steroid. Sex hormones can be distinguished easily as being androgens (C_{19}), estrogens (C_{18}), or progestational or adrenal steroids (C_{21}). Certain substituents in the ring system are characteristic. For example, glucocorticoids and mineralocorticoids (typically aldosterone) possess a C11 OH or oxygen moiety. Estrogens lack a C19 methyl group and their A ring contains three double bonds. Many steroid receptors recognize primarily the A ring of their specific hormone. For instance, the estrogen receptor can distinguish the A ring of estradiol, which is stretched out of the plane of the B–C–D rings, from the A rings in other steroids, which are coplanar with the B–C–D rings. This relationship between the A ring and the B–C–D rings is illustrated in Figure 22.37, p. 918.

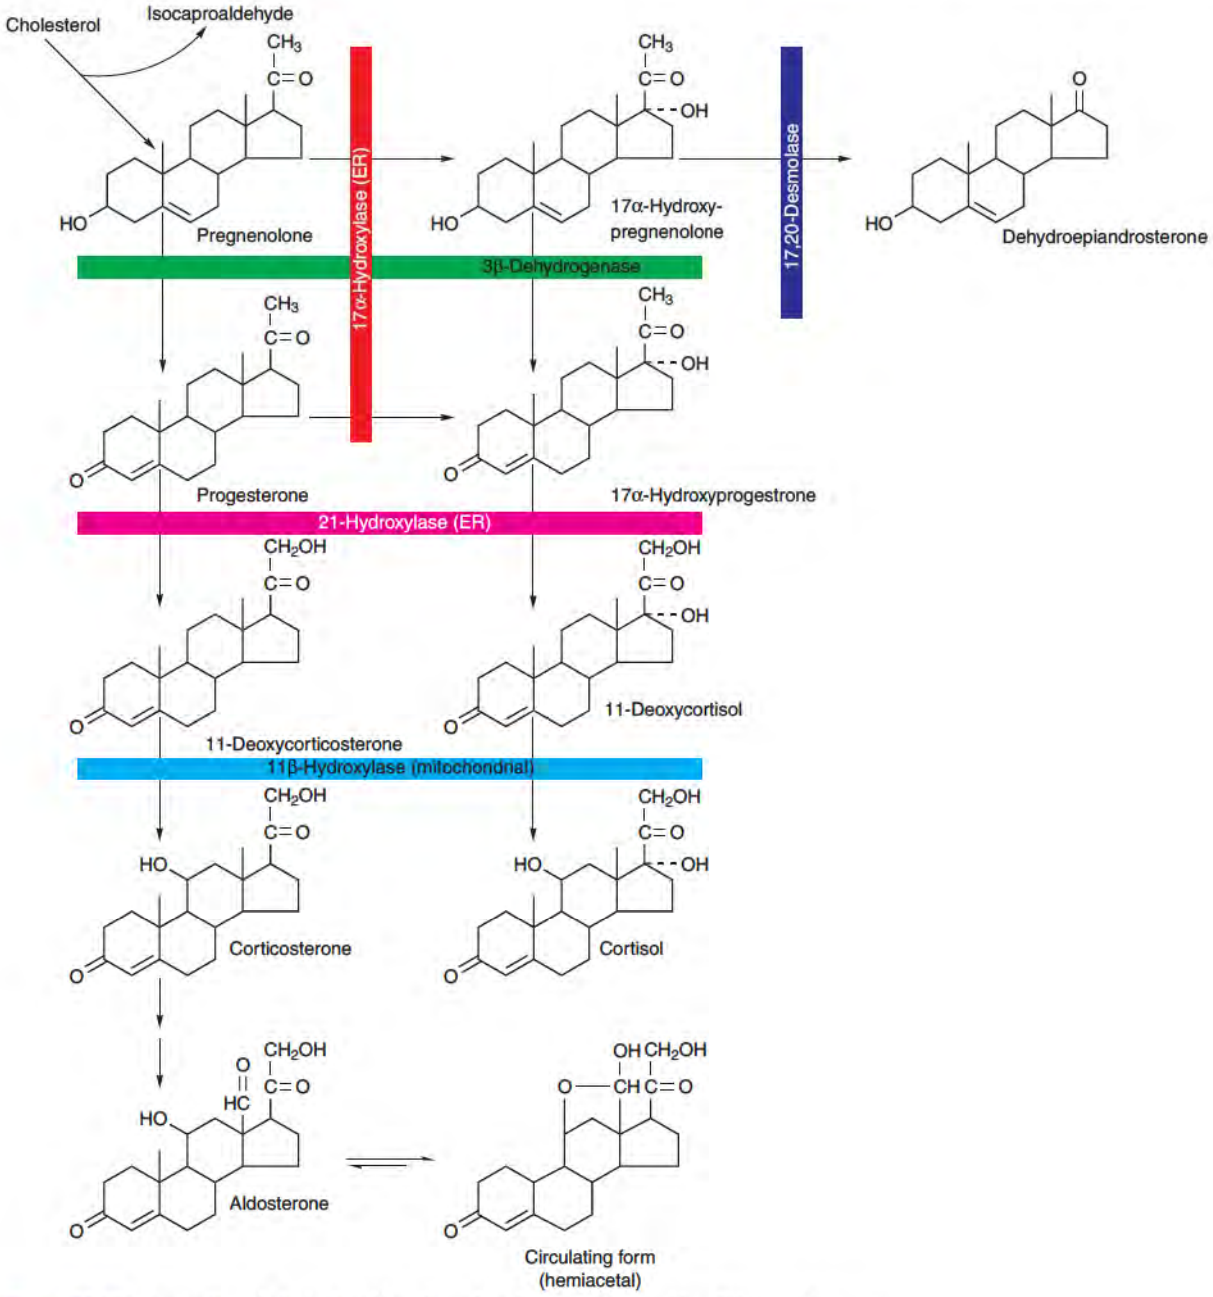

Figure 22.38 Conversion of cholesterol to adrenal cortical hormones. Not all intermediates are included and only enzymes of clinical significance are shown. ER, endoplasmic reticulum. Redrawn based on figure in Porterfield, S. P., ed. *Endocrine Physiology.* New York: Mosby, 1997, 136.

Biosynthesis of Steroid Hormones

Pathways for conversion of cholesterol to the adrenal cortical steroid hormones are presented in Figure 22.38. Cholesterol undergoes side chain cleavage to form Δ^5-pregnenolone and isocaproaldehyde. **Δ^5-Pregnenolone** is a required precursor in the synthesis of all steroid hormones. Pregnenolone is converted directly to progesterone by **3β-ol dehydrogenase** and **$\Delta^{4,5}$-isomerase**. The dehydrogenase converts the 3-OH group of pregnenolone to a 3-keto group and the isomerase moves the double bond from the B ring to the A ring to produce progesterone. In the ovarian corpus luteum the bulk of steroid synthesis stops at this point. Conversion of pregnenolone to **aldosterone** in the adrenal zona glomerulosa cells requires the endoplasmic reticulum 21-hydroxylase, and 11β-hydroxylase and 18-hydroxylase located in mitochondria. To form cortisol, primarily in adrenal zona fasciculata cells, **17-hydroxylase** and **21-hydroxylase** in the endoplasmic reticulum are

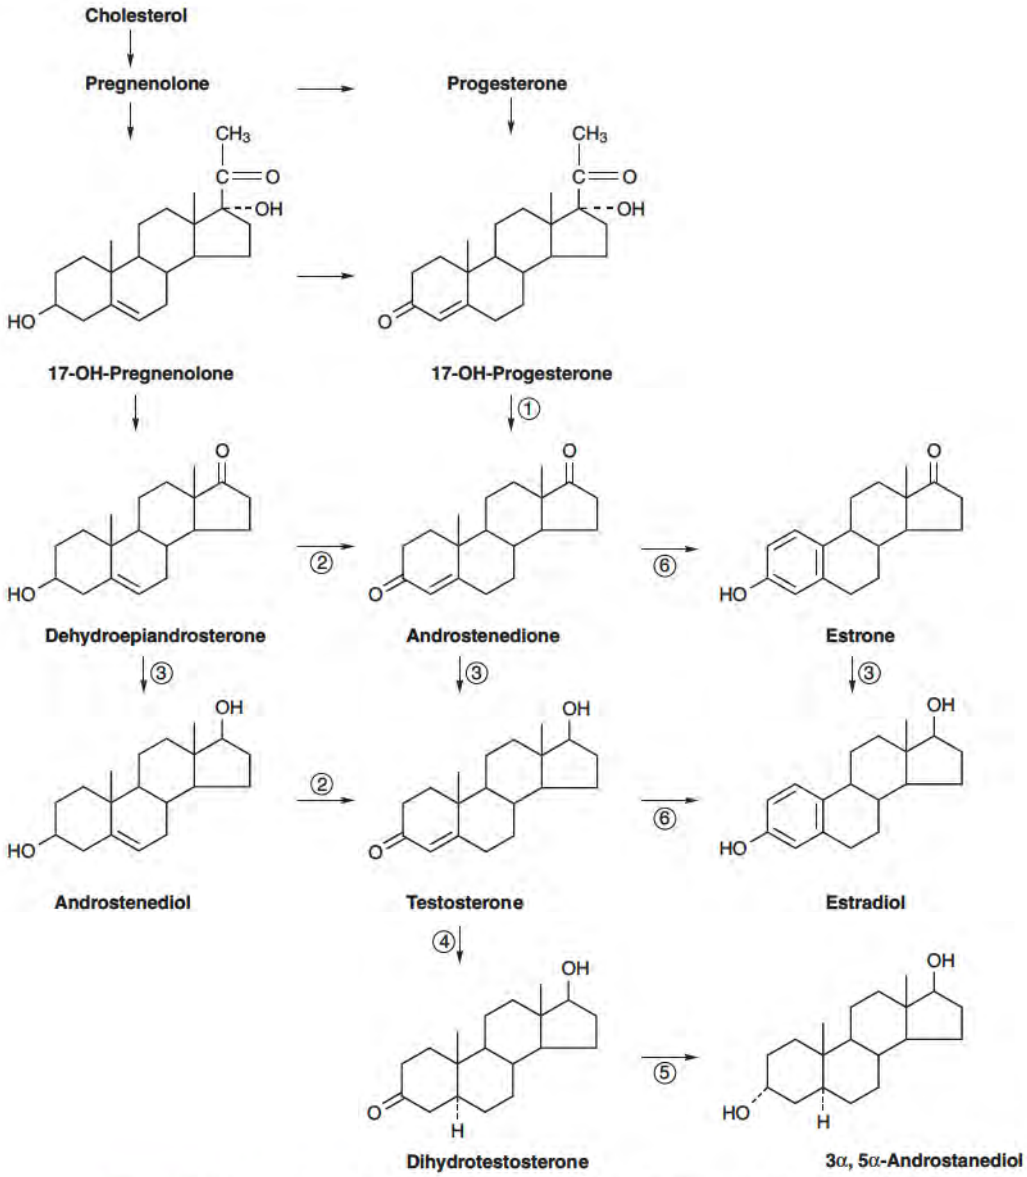

Figure 22.39 Conversion of cholesterol to sex hormones. Testosterone is the major steroid secreted by the testis. Estradiol and progesterone are the major steroids secreted by the ovary. Enzymes are (1)17,20-desmolase, (2) dehydrogenase and isomerase, (3) 17β-OH dehydrogenase, (4) 5α-reductase, (5) 3α-reductase, and (6) aromatase.

required along with mitochondrial **11β-hydroxylase**. The endoplasmic reticulum hydroxylases are cytochrome P450 (CYP) enzymes (p. 426). Δ^5-Pregnenolone is converted to **dehydroepiandrosterone** in the adrenal zona reticularis cells by 17α-hydroxylase localized in the endoplasmic reticulum to form 17α-hydroxypregnenolone and then by a side chain cleavage system to form dehydroepiandrosterone. Cholesterol is converted to the sex steroids by way of Δ^5-pregnenolone and progesterone (Figure 22.39). **Progesterone** is converted to testosterone by the action of cytoplasmic enzymes and 17-dehydrogenase. **Testosterone** is a major secretory product in the Leydig cells of the testis and is converted to dihydrotestosterone in some, but not all, androgen target cells before binding with high affinity to the intracellular androgen receptor. This reduction requires the activity of **5α-reductase** located in the endoplasmic reticulum and nucleus. Pregnenolone can enter an alternative pathway to form dehydroepiandrosterone as described above. This weak androgen can then be converted to androstenedione and then to testosterone. Estradiol is formed from testosterone by the action of the **aromatase** system.

The endoplasmic reticulum hydroxylases involved in steroid hormone synthesis use molecular oxygen (O_2) to introduce one oxygen atom into the steroidal substrate (as an

OH), while the second atom is reduced to water. Electrons generated from NADH or NADPH through a flavoprotein are transferred to ferredoxin or a similar nonheme protein. Note that there is movement of intermediates in and out of the mitochondrial compartment during biosynthesis of steroids. Once the specific steroids are synthesized, they diffuse through the plasma membrane and enter the general circulation, where they often bind to transport proteins. Unlike peptide hormones, steroids are not stored in secretory vesicles.

Metabolism of Steroid Hormones

Steroid hormones are metabolized slowly because of their binding to plasma proteins, which protects them from degradation. In humans, cortisol binds extensively to serum transcortin and has a plasma half-life of about 60–70 min. In contrast, aldosterone, which is not extensively bound to plasma proteins, has a half-life of only about 20 min. The liver is the principal site for steroid metabolism and a large number of metabolites are produced for each steroid. In general, the enzymatic reactions involved tend to decrease biological activity and increase solubility in water, thus facilitating their excretion in urine. Conjugation (p. 438) also increases the water solubility of steroid metabolites; glucuronides and sulfates are the most common conjugates. Estimates of steroid hormone secretion are often based on urinary metabolite levels. A number of factors influence the hepatic metabolism of steroids and hence their elimination from the circulation. For example, age influences hepatic steroid metabolism and the clearance of some steroids is slower (lower metabolic clearance rate) in infants and the elderly. The rates of steroid metabolism are also increased in patients with hyperthyroidism and decreased in patients with hypothyroidism and in different types of liver disease.

An example of steroid metabolism, more specifically testosterone metabolism, is presented in Figure 22.40. This does not necessarily inactivate this androgen. Testosterone

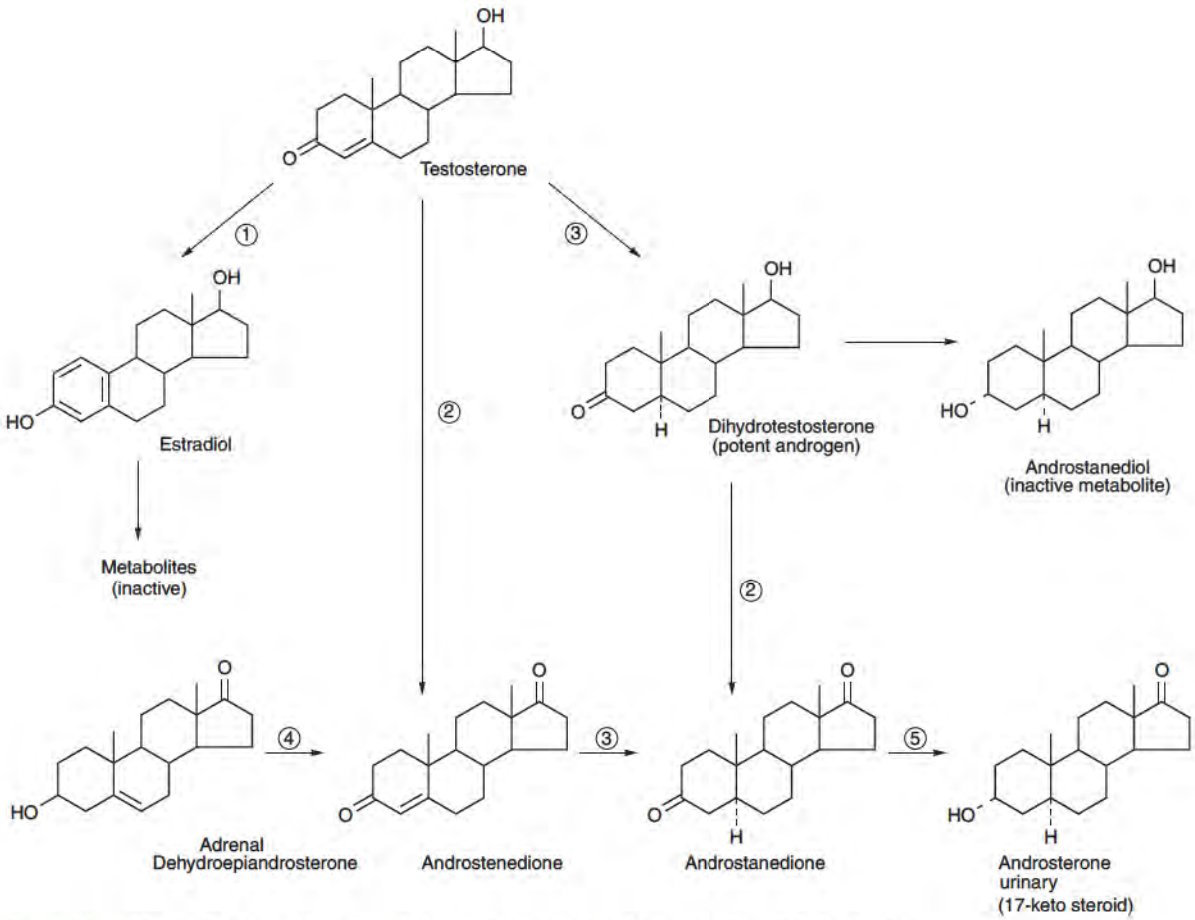

Figure 22.40 Metabolism of testosterone to generate active steroids or inactive 17-ketosteroids. Enzymes indicated (1) aromatase, (2) 17β-hydroxysteroid dehydrogenase, (3) 5β reductase; (4) 3β-hydroxysteroid dehydrogenase isomerase; and (5) 3β-hydroxysteroid dehydrogenase.

is converted to the active steroid, estradiol, by **aromatase**. Reduction of testosterone by 5α-reductase in some target cells generates **dihydrotestosterone**, which is a more potent androgen. Androsterone, the major inactive metabolic end product produced in this pathway, is conjugated and excreted in the urine. The major adrenal androgen, dehydroepiandrosterone (DHEA), is a known source of urinary 17-ketosteroids. Two other testosterone metabolites appear in urine in relatively small amounts. These are androstanediol, which is formed by reduction of the 3-keto group of dihydrotestosterone, and estrogen metabolites, which are formed once testosterone has been converted into estradiol.

Regulation of Steroid Hormone Synthesis

Regulation of steroid hormone biosynthesis is mediated by increased intracellular concentrations of cAMP and Ca^{2+}, although generation of IP_3 may also be involved (Figure 22.41). cAMP exerts rapid (seconds to minutes) and slow (hours) effects on steroid synthesis. The rapid effect is the mobilization and delivery of cholesterol to the inner membrane of mitochondria, where it is metabolized to pregnenolone by the cholesterol side chain cleavage enzyme (p. 434). In contrast, the slower effects involve increased transcription of genes for steroidogenic enzymes that are responsible for maintaining optimal long-term steroid production. The 30-kDa phosphoprotein, **steroidogenic acute regulatory (StAR)** protein, facilitates translocation of cholesterol from the outer to the inner mitochondrial membranes. In humans, StAR mRNA is specifically expressed in testes, ovaries, and adrenals, which are known sites of steroidogenesis. Patients with lipoid congenital adrenal hyperplasia (LCAH), an inherited disease in which adrenal and gonadal steroidogenesis is significantly impaired and lipoidal deposits occur, express truncated and nonfunctional StAR proteins. This suggests that the StAR protein is the hormone-induced protein that mediates acute regulation of steroid hormone biosynthesis.

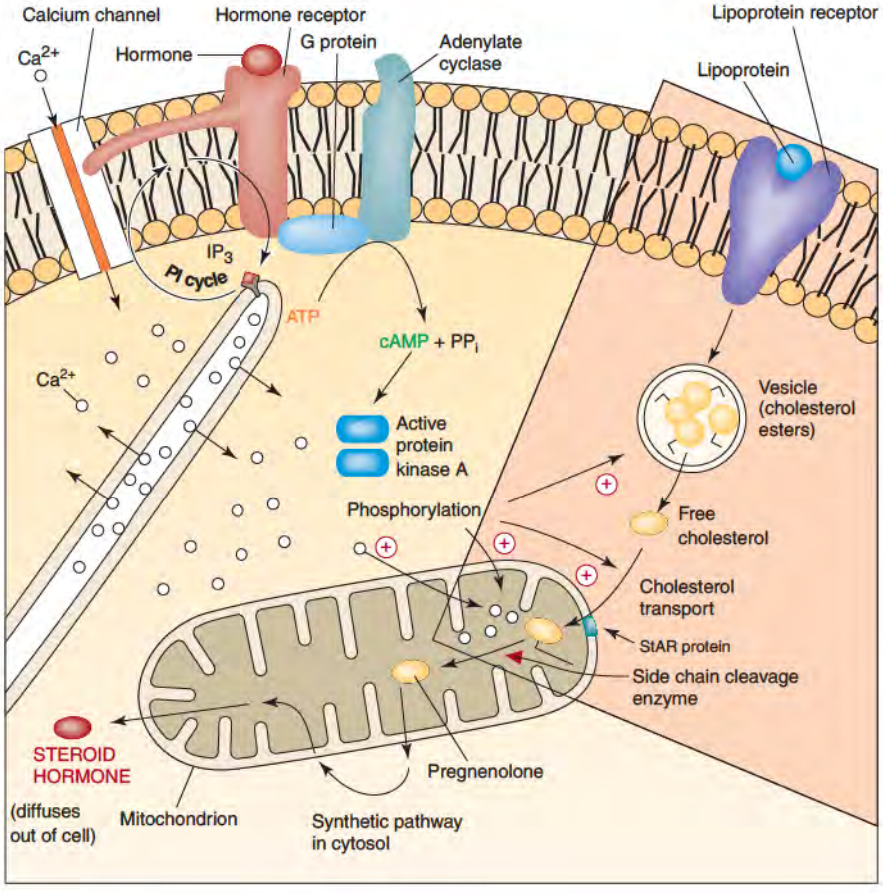

Figure 22.41 Overview of hormonal stimulation of steroid hormone biosynthesis. Nature of the hormone (top of figure) depends on the cell type and receptor (ACTH for cortisol synthesis, FSH for estradiol synthesis, LH for testosterone synthesis, etc., as given in Table 22.1). This activates adenylate cyclase via a stimulatory G protein or may stimulate a calcium channel directly or indirectly by activating the phosphatidylinositol cycle (PI cycle). If the PI cycle is stimulated, IP_3 augments cytosol Ca^{2+} levels from the ER store. cAMP activates protein kinase A, which, via phosphorylation, increases hydrolysis of cholesteryl esters from the vesicles to free cholesterol and increase cholesterol transport into the mitochondrion. The elevated Ca^{2+} levels and protein phosphorylation and induction of the StAR protein, result in increased side chain cleavage and steroid biosynthesis. These reactions overcome the rate-limiting steps (availability of cholesterol from cholesterol esters stored in vesicles, transport of cholesterol to inner mitochondrial membrane, and side chain cleavage reaction) in steroid biosynthesis, and more steroid is synthesized and secreted.

TABLE 22.9 • Hormones that Directly Stimulate Synthesis and Release of Steroid Hormones

Steroid Hormone	*Steroid-Producing Cell or Structure*	*Signal*[a]	*Second Messenger*	*Signal System*
Cortisol	Adrenal zona fasciculata	ACTH	cAMP, PI cycle, Ca^{2+}	Hypothalamic-pituitary cascade
Aldosterone	Adrenal zona glomerulosa	Angiotensin II/III	PI cycle, Ca^{2+}	Renin-angiotensin system
Testosterone	Leydig cell	LH	cAMP	Hypothalamic-pituitary cascade
17β-Estradiol	Ovarian follicle	FSH	cAMP	Hypothalamic-pituitary-ovarian cycle
Progesterone	Corpus luteum	LH	cAMP	Hypothalamic-pituitary-ovarian cycle
$1,25(OH)_2\ D_3$	Kidney	PTH	cAMP	Sunlight, parathyroid glands, plasma Ca^{2+} level

[a]ACTH, adrenocorticotropic hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; PI, phosphatidylinositol; PTH, parathyroid hormone.

Polypeptide hormones that stimulate biosynthesis and secretion of steroid hormones are summarized in Table 22.9. They operate through cognate cell membrane receptors. Where both the cAMP and the phosphatidylinositol cycle are involved, it is not clear whether one second messenger predominates. For the synthesis and secretion of aldosterone, probably several components (i.e., acetylcholine muscarinic receptor, atriopeptin receptor) and their second messengers are involved in addition to those listed in Table 22.9. Figure 22.42 summarizes the effects of ACTH on cortisol biosynthesis and secretion.

Aldosterone

Figure 22.43 shows reactions leading to secretion of aldosterone in a cell located in the adrenal zona glomerulosa. This outermost zone of the adrenal cortex cannot synthesize cortisol because it does not express the 17α-hydroxylase enzyme. A major driving force for aldosterone biosynthesis is **angiotensin II**, which is generated by the **renin–angiotensin system** shown in Figure 22.44. The signal for aldosterone secretion is generated under conditions when blood Na^+ concentration and blood pressure (blood volume) need to be increased. The N-terminal decapeptide of a plasma **α_2-globulin (angiotensinogen)** is cleaved by the proteolytic enzyme **renin**. This decapeptide is the inactive angiotensin I, which is then converted to the active octapeptide, angiotensin II, by **angiotensin-converting enzyme (ACE)**, which is found on the surface of pulmonary and renal endothelial cells. Angiotensin II is then converted to the heptapeptide, angiotensin III, by an aminopeptidase. Both angiotensins II and III bind to the angiotensin receptor (see Figure 22.43), which activates phospholipase C to generate IP_3 and DAG. The IP_3 then triggers release of Ca^{2+} from the endoplasmic reticulum. In addition, the plasma membrane Ca^{2+} channel is opened by the angiotensin–receptor complex. These events lead to a greatly increased level of cytoplasmic free Ca^{2+}, which together with DAG stimulates protein kinase C. **Acetylcholine** released through neuronal stress signals produces similar effects on calcium levels and protein kinase C activity, effects that are mediated by the muscarinic acetylcholine receptor (p. 515). Phosphorylation of enzymes that stimulate the rate-limiting steps in aldosterone synthesis lead to increased synthesis of aldosterone. In renal distal tubule cells, this adrenal steroid binds to its intracellular receptor and enhances expression of genes for proteins, including subunits for membrane Na^+ channels, which increase absorption of Na^+ from the glomerular filtrate. Although ACTH is not considered a major regulator of aldosterone synthesis, it promotes maximal secretion of this mineralocorticoid hormone. In contrast, ACTH is the major stimulator of the synthesis and secretion of cortisol by cells in the zona fasciculata (see Figure 22.42). Cortisol also accounts for substantial reabsorption of Na^+ in the kidney, probably through glucocorticoid stimulation of the Na^+/H^+ antiport transporter in the luminal membrane of renal epithelial cells.

Physiological conditions opposite to those that activate the formation of angiotensin I and II generate **atrial natriuretic factor (ANF)**, or atriopeptin, from the heart atria (see Figures 22.43 and 22.44). An increase in blood volume results in increased stretching of the atria and increased synthesis and secretion of ANF. In the zona glomerulosa cell, ANF

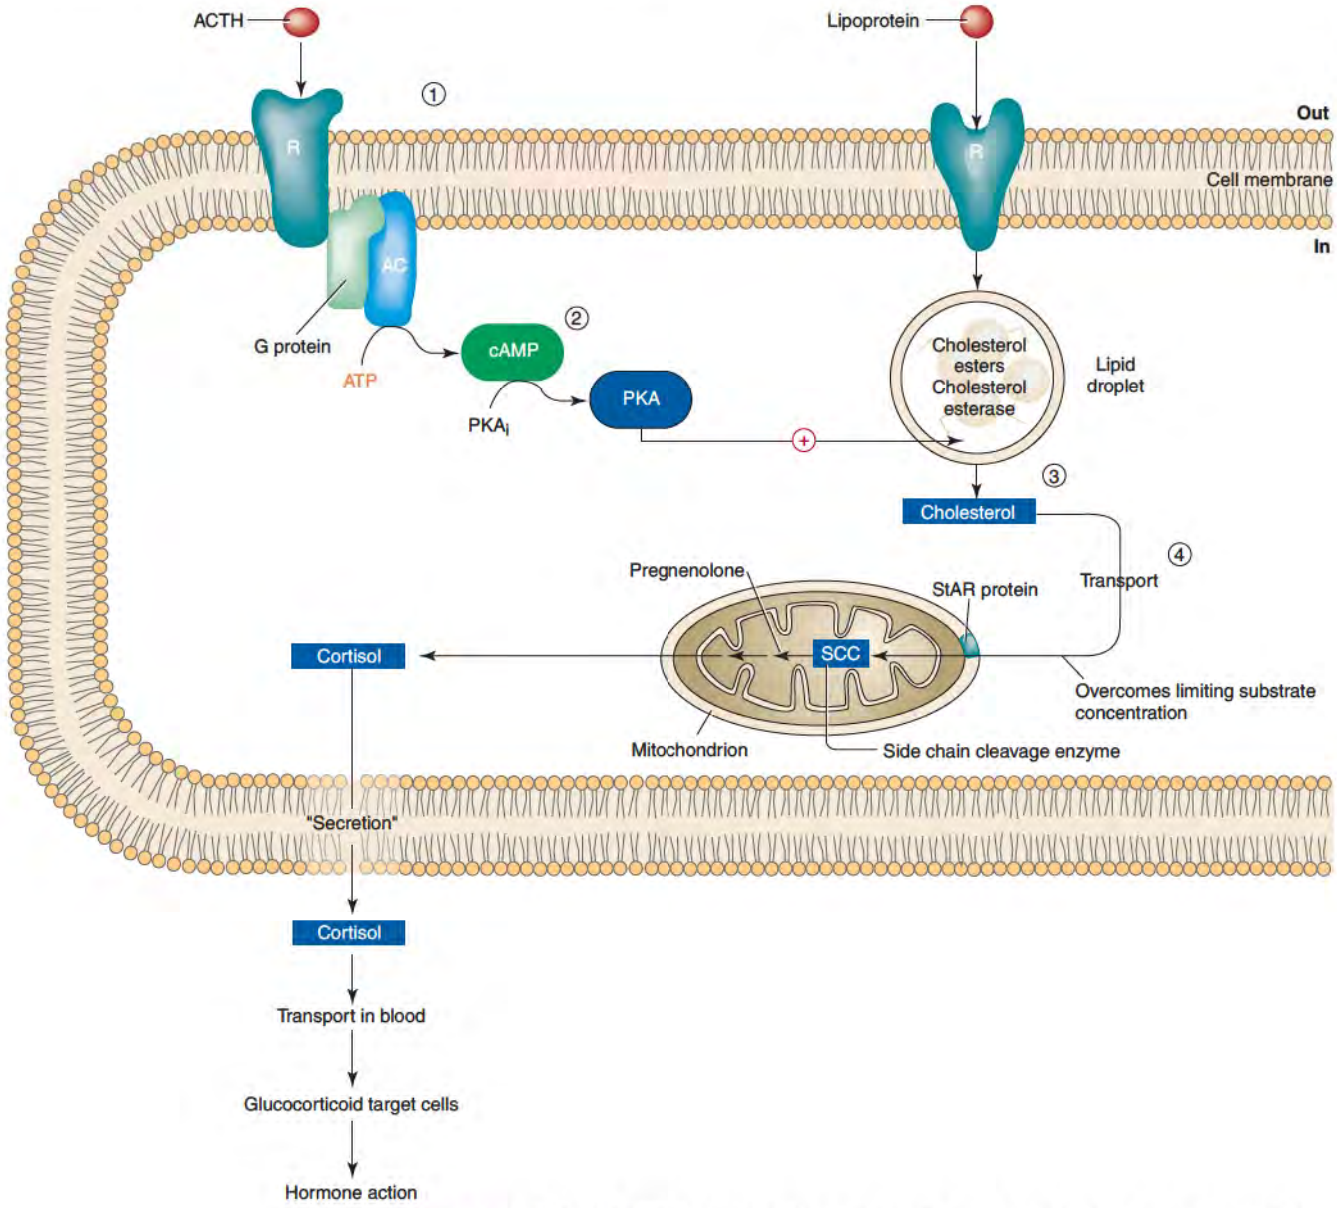

Figure 22.42 Action of ACTH on adrenal fasciculata cells to enhance production and secretion of cortisol. StAR (steroidogenic acute regulatory) protein is a cholesterol transporter functioning between the outer and inner mitochondrial membranes.

activates its receptor guanylate cyclase activity to increase cGMP levels and inhibit synthesis and secretion of aldosterone and formation of cAMP by adenylate cyclase.

Estradiol

Hormonal control of synthesis and secretion of **17β-estradiol** is shown in Figure 22.45. At puberty in females the secretion of GnRH, which is under control from higher brain centers, increases significantly. During adult life this hypothalamic-releasing hormone stimulates the release of FSH and LH from the anterior pituitary gonadotropes (p. 901). The FSH stimulates synthesis and secretion of 17β-estradiol in the ovary. This steroid exerts negative feedback on the pituitary **gonadotropes**, to suppress further secretion of FSH, and on the hypothalamic cells that secrete GnRH. Near ovarian midcycle, however, 17β-estradiol exerts a positive effect on the gonadotropes, (Figure 22.45), which causes very high levels of LH to be released (LH spike), as well as increased secretion of FSH (see Figure 22.19, p. 904). This LH spike is essential for ovulation to occur (p. 904). After

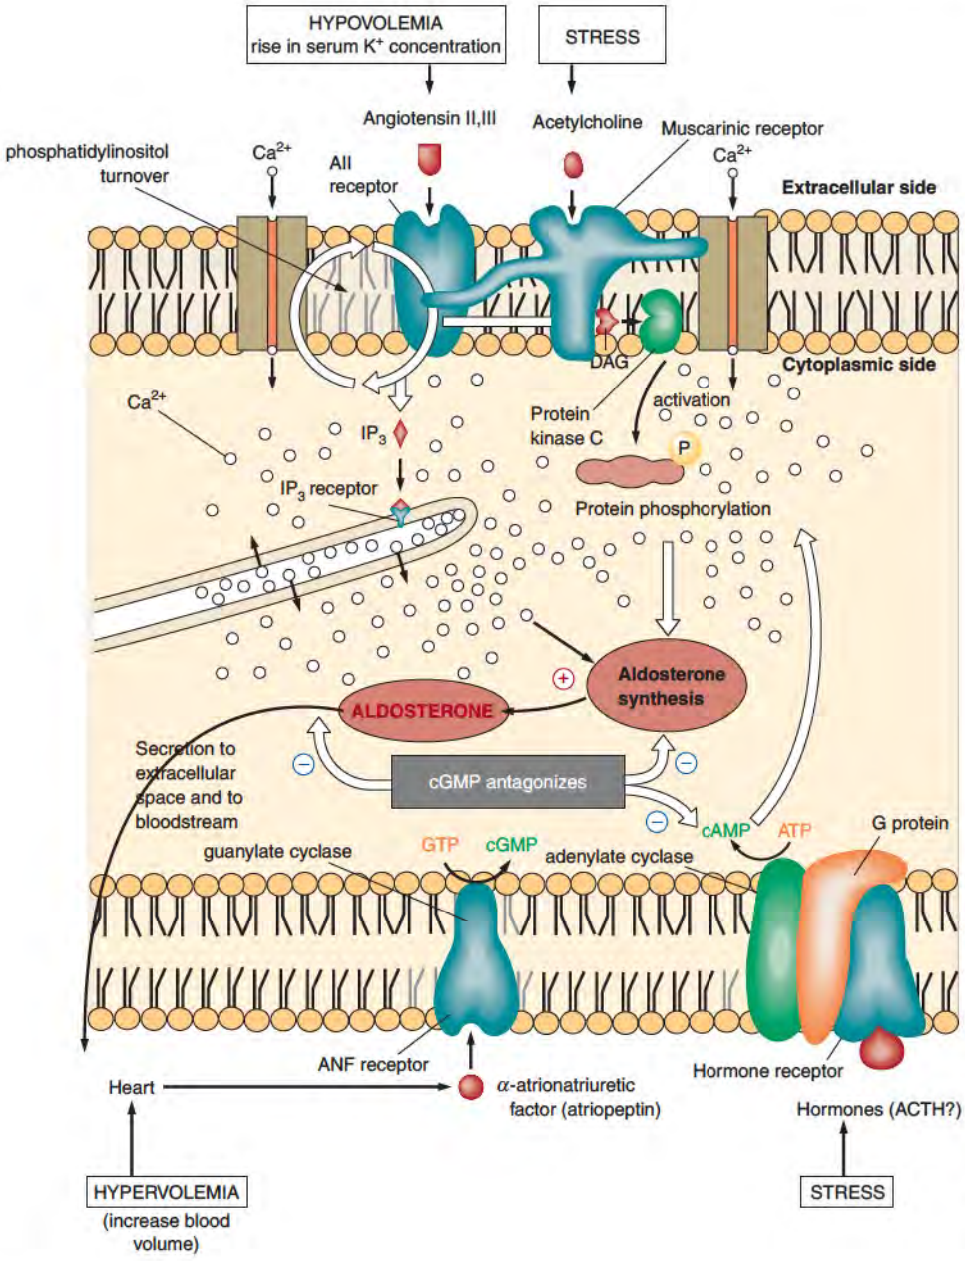

Figure 22.43 Reactions leading to secretion of aldosterone in adrenal zona glomerulosa cell. Abbreviations: cGMP, cyclic GMP; ANF, atrial natriuretic factor; see Figure 22.42, p. 924, for additional abbreviations.

ovulation has occurred, a functional corpus luteum (CL) forms from the ruptured follicle and synthesizes progesterone and some estradiol. Progesterone, however, inhibits continued LH synthesis and release. Eventually the corpus luteum dies (involutes), owing to a fall in the plasma LH level. The blood levels of progesterone and estradiol fall significantly, resulting in menstruation and a decline in their negative effects on the anterior pituitary and hypothalamus. Once the negative feedback exerted by estradiol and progesterone has been eliminated, a new menstrual cycle is initiated. Clin. Corr. 22.4 describes how oral contraceptives interrupt this sequence.

In males LH acts principally on Leydig cells to stimulate synthesis of testosterone. FSH acts on Sertoli cells to stimulate the conversion of testosterone secreted by the Leydig cells, into 17β-estradiol, which is required for **spermatogenesis**. FSH also stimulates Sertoli cells to secrete an androgen-binding protein that binds testosterone and estradiol and carries them into the lumen of the seminiferous tubules, where they are required by the maturing sperm. Testosterone itself exerts negative feedback that decreases secretion of GnRH. Sertoli cells also secrete the glycoprotein hormone **inhibin B**, the same hormone secreted by ovarian granulosa cells, which selectively inhibits FSH secretion. These hormonal negative feedback loops

CLINICAL CORRELATION 22.4

Oral Contraception

Many forms of oral contraception are based on the fact that estrogens and progesterone can inhibit pituitary secretion of FSH and LH, thereby preventing maturation of the ovarian follicle and ovulation. Most oral contraceptives are a combination of a synthetic estrogen and a progesterone-like substance or progestin. This combination of steroids blocks the LH surge required for ovulation and results in thickening and increased vascularization of the uterine endometrium. Pills that lack any steroids (placebos) are usually inserted in the regimen at about the 28th day, causing blood levels of estrogens and progestins to fall dramatically and menstruation to occur. When the combination oral contraceptives are resumed, the blood levels of estrogen and progestin increase again and the uterine endometrium thickens. This creates a false cycling because of the occurrence of menstruation at the expected time point in the cycle. Some oral contraceptives, such as the minipill, contain only a progestin. Although these pills do not block the LH surge required for ovulation, they are still effective at blocking fertility because they mediate other contraceptive effects. For example, these progestins can affect the composition of the cervical mucus, thus preventing passage of sperm through the cervix. They also inhibit the estrogen-induced proliferation of the endometrium and thus prevent implantation. Other hormonal methods of contraception include surgical implantation of progestin-containing silicone capsules under the skin. In this situation the progestin is released slowly, thus providing contraception for up to 3–5 years.

Zatuchni, G. I. Female contraception. In Becker, K. L. (Ed.), *Principles and Practice of Endocrinology and Metabolism.* New York: Lippincott, 1990, 861; and Shoupe, D., and Mishell, D. R. Norplant: Subdermal implant system for long term contraception. *Am. J. Obstet. Gyn.* 160:1286, 1988.

thus reduce testosterone and estradiol secretion and inhibit the process of spermatogenesis. The biosynthesis of testosterone from cholesterol is summarized in Figure 22.39, p. 920.

Vitamin D_3

The active form of vitamin D, called **calcitriol**, is referred to as a **secosteroid**, which is a steroid in which one of the rings has been opened. As shown in Figure 22.46, 7-dehydrocholesterol is activated in the skin by sunlight to generate **vitamin D_3 (cholecalciferol)**. This then is

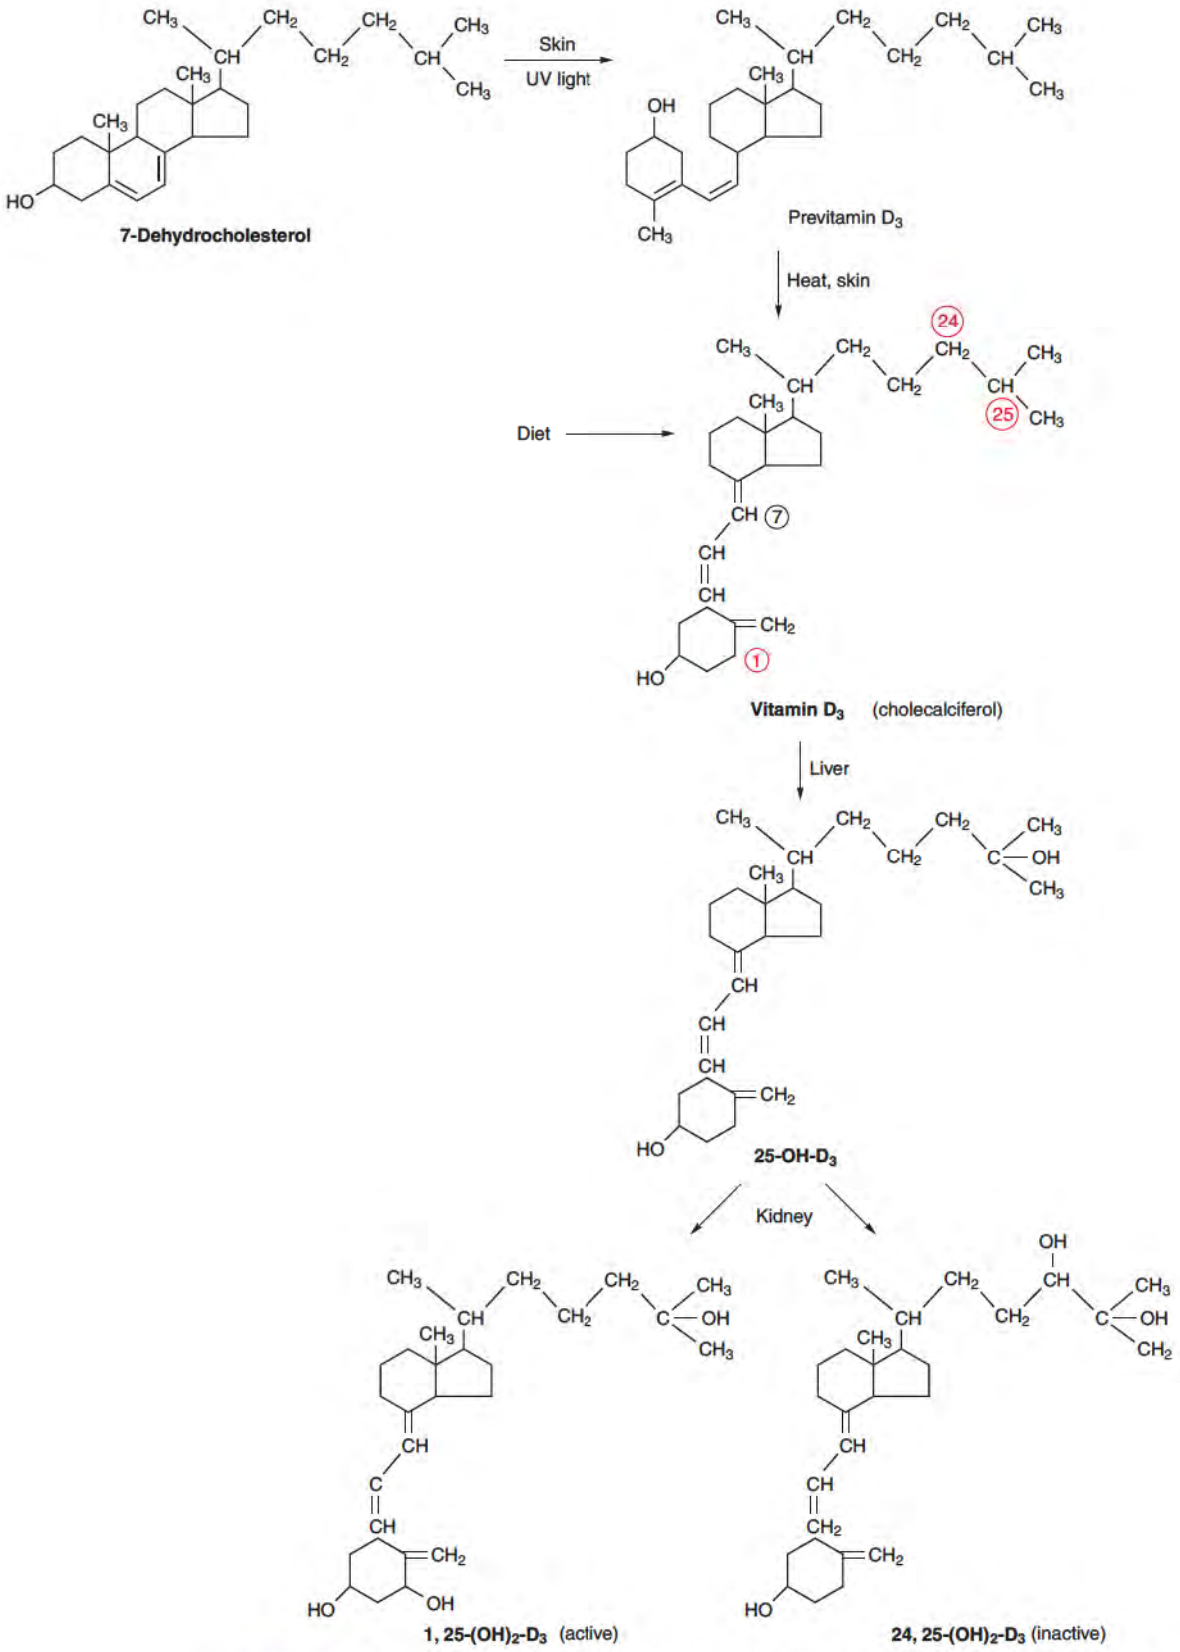

Figure 22.46 **Structure of 1α,25-dihydroxycholecalciferol (calcitriol), the biologically active form of vitamin D.**

hydroxylated in the liver to generate **25-hydroxy vitamin D_3 (25-hydroxycholecalciferol)**. In the kidney this is further hydroxylated to either **1α,25-vitamin D_3 (1,25$(OH)_2D_3$) (1α, 25-dihydroxychol-ecalciferol)**, which is the active form of the hormone, or **24,25-vitamin D_3 (24, 25 $(OH)_2$ D_3) (24,25-dihydroxycholecaliciferol)**, which is an inactive metabolite of the hormone. Nuclear 1,25$(OH)_2D_3$ receptors are expressed in target cells including intestinal epithelial cells, bone cells, and cells of kidney tubules. Binding of 1,25$(OH)_2D_3$ induces receptor phosphorylation, and binding of the hormone–receptor complex to vitamin D_3 -response elements in the DNA. This binding results in an increased rate of transcription of vitamin D_3-responsive genes that encode a number of Ca^{2+}-binding proteins called **calbindins**, Ca^{2+}-ATPase and other ATPases, and membrane components and facilitators of vesicle formation. Calbindins may ferry Ca^{2+} across the intestinal cell, or may simply buffer the cytoplasm against high Ca^{2+} levels (Figure 22.47). 1,25$(OH)_2$ D_3 also increases the number of Ca^{2+} pump molecules in the basolateral membrane. The major effect of 1,25$(OH)_2D_3$ is to stimulate the transcellular (across intestinal epithelial cells) absorption of Ca^{2+} and phosphate from the intestinal lumen against a concentration gradient, and thus it plays an important role in bone mineralization. However, elevated 1,25$(OH)_2D_3$ levels can actually stimulate bone resorption by osteoclasts, which surprisingly do not express nuclear receptors for 1,25$(OH)_2D_3$. Osteoblasts do express these receptors and 1,25$(OH)_2D_3$ may stimulate them to secrete a paracrine factor that increases the recruitment and differentiation of precursors into active osteoclasts, which can then mediate bone resorption. Vitamin D may also be responsible for autocrine and paracrine effects that are important in the regulation of immune responses. In the kidney 1,25$(OH)_2D_3$ weakly stimulates Ca^{2+} reabsorption by increasing the number of Ca^{2+} pumps.

Transport of Steroid Hormones: Plasma-Binding Proteins

Four major plasma proteins bind the steroid hormones in blood. They are corticosteroid-binding globulin, sex-hormone-binding globulin, androgen-binding protein, and albumin. Most of the circulating cortisol (75%–80%) binds to a specific **corticosteroid-binding α2-globulin (CBG)** known as **transcortin**. About 15% of plasma cortisol is bound to albumin with a much lower affinity. Thus even though albumin is present at 1000-fold the concentration of CBG, the cortisol occupies the CBG-binding sites first. The concentration of transcortin increases during pregnancy and after estrogen administration. During stress, when cortisol levels are high, the CBG binding sites become saturated first and the excess cortisol binds to albumin. Only 5%–10% of plasma cortisol is normally free (unbound). It is this free cortisol that diffuses across the plasma membrane, binds to glucocorticoid receptors, and mediates a biological response. About 50%–70% of the circulating aldosterone binds with low affinity to albumin and transcortin, and the remainder is unbound. Thus aldosterone has a lower plasma half-life (20 min) as compared to cortisol (70 min).

About 65% of circulating testosterone is bound to a liver-derived glycoprotein called **sex hormone-binding globulin (SHBG)**. Only 1%–2% of circulating testosterone is in the free form and the rest is bound to albumin and other proteins. The SHBG-bound fraction thus serves as circulating reservoir of testosterone. Approximately 60% of estrogens are transported bound to SHBG, 20% are bound to albumin, and 20% are in the free form. However, estradiol binds to SHBG with a much lower affinity than testosterone. Thus, estradiol bound to SHBG dissociates very rapidly, and it is taken up by target tissues. Adult males have about one-half as much circulating SHBG as females, so free testosterone is about 20 times greater in males than in females. In addition, the total (bound plus unbound) concentration of testosterone is about 40 times greater in males. Testosterone itself lowers SHBG levels and increases the amount of free testosterone in blood, whereas 17β-estradiol and thyroid hormone raise SHBG levels in blood. These effects have important ramifications in pregnancy and in other endocrine conditions.

Androgen-binding protein (ABP) is produced by the Sertoli cells in response to testosterone and FSH. ABP is also called **testosterone-estrogen-binding globulin (TeBG)** and this protein helps to maintain high androgen levels within the testis and seminal fluids. These high local androgen levels are important for the development and maturation

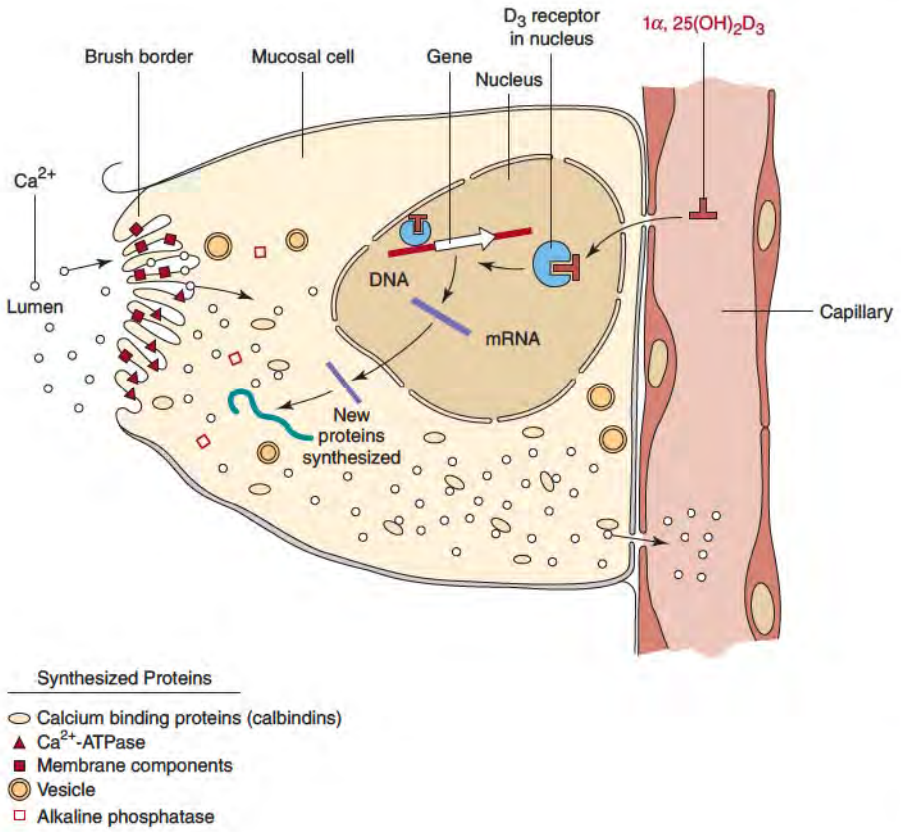

Figure 22.47 Schematic model of action of $1,25(OH)_2D_3$ in intestinal mucosal cell in stimulating calcium absorption from lumen. Redrawn from Nemere, I., and Norman, A. W. *Biochim. Biophys. Acta* 694:307, 1982.

of sperm. Progesterone binds primarily to transcortin and albumin. Because this steroid has a relatively low affinity for these plasma proteins, its circulating half-life is only about 5 min.

22.8 • STEROID HORMONE RECEPTORS

Steroid Hormones Bind Intracellular Receptor Proteins

Receptors for steroids and receptors for nonsteroid hormones (i.e., thyroid hormone, retinoic acid, and Vitamin D_3) are located intracellularly. The unbound glucocorticoid receptor and possibly the aldosterone receptor appear to reside in the cytoplasm, whereas the rest are located within the nucleus, presumably in association with chromatin. In Figure 22.48, step 1 shows a steroid hormone dissociating from a plasma transport protein. The free steroid diffuses into the cell through the lipid bilayer (step 2). Cortisol binds to its receptor with a binding constant of 10^9/M, compared to a binding constant of about 10^7/M for CBG. The unbound receptor, in this case glucocorticoid receptor, is a complex (~300 kDa) that contains other associated proteins, including a dimer of a 90-kDa **heat shock protein** which masks the DNA-binding domain of the receptor (Figure 22.49), and heat shock protein Hsp56, which is an immunophilin that binds several potent immunosuppressive drugs. Binding of the steroidal ligand (step 3) causes a conformational change (activation) in the receptor protein causing release of the associated proteins, including the dimer of Hsp 90, and exposure of positively charged amino acid residues located within the DNA-binding domain (step 4). The ligand–receptor complex translocates to the nucleus (step 5), binds to DNA, frequently as a homodimer, and searches the DNA for specific, high-affinity acceptor sites. Once the ligand–receptor complex has bound to specific hormone response elements (HRE) (step 6) in the DNA, it regulates gene transcription and frequently enhances gene transcription. New mRNAs are translocated to the cytoplasm and direct the synthesis of proteins (step 7) that alter the metabolism and functioning of

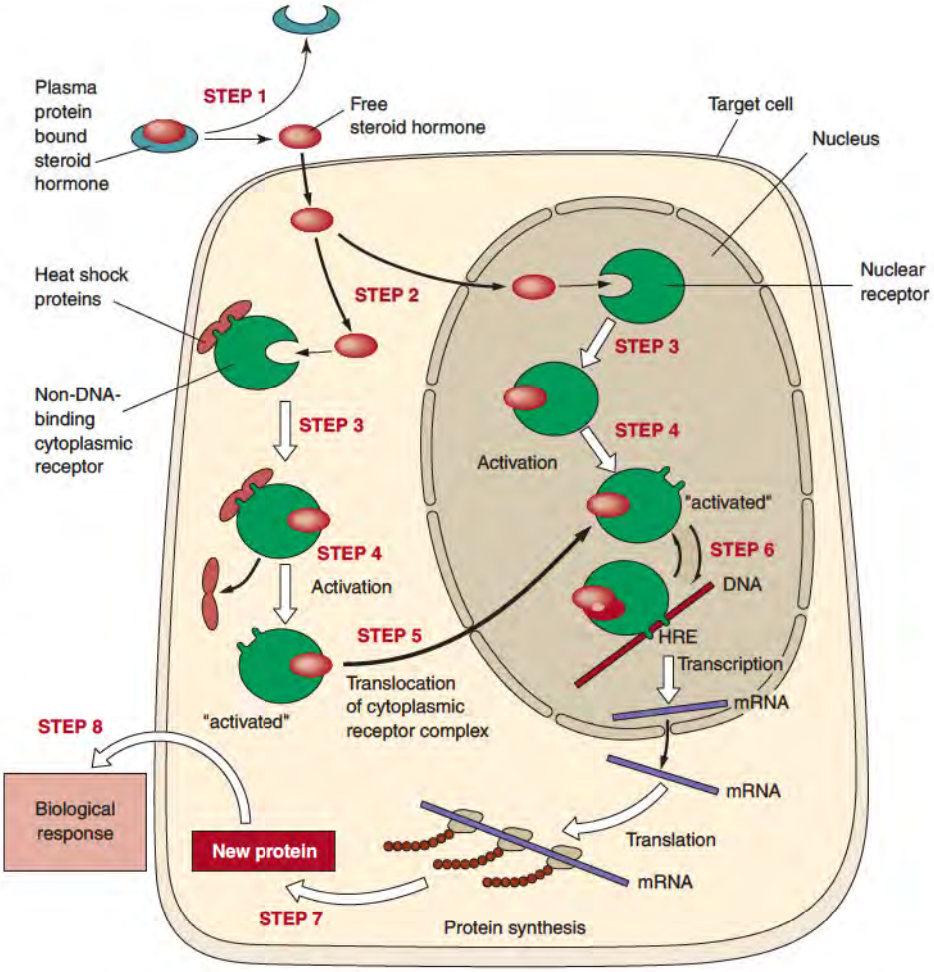

Figure 22.48 Model of steroid hormone action. Step 1: Dissociation of free hormone from circulating transport protein; step 2: diffusion of free ligand into cytosol or nucleus; step 3: binding of ligand to cytoplasmic or nuclear receptor; step 4: activation of cytosolic or nuclear hormone–receptor complex to DNA-binding form; step 5: translocation of activated cytosolic hormone-receptor complex into nucleus; step 6: binding of activated hormone receptor complexes to specific response elements within the DNA; step 7: synthesis of new proteins encoded by hormone-responsive genes; and step 8: alteration in phenotype or metabolic activity of target cell mediated by specifically induced proteins.

the target cell (step 8). In some situations steroid–receptor complexes repress, rather than induce, specific gene transcription.

The unbound steroid hormone receptors for estradiol, progesterone, androgens, and the secosteroid vitamin D_3 (see Figure 22.48) are located in the nucleus. Once inside the nucleus the hormone binds to its specific receptor, induces the dissociation of receptor-associated proteins, and regulates gene transcription. The transcriptional effects of 17β-estradiol in humans and rodents are mediated by the α and β forms of the **estrogen receptor** (**ERα** and **ERβ**, respectively). Both bind 17β-estradiol with the same high affinity and bind to estrogen response elements within the DNA. The ERα and ERβ are highly homologous. ERα contains two distinct transcriptional activation domains, AF-1 and AF-2. ERβ contains an AF-2 domain and a repressor domain. ERβ is an inhibitor of ERα transcriptional activity at subsaturating hormone levels and decreases overall cellular sensitivity to 17β-estradiol. Results from knockout mice suggest that these two forms of the ER may have two different biological roles. When ERα and ERβ are coexpressed in neurons, they trigger different intracellular signals and distinct metabolic responses. ERβ may be relevant for neural cell differentiation, whereas ERα may be implicated in synaptic plasticity, both during development and in mature neurons. ERα and Erβ may also play different roles in the uterus. The uterus contains a variety of cell types that undergo continuous synchronized changes in proliferation rates and differentiation in response to estrogens and progesterone. ERα and ERβ levels in uterine tissue vary during the menstrual cycle, the highest level for both occurs during the proliferative phase. 17β-Estradiol regulates the expression of the gene for the **progesterone receptor (PR)** in uterine and breast tissue. ERα induces PR in the uterine stroma and glandular epithelial cells. In contrast, ERβ down-regulates PR in the luminal epithelium. Thus, the differential expression of ERα and ERβ within specific cell types dictates what type of response will be elicited by 17β-estradiol.

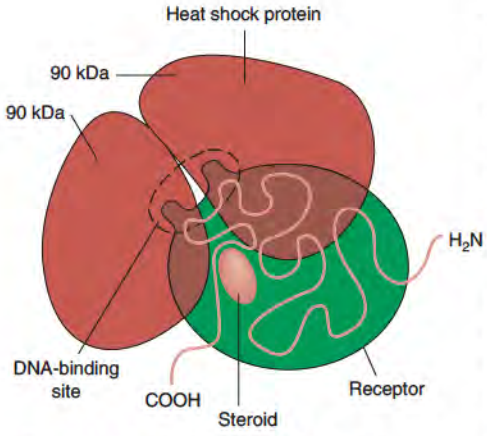

Figure 22.49 Hypothetical model of a non-DNA-binding form of a steroid receptor. This form of the receptor cannot bind to DNA because the DNA-binding site is blocked by the 90 kDa hsp proteins or by some other constituent. Mass of this complex is approximately 300 kDa.

[a]n, any nucleotide; Y, a purine; W, a pyrimidine

Consensus DNA sequences have been defined for specific **hormone response elements (HREs)** (Table 22.10). Receptors for glucocorticoids, mineralocorticoids, progesterone, and androgen bind to the same HRE. Thus, in a given target cell, the type of receptor expressed determines the hormone sensitivity. Sex hormone and progesterone receptors are expressed in only a few cell types, whereas the glucocorticoid receptor is present in a wide variety of cells. Where aldosterone and cortisol receptors are coexpressed, only one receptor form may predominate. However, tissues such as the kidney and colon are targets for aldosterone and express relatively high levels of both mineralocorticoid and glucocorticoid receptors. They also express **11β-hydroxysteroid dehydrogenase** type 2 (Clin. Corr. 22.5) that converts cortisol, which binds to the mineralocorticoid receptor with high affinity, to cortisone, which binds poorly to this receptor. This inactivation of cortisol facilitates binding of aldosterone to mineralocorticoid receptors in these tissues. In certain tissues, mineralocorticoid receptors may mediate the effects of low, circulating levels of cortisol, which are approximately 100-fold higher than the circulating aldosterone levels. Thus, the mineralocorticoid and glucocorticoid receptors may regulate the expression of an overlapping gene network in various target tissues. Note that the estrogen–receptor complex recognizes a unique response element (Table 22.10). Glucocorticoids inhibit transcription of the **proopiomelanocortin (POMC)** gene and thus regulate the rate of secretion of ACTH and hence of cortisol. **Negative glucocorticoid response elements (nGREs)** mediate repression of the POMC gene and of other genes.

Numerous models have been proposed to explain how steroid–receptor complexes function as positive or negative regulators of gene transcription. Binding of a steroid–receptor homodimer to a hormone response element (HRE) may allow it to interact synergistically with a positive transcription factor and hence induce gene transcription. Alternatively, binding of the homodimer to a HRE may sterically block the binding of a positive transcription factor, thus causing repression of gene transcription. Direct protein–protein interactions between a steroid receptor and a positive transcription factor could, at least theoretically, prevent either from binding to DNA and result in a decreased rate of transcription.

Complex physiological responses to steroid hormones may involve induction or inhibition of gene transcription. For example, glucocorticoids exert major anti-inflammatory actions and they have been utilized for decades for this very purpose. They suppress the immune system in several ways. Glucocorticoids inhibit immune responses by inhibiting **prostaglandin** production. Glucocorticoid–receptor complexes induce **annexin-I** (or **lipocortin**), a 40-kD protein, which inhibits membrane phospholipase A_2, and hence the release of arachidonic acid for prostaglandin synthesis. Glucocorticoids also inhibit expression of **cyclooxygenase (COX)** (p. 741) that generates prostaglandins and related compounds. COX1 is constitutively expressed and produces prostaglandins under noninflammatory conditions. COX2 is induced in inflammatory cells and suppression of its synthesis by glucocorticoids accounts for a major part of their anti-inflammatory effects.

CLINICAL CORRELATION 22.5

Apparent Mineralocorticoid Excess Syndrome

Some patients (usually children) exhibit the hypertension, hypokalemia, and suppression of the renin–angiotensin–aldosterone system that would be expected if they were hypersecreting aldosterone. Since assays of plasma and urine may fail to identify excess mineralocorticoids, these patients are said to have the *apparent mineralocorticoid excess (AME)* syndrome. This syndrome is an autosomal recessive disease caused by a deficiency in 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2). Since the plasma levels of cortisol are about 100-times higher than the plasma levels for aldosterone, cortisol saturates the renal mineralocorticoid receptor, causing sodium retention and suppression of the renin–angiotensin–aldosterone axis. Although this syndrome can result from a congenital defect in renal 11β-HSD2, it can also be acquired by ingesting excessive amounts of licorice. The major components of licorice are glycyrrhizic acid and its hydrolytic product, glycyrrhetinic acid (GE), which is a potent inhibitor of 11β-HSD2. By blocking the activity of this inactivating enzyme, GE facilitates the binding of cortisol to renal mineralocorticoid receptors and hence induces the hypertension and hypokalemia characteristic of the AME syndrome.

The hypertension of apparent mineralocorticoid excess syndrome. In Biglieri, E. G., and Melby, J. C. (Eds.), *Endocrine Hypertension.* New York: Raven, 1990, 155; and Mumoli, N., and Cei, M. Licorice-induced hypovolemia. *Int. J. Cardiol.* 124(3):e42, 2008.

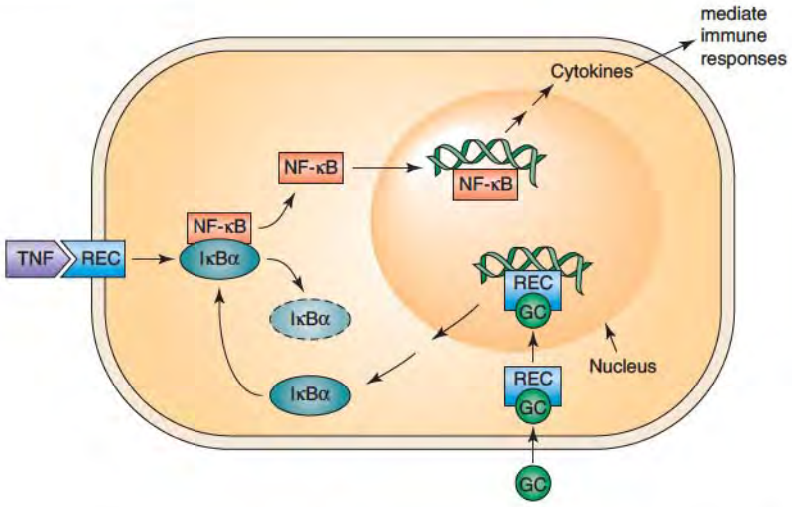

Figure 22.50 Action of glucocorticoids in suppressing immune and inflammatory responses mediated by cytokines. Abbreviations: REC, glucocorticoid receptor; GC, glucocorticoid hormones; TNF, tumor necrosis factor; and NF-κB, nuclear factor kappa B. Redrawn from Marx, J. *Science* 270:232, 1995.

Glucocorticoids also interfere with the transcription factor **nuclear factor kappa B (NF-κB)**, which in unstimulated immune cells is retained in the cytoplasm complexed with either **IκBα** or the structurally related **IκBβ** (I for "inhibitor"). Stimulation of immune cells by any one of several immune signals, for example tumor necrosis factor, causes phosphorylation of **IκBα** on serines 32 and 36, which leads to ubiquitination and subsequent degradation via proteasomes. This degradation then releases NF-κB, which has been trapped in the cytoplasm in an inactive form, from this complex and it migrates into the nucleus. Once in the nucleus it induces genes for cytokines, such as interferons and interleukins, which activate immune cells, as well as cell adhesion molecules that draw immune cells into inflammatory sites. Glucocorticoids suppress this immune cell activation (Figure. 22.50) by inducing IκBα gene transcription and ensuring that NF-κB is retained in the cytoplasm in its inactive form under conditions where it should migrate into the nucleus and induce gene transcription.

Some members of the steroid receptor super family mediate gene silencing. Silencer elements in DNA, like enhancer elements, function independently of their position and orientation. The silencer for a gene consists of modules that independently repress gene activity. Unliganded **thyroid hormone receptors (T_3R)** and **retinoic acid receptors (RAR)** bind specific silencer elements and repress gene transcription. After ligand binding, these receptors lose this silencing activity and function as transactivators.

Dimerization is a prerequisite for efficient DNA binding and transcriptional activation by most steroid receptors, and is mediated by their ligand-binding domains. The dimerization region of this domain may form a leucine zipper-like structure or a helix-turn-helix motif (p. 322), which is necessary for dimerization in other transcription factors. Most steroid receptors form homodimers. However, **retinoid X receptors** (RXRs) form heterodimers with the retinoic acid receptor, the thyroid hormone receptor, or other members of this receptor superfamily. A model for the stabilization of the transcriptional preinitiation complex by an RXR/RAR heterodimer is presented in Figure 22.51.

Steroid Receptor Domains

Glucocorticoid receptors contain three major **functional domains** (Figure 22.52). Located at the C-terminus, the steroid-binding domain has 30%–60% homology with the **ligand-binding domains** of other steroid receptors (Clin. Corr. 22.6). This domain may also be involved in the binding of a dimer of the 90-kDa heat shock protein, which (1) maintains this domain in optimal conformation for steroid binding and (2) prevents unliganded receptor from binding to DNA. To the left of this domain are a transcription activation region and a nuclear localization signal, which appear to provide recognition for the nuclear pore. At about the center is the **DNA-binding domain**, which shows 60%–95% homology among steroid receptors and contains two zinc fingers that recognize specific HREs and stabilize binding to these DNA sequences. The N-terminal

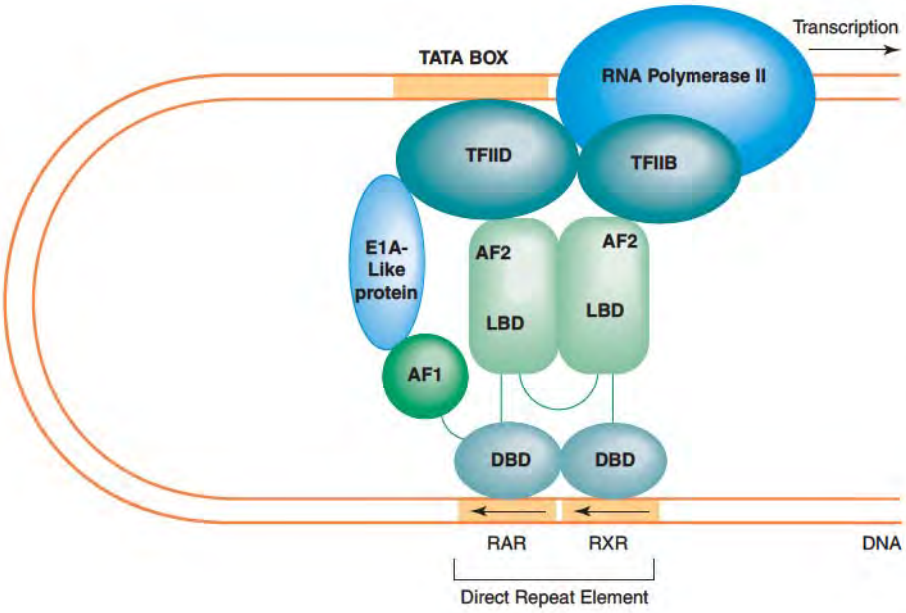

Figure 22.51 Model for stabilization of preinitiation complex by an RXR/RAR heterodimer. Abbreviations: TF, transcription factor; LBD, ligand-binding domain; DBD, DNA-binding domain; AF1, activation function located in amino terminal region of receptor, which may provide contact with cell specific proteins; AF2, activation function located within ligand-binding domain, which interacts directly with transcriptional machinery; and E1A, adenovirus oncoprotein that functions as a tumor suppressor.

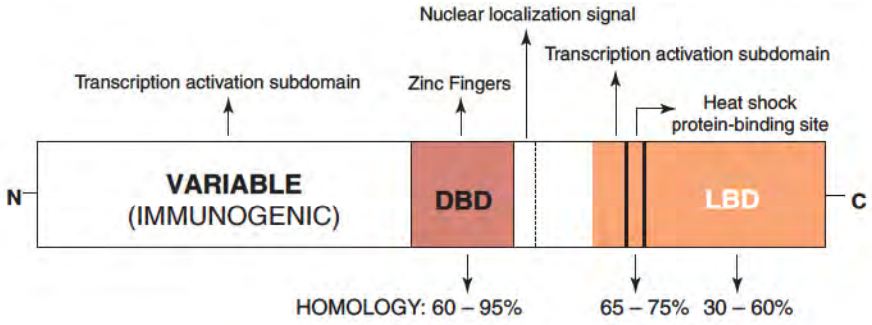

Figure 22.52 Major functional domains of steroid receptor proteins. Abbreviations: DNA, DNA-binding domain; and LBD, ligand-binding domain.

CLINICAL CORRELATION 22.6

Mineralocorticoid Receptor Mutation Results in Hypertension and Toxemia of Pregnancy

The underlying causes of hypertension, especially the hypertension associated with the toxemia of pregnancy, which is called eclampsia, include the renin–angiotensin system and the aldosterone receptor. Hypertension occurs in about 6% of pregnancies and in some cases is associated with a mutation in the mineralocorticoid receptor in which a serine residue at position 810 is replaced by a leucine residue (referred to as S810L mutation). The mutated serine is in the hormone-binding domain of the receptor and is conserved in all mineralocorticoid receptors across many species. Interestingly, the S810L mutant receptor binds progesterone with the same high affinity as aldosterone. In the normal wild-type receptor, progesterone binds with low affinity and functions as an antagonist. However, in the mutant form of the receptor progesterone functions as an agonist and induces reabsorption of sodium ions in the kidney. Since plasma progesterone levels increase significantly during pregnancy (see Figure 22.20, p. 905), the mutated receptor is continuously saturated with this steroid. In subjects under age 35 carrying the mutated receptor, the systolic to diastolic blood pressure ratio is 167/110, as compared with 126/78 (normal range) in noncarriers. Spironolactone, which functions as an aldosterone antagonist when bound to the normal wild-type receptor, functions as an agonist when bound to the mutated receptor. Therefore, spironolactone should not be used to treat hypertensive patients bearing the S810L mutation. This mutated receptor could be an important factor contributing to the early development of heart failure in seriously hypertensive patients.

Geller, D. S., Farhi, A., Pinkerton, N., Fradley, M., et al. Activating mineralocorticoid receptor mutation in hypertension exacerbated by pregnancy. *Science* 289:119, 2000.

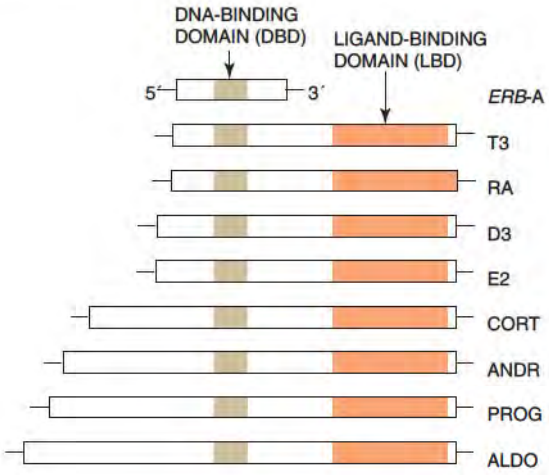

Figure 22.53 Steroid receptor gene superfamily. Abbreviations: T3, triiodothyronine; RA, retinoic acid; D3, dihydroxy vitamin D3; E2, estradiol; CORT, cortisol; ANDR, androgen; PROG, progesterone; ALDO, aldosterone. Figure shows roughly the relative sizes of the genes for these receptors.

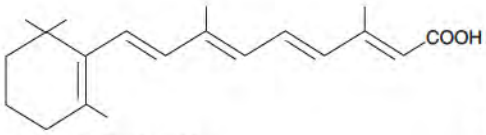
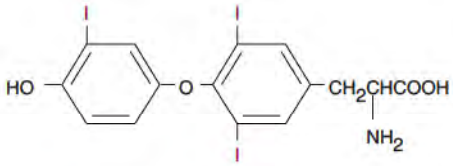


Retinoic acid
(vitamin A acid)



3,5,3' - Triiodothyronine

Figure 22.54 Structures of retinoic acid (Vitamin A acid) and 3,5,3′-triiodothyronine.

domain is highly variable and contains the principal **antigenic region** and a region that modulates transcriptional activation. These features are common to all members of the steroid receptor superfamily (Figure 22.53). The ancestor of these receptor genes is the gene for v-erbA or c-erbA, which is an oncogene product that binds to DNA but has no ligand-binding domain. The DNA-binding domains of some of these receptors are homologous enough that more than one receptor binds to a common responsive element (see Table 22.10). The **aryl hydrocarbon receptor** (Ah) may also be a member of this family. It binds carcinogens with an affinity that parallels their carcinogenic potency and translocates these compounds into the nucleus. Thyroid hormone and retinoic acid receptors are members of this superfamily of receptors. Their ligands are not steroids, but do contain two or one six-membered rings, respectively, as shown in Figure 22.54. The A ring of most steroids is recognized by the appropriate receptor and inserts into the pocket of the ligand-binding domain. Again, all of these receptors form homodimers or heterodimers, function as ligand-activated transcription factors, and modulate (induce or repress) the expression of specific genes.

Orphan Receptors

Many related receptors were originally called **orphan receptors**, as no physiological ligands or activators were known for them. They are found in almost all animal species. Examples of orphan receptors for which the ligand has now been identified include BXR (**b**enzoate **X** **r**eceptor), **RXR** (**r**etinoid **X** **r**eceptor), **PPAR** (**p**eroxisome-**p**roliferator-**a**ctivated **r**eceptor), **CAR**β (**c**onstitutive **a**ndrostane **r**eceptor), PXR (**p**regnane **X** **r**eceptor); **SXR** (**s**teroid and **x**enobiotic **r**eceptor), and **FXR** (**f**arnesoid **X** **r**eceptor). PXR, SXR, and CARβ are highly expressed in the liver, respond to specific steroid ligands, and require heterodimerization with RXR for DNA binding. They and their respective ligands may be important physiologically and have an impact on specific human diseases. For example, the human SXR can be activated by a diverse group of steroid agonists and antagonists. The activation induces transcription of several genes encoding key degrading enzymes and may facilitate the detoxification and removal of various endogenous hormones, dietary steroids, drugs, and xenobiotic compounds with biological activity. In patients receiving steroid therapy or women taking oral contraceptives, certain drugs (i.e., rifampicin) that bind to SXR can cause rapid depletion of the administered steroids by this increased steroid catabolism.

Down-regulation of Steroid Receptor by Ligand

Many hormone receptors are down-regulated when the cell has been exposed to a certain concentration of the cognate hormone. In the case of intracellular hormone receptors,

down-regulation generally means a ligand-induced decrease in the half-life of the receptor protein and a decreased receptor gene expression with a decrease in the concentration of receptor molecules. The promoter of a receptor gene may thus have a negative response element and binding of the steroid–receptor complex to that element will repress transcription of the receptor gene. Down-regulation of receptors by their own ligands plays an important physiological role, because it desensitizes the target cell and therefore prevents overstimulation when circulating hormone levels are elevated.

Although down-regulation of steroid receptors by their cognate hormones appears to be the most common form of autoregulation, it is not detected in all target cells. Glucocorticoid-mediated up-regulation of its own receptor levels has been reported in a number of responsive cells. In theory this **homologous up-regulation** could increase hormonal responsiveness. The ability of the estrogen receptor to increase the concentration of progesterone receptors in key target tissues is an example of **heterologous up-regulation**.

Nuclear Hormone Receptors, Coactivators, and Corepressors

Coactivators and corepressors are cofactors that increase or decrease the transcriptional functions of most nuclear steroid–receptor complexes. Coactivators, such as the p160 family of coactivators, steroid receptor coactivator 1, transcriptional intermediary factor 2 (TIF2), and GR-interacting protein (GRIP1) all increase the amount of induced gene product with a saturating concentration of a steroid hormone. Conversely, corepressors such as nuclear receptor corepressor (NcoR) and the silencing mediator of retinoid and thyroid hormone receptor (SMRT) decrease the amount of gene product. Binding of the cognate ligand to one of these receptors acts like a "molecular switch", causing dissociation of corepressors from the receptor and association of coactivators. The sites of interaction in steroid and nuclear receptors for both coactivators and corepressors have been shown to be present in the ligand-binding domain, and these two binding sites may overlap.

Although corepressors do not bind to ligand-bound nuclear receptors such as the thyroid hormone receptor, they do appear to interact with nuclear ligand-bound steroid receptors. This interaction may provide a mechanism of differentiating between activated complexes of various steroid receptors (androgens, glucocorticoid, mineralocorticoid, and progestin) in a cell-specific manner. Although each of theses receptors binds its ligand specifically, once activated they bind to the same hormone response element (see Table 22.10). Interactions between cell-specific corepressors and DNA-bound receptors can restore some of the specificity that appears to be lost on binding to a common HRE.

Nongenomic Steroid Effects

Not all effects of steroid hormones are mediated at the level of gene transcription. Many steroid hormones, including aldosterone, 17β-estradiol, progesterone, glucocorticoids, and androgens, exert rapid (within minutes) stimulatory effects on the activities of a wide variety of signal transduction molecules (protein kinase C, diacylglycerol, and IP_3) and pathways. These **nongenomic effects** appear to be initiated at the plasma membrane rather than in the nucleus of a target cell. These non-transcriptional responses may be mediated either by a subpopulation of conventional nuclear receptors localized in the cell membrane or by distinct **membrane receptors** that are unrelated to classical intracellular steroid receptors. Some arguments in favor of novel membrane receptors include (1) rapid steroid responses appear to be mediated through receptors with pharmacological properties very different from those of classic intracellular receptors. (2) steroids exert rapid nongenomic effects in cells or tissues that do not express classic intracellular receptors, and (3) these rapid steroid effects are not blocked by classic receptor antagonists. The cloning and functional reexpression of unrelated proteins transmitting rapid steroid effects has yet to be accomplished. Drugs that specifically affect nongenomic steroid action may find applications in various clinical areas including cardiovascular and central nervous system disorders, electrolyte homeostasis, and infertility.

11β-hydroxysteroid dehydrogenase
cyclooxygenase
nuclear factor kappa B
DNA-binding domain
nongenomic effects

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. If a single gene contains information for synthesis of more than one hormone molecule,
   - **A.** all the hormones are produced by any tissue that expresses the gene.
   - **B.** all hormone molecules are identical.
   - **C.** cleavage sites in the gene product are typically pairs of basic amino acids.
   - **D.** all peptides of the gene product have well-defined biological activity.
   - **E.** hormones all have similar function.

2. In the interaction of a hormone with its receptor, all of the following are true except
   - **A.** more than one polypeptide chain of the hormone may be necessary.
   - **B.** more than one second messenger may be generated.
   - **C.** an array of transmembrane helices may form the binding site for the hormone.
   - **D.** receptors have a greater affinity for hormones than for synthetic agonists or antagonists.
   - **E.** hormones released from their receptor after endocytosis could theoretically interact with a nuclear receptor.

3. Some hormone–receptor complexes are internalized by endocytosis. This process may involve
   - **A.** binding of hormone–receptor complex to a clathrin coated pit.
   - **B.** recycling of receptor to cell surface.
   - **C.** degradation of receptor and hormone in lysosomes.
   - **D.** formation of a receptosome.
   - **E.** all of the above.

4. Epinephrine
   - **A.** mediates its effects by binding to cytoplasmic receptors.
   - **B.** is synthesized in the adrenal cortex.
   - **C.** is synthesized from norepinephrine by a methyl transferase (PNMT).
   - **D.** leads to the formation of cGMP.
   - **E.** produces DAG and IP_3.

5. Binding of insulin to its receptor
   - **A.** occurs on the β-subunit.
   - **B.** induces autophosphorylation.
   - **C.** reduces binding of cytosolic substrate proteins.
   - **D.** leads only to phosphorylation of proteins.
   - **E.** does not lead to release of a second messenger.

6. Glucocorticoid receptors are in the cytoplasm. All of the following statements about the process by which the hormone influences transcription are correct except
   - **A.** the hormone must be in the free state to cross the cell membrane.
   - **B.** cytoplasmic receptors may be associated with heat shock proteins.
   - **C.** the receptor–hormone complex is not activated/transformed until it is translocated to the nucleus.
   - **D.** in the nucleus, the activated/transformed receptor–hormone complex searches for specific sequences on DNA called HREs (hormone receptor elements).
   - **E.** the activated receptor–hormone complex may either activate or repress transcription of specific genes (only one activity per gene).

Questions 7 and 8: Aldosterone bound to its receptor promotes sodium reabsorption in the distal nephron of the kidney. Elevated sodium in the blood leads to hypertension which can be a serious problem in pregnancy. In some cases, hypertension that appears in early pregnancy and increases with time has been shown to be caused by a mutation in the mineralocorticoid receptor. The mutation allows progesterone to bind with the same affinity as aldosterone and thus act as an agonist. Because of the high levels of progesterone during pregnancy, the mutated receptor remains saturated and blood pressure can become dangerously high. Spironolactone, which acts as an antagonist of aldosterone with a normal receptor, acts as an agonist with the mutated receptor and should not be used to treat this kind of hypertension.

7. All of the following are normal events leading to secretion of aldosterone from the adrenal gland except
   - **A.** renin is released by the kidney in hypovolemia.
   - **B.** angiotensinogen binds to membrane receptors.
   - **C.** the PI cycle is activated producing IP_3 and DAG.
   - **D.** Ca^{2+} levels in the cell rise.
   - **E.** aldosterone is secreted into the blood.

8. Once ovulation occurs, the pathway followed differs when the egg is fertilized and when it is not. Which of the following statements about this process is/are correct?
   - **A.** FSH, via cAMP as a second messenger, stimulates the follicle to release 17β-estradiol.
   - **B.** Blood levels of progesterone fall as pregnancy progresses as the corpus luteum dies.
   - **C.** Inhibin produced by the follicle prevents release of LH.
   - **D.** The primary influence for the corpus luteum to produce progesterone and estradiol is FSH.
   - **E.** All of the above.

Questions 9 and 10: Hypopituitarism may result from trauma, such as an automobile accident severing the stalk connecting the hypothalamus and anterior pituitary, or from tumors of the pituitary gland. In trauma, usually all of the releasing hormones from hypothalamus fail to reach the anterior pituitary. With a tumor of the gland, some or all of the pituitary hormones may be shut off. Posterior pituitary hormones may also be lost. Hypopituitarism can be life threatening. Usual therapy is administration of end organ hormones in oral form.

9. If the stalk between the hypothalamus and anterior pituitary is severed, the pituitary would fail to cause the ultimate release of all of the following hormones except
   - **A.** ACTH.
   - **B.** estradiol.
   - **C.** oxytocin.
   - **D.** testosterone.
   - **E.** thyroxine.

10. In hypopituitarism the ovarian cycle would be affected because
    - **A.** FSH and LH are synthesized in the anterior pituitary.
    - **B.** gonadotropin-releasing hormone (GnRH) from the hypothalamus stimulates the release of FSH and LH.
    - **C.** inhibins would be secreted in much larger than normal amounts.
    - **D.** the corpus luteum would be maintained.
    - **E.** GnRH would bind to receptors to activate protein kinase A.

Questions 11 and 12: Manic-depression may be caused by overactivity of certain central nervous system cells, perhaps caused by an overstimulation of the phosphatidylinositol (PI) cycle. Lithium has been used in the treatment of this condition as it slows the PI cycle despite continued stimulation and cells may become less sensitive to these stimuli. Li^+ may have two functions: inhibition of the phosphatase that dephosphorylates IP_3 and direct interference with the function of G proteins.

11. The PI cycle begins with activation of phospholipase C; this initiates a sequence of events including all of the following except
    A. activation of IP_3 by action of a phosphatase.
    B. increase in intracellular Ca^{+2} concentration.
    C. release of diacylglycerol (DAG).
    D. activation of protein kinase C.
    E. phosphorylation of certain cytoplasmic proteins.

12. Which of the following statements concerning G proteins is correct?
    A. G proteins bind the appropriate hormone at the cell surface.
    B. G proteins interact with cytoplasmic receptors.
    C. G proteins are second messengers.
    D. G protein causes the regulatory subunits of the protein kinase to dissociate from the catalytic subunits.
    E. activated G protein may either activate or inhibit the production of second messenger.

Problems

13. How is the iodine present in thyroid hormones conserved by the body?

14. What is the relationship between 7-dehydrocholesterol and 1α,25-dihydroxycholecalciferol?

Answers

1. **C** One or more trypsin-like proteases catalyze the reaction. A: The POMC gene product is cleaved differently in different parts of the anterior pituitary. B: Multiple copies of a single hormone may occur, but not necessarily. D: Some fragments have no known function. E: ACTH and β-endorphin, for example, hardly have similar functions.
2. **D** β-receptors bind isoproterenol more tightly than their hormones. A and B: These are true of glycoprotein hormones. C: This appears to be true for β_1-receptor. E: This is possible, but entirely speculative; there are currently no known examples.
3. **E** A and D always happen. B or C happens sometimes.
4. **C** This is induced by cortisol under stress. A: Its receptor is on the plasma membrane. B: This is where steroid hormones are made. Epinephrine is made in the adrenal medulla. D and E: Epinephrine stimulates protein kinase A and leads to cAMP.
5. **B** This occurs on tyrosine residues of the β-subunit. A: Binding is to the α-subunit. C: Autophosphorylation facilitates binding. D: Some proteins are dephosphorylated. E: A second messenger may account for short-term metabolic effects.
6. **C** Dissociation of the heat shock protein from the receptor–hormone complex in the cytosol activates the complex. A: Steroid hormones travel bound to plasma proteins, but some is always free. D: These are consensus sequences in DNA. E: Activation is more common, but glucocorticoids repress transcription of the proopiomelanocortin gene.
7. **B** Angiotensinogen is cleaved by renin to angiotensin I, which must further be cleaved by converting enzyme to active angiotensin II. A: This is a major signal. C and D: These lead to increased Ca^{2+} and activation of protein kinase C.
8. **A** Activation of cAMP-dependent protein kinase stimulates the synthesis and secretion of estradiol. B: This is what happens in the absence of fertilization. In pregnancy, the corpus luteum eventually dies but the placenta produces high levels of progesterone. C: Inhibin controls FSH release. D: LH controls the corpus luteum.
9. **C** Oxytocin is released from the posterior pituitary. A, B, D, and E all require releasing hormones from the hypothalamus for the anterior pituitary to release them.
10. **B** FSH and LH are released from the anterior pituitary. A: See previous statement. C: Inhibins are formed and secreted by the ovarian follicle. D: FSH and LH are needed to stimulate the ultimate formation of the corpus luteum. E: GnRH receptors are in the anterior pituitary and stimulate the PI second messenger system.
11. **A** IP_3 is the active form. Action of phosphatase renders IP_3 inactive. B: IP_3 causes release of Ca^{+2}. C and D: This is a second messenger and it activates protein kinase C. E: This is what protein kinase C does.
12. **E** There are both stimulatory and inhibitory G protein subunits; which is activated depends on the hormone–receptor complex. A: G protein interacts with receptors, not with the hormone. B: This is a plasma membrane phenomenon. C: They lead to the production of the second messenger. D: That is the function of the second messenger.
13. Various levels of iodinated tyrosyl residues are present in thyroglobulin, which is taken into cells by endocytosis. Hydrolysis by lysosomal proteases releases the hormones T_3 and T_4, and also mono- and diiodothyronines. The last two are deiodinated and the iodide ion trapped and reused for thyroid hormone synthesis.
14. 1α,25-dihydroxycholecalciferol ($1,25(OH)_2D_3$) is the active from of vitamin D. Ultraviolet light acting on the skin converts 7-dehydrocholesterol to cholecalciferol. This compound must be hydroxylated in liver to 25-hydroxycholecalciferol and subsequently in kidney to yield the active $1,25(OH)_2D_3$.

Key Concepts

NERVOUS TISSUE: METABOLISM AND FUNCTION

- Nerve tissue primarily uses glucose as an energy source. The membrane potential of nerve cells is maintained at –70 mV through the action of the Na^+, K^+ ion pump.
- Nerve impulses are propagated through a depolarization process involving voltage-gated ion channels leading to localized depolarization. Transmission from neuron to neuron proceeds through synapses that are electrically or chemically coupled.
- Chemically coupled synapses operate by secreting into the spaces between neurons neurotransmitters that bind to receptors on the postsynaptic side. This initiates an electrical response.
- Actions of neurotransmitters can be either excitatory or inhibitory. Effects are rapid and transient and are terminated by reuptake, metabolism, and/or diffusion of the neurotransmitter.

THE EYE: METABOLISM AND VISION

- The eye is an extension of the nervous system and derives most of its energy from glucose metabolism. Eye structures through which light must pass before reaching the retina have very few mitochondria or other pigmented subcellular particles.
- The corneal epithelium is permeable to atmospheric oxygen and is protected from active oxygen species by operation of the NADPH glutathione reductase system.

- The lens is an active metabolizing tissue with no blood supply and no subcellular structures. Osmotic balance is maintained by Na^+/K^+ ATPase and redox balance by a glutathione reductase system.
- The retina is a vascular tissue that contains the photo (visual) receptors (rods and cones). It has no blood vessels in the area of greatest visual acuity, but the rods and cones contain a blood supply and mitochondria.
- Vision is a four-event process: involving photons of light, a light-induced isomerization, a signal transduction, and a mental interpretation of the objects in question—"in the mind's eye."
- The proteins of the visual pigments contain 11-*cis* retinal, a derivative of β-carotene (vitamin A_1). Isomerization of 11-*cis*-retinal to all-*trans*-retinal forces a conformation change of the protein of the visual pigments, leading to activation of transducin, a G-protein.
- The α-transducin–GTP subunit complex activates a phosphodiesterase that hydrolyzes cGMP resulting in closure of Na^+ channels, hyperpolarization of the membrane, and generation of an electric impulse. Hydrolysis of GTP in the α-transducin-GTP complex allows return of the membrane to the resting state.
- The same processes occur in the cones for color vision. There are three different pigments sensitive to red, green, or blue light found in different cones. Color vision results from graded stimulation of cones containing specific pigments and interpretation of these stimuli by the brain—"in the mind's eye."

MOLECULAR MOTORS AND ASSOCIATED PROTEINS

- Muscles contract when myosin and actin are pulled past each other shortening the sarcomere, the contractile unit. Myosin's actions are driven by the different conformations it takes when bound to ATP, ADP, and during the myosin catalyzed conversion of ATP to ADP.
- Signal transduction for contraction goes from electrical to chemical to mechanical. The initial stimulus originates at the neuromuscular junction with release of acetylcholine and its binding to receptors. This results in release into the sarcomere of Ca^{+2} that binds troponin-C. Troponin-C–Ca^{2+} complexes cause conformation changes in tropomyosin that initiates the contractile process.
- In skeletal muscle the *power stroke* for contraction occurs upon release of phosphate following ATP hydrolysis. The concentration of ATP in muscle is maintained by metabolism, and by actions of creatine phosphokinase and adenylate kinase.
- Smooth muscle contraction occurs more slowly. Ca^{2+} influx and the phosphorylation of myosin by a specific Ca^{2+}-calmodulin-activated kinase initiates contraction. Control is influenced by hormones that affect Ca^{2+} influx.
- Several classes of *unconventional myosins* are involved in cellular functions such as membrane–membrane interaction, melanosome transport, and movement of hairs in the inner ear.
- Kinesins are microtubule-based molecular motors that generate motion by conformational changes associated with ATP binding and hydrolysis. A major function of kinesins is to effect movement of intracellular cargo.
- The two classes of dynein molecular motors are axonemal and cytoplasmic. Dynein movement along tubules is in the opposite direction of that of kinesins and they are cargo-moving motors. Their movement is load dependent; the heavier the load of the cargo, the shorter the individual steps.

MECHANISM OF BLOOD COAGULATION

- The process of blood coagulation begins at the site of injury to the blood vessel with formation of multienzyme complexes. There are two general pathways: extrinsic and intrinsic. They merge at the point of activation of factor X, an enzyme that converts prothrombin to thrombin.
- The extrinsic pathway plays a major role in initiating the process and the intrinsic pathway plays a major role in amplifying the process.
- Thrombin catalyzes the conversion of fibrinogen to fibrin, the major clot-forming protein. Formation of some of the active multienzyme complexes requires protein cofactors and Ca^{2+}, which facilitates formation of the complexes by binding to γ-carboxyglutamate residues in the proteins.
- Catalytic action of the proteases is inhibited by interaction with specific protein inhibitors in the blood.
- The clot is dissolved through action of plasmin formed by activation of plasminogen by tissue plasminogen activator, t-PA.

23.1 • NERVOUS TISSUE: METABOLISM AND FUNCTION

Essential Concepts

Approximately 2.4% of an adult's body weight is nerve tissue, 83% of which is the brain. The nervous system provides the communications network between the senses, the environment, and all parts of the body. The brain is the command center. It must function all the time, and as a consequence of this demand, it requires a large amount of energy. Under normal conditions, the brain derives its energy from glucose metabolism. Ketone bodies can cross the **blood–brain barrier** and are metabolized by brain tissue, especially during **starvation**, but they cannot replace the requirement for glucose. The human brain uses approximately 103 to 120 grams of glucose/day. For a 1.4-kg brain, this corresponds to an average rate of utilization of approximately 0.3 micromole/min/g of tissue and represents a capacity for ATP production through the tricarboxylic acid (TCA) cycle alone of approximately

6.2 micromoles/min/g of tissue. The TCA cycle is multifunctional, and all of the carbon that flows through it is not used for ATP production. Also, all glucose metabolized by nerve tissue is not metabolized by the TCA cycle. The TCA cycle, however, does function at near maximum capacity and generates most of the ATP used by nerve tissue. Much of the energy used by nerve tissue is to maintain ionic gradients across plasma membranes, to affect various storage and transport processes, and to synthesize neurotransmitters and other cellular components. Glycolysis functions at approximately 20% capacity, and in some parts of the nervous system is the predominant source of ATP production.

The central nervous system contains a higher level of lipids than any other tissue in the body except adipose tissue. Many of these lipids are specialized and complex lipids, and they play important roles in many aspects of brain metabolism, but generally not as a major source for energy production.

There is a relatively rapid **turnover rate** of brain proteins compared to that of other tissues such as muscle and liver although neuronal cells generally do not divide after they have differentiated. Nerve tissue can be injured in many ways. and there is experimental evidence suggesting that regeneration of neuronal tissues may occur faster than originally thought.

Cells of the nervous system responsible for collecting and transmitting messages are highly specialized **neurons** (Figure 23.1). Each neuron consists of a cell body, **dendrites** that are short antenna-like protrusions that receive signals from other cells, and an **axon** that extends from the cell body (presynaptic neuron) to other neurons (postsynaptic neurons), cells to which it transmits signals. The central nervous system (CNS) is highly integrated where individual neurons can receive inhibitory and excitatory stimuli from a variety of different sources. A normal adult has between 10^{11} and 10^{13} neurons, and communication between them is by electrical and chemical signals. Stem cells found in brain can produce three major types of cells: neurons, **astrocytes**, and oligodendrocytes. Astrocytes are glial cells that are associated with greater than 90% of the blood–brain-barrier endothelium and help to determine blood–brain-barrier morphology and function. Astrocytes send out processes at the external surfaces of the CNS that are linked, with other cell types, to form anatomical complexes that provide sealed barriers at the level of the capillaries and isolate the CNS from the external environment. These tight junctions prevent the passive entry into the brain of water-soluble molecules and form what is commonly known as the **blood–brain barrier** (Figure 23.2). In general, therefore, water-soluble compounds enter the brain only if there are specific membrane transporters for them (Clin. Corr.23.1). Oligodendrocytes surround the axons like insulators and facilitate efficient signal conduction. There are other types of glial cells, each of which has a specialized function, but only astrocytes appear to be directly associated with a biochemical function related to metabolic neuronal activity (p. 950). Some glial cells, astrocytes specifically, have been shown to use intermediary metabolites other than glucose as a source of energy. Astrocytes in culture can oxidize fatty acids; apparently by β-oxidation, but also yielding ketone bodies, specifically from the last four carbons (ω-end) of the chain, as major products. Ketone bodies can be used by other brain cells as a source of energy.

CLINICAL CORRELATION 23.1

The Blood–Brain Barrier and Defects in Glucose Transport

De Vivo disease is an inherited autosomal dominant disease caused by a deficiency of glucose in brain due to defective GLUT1, a glucose transporter responsible for getting glucose across the blood–brain barrier (p. 489) (OMIM 138140). The symptoms of De Vivo disease, also referred to as GLUT1 syndrome, are expressed early in life. Deficiency of brain glucose may result in infantile seizures, delayed development, microcephaly, and other mental disorders. Infantile seizures may appear at 1–4 months of age. The frequency of seizures may decrease during an illness that causes the infant to become somewhat ketotic. A ketogenic diet is used to help control the seizures. There appears to be a critical time during developmental stages when glucose and/or some of its metabolites are essential for activities other than energy production.

ATP and Transmembrane Electrical Potential in Neurons

Neurons have a resting transmembrane potential of approximately −70 mV. This transmembrane potential is due to the following factors: The membrane is essentially completely permeable to K^+, only very slightly permeable to Na^+, and impermeable to intracellular anions; the membrane also contains a **Na^+/K^+-exchanging ATPase** that pumps Na^+ out of the cell by an antiport mechanism where K^+ is moved into the cell. The action of the pump (Na^+/K^+ ATPase) and differential permeability of the membrane to Na^+ and K^+ establish ionic gradients across the membrane where Na^+ is higher on the outside and K^+ is higher on the inside of the cell. There is the tendency for K^+ to flow out of the cell down its chemical concentration gradient; this would leave the inside negative due to the intracellular concentrations of anions that cannot cross the membrane. As K^+ tends to flow out of the cell down its concentration gradient, negative charges of the anions tend to pull K^+ back into the cell. These two opposing forces (plus the very slight permeability to Na^+) achieve an equilibrium at a transmembrane potential of −70 mV; that is, the chemical concentration gradient that moves K^+ out of the cell is balanced by the negative charge inside the cell that operates to pull K^+ back into the cell.

Generation of an action potential in a neuron requires the initiation of an event that will effect depolarization of the membrane such that the transmembrane potential reaches +20 to +30 mV. This is accomplished by opening Na^+ channels and permitting enough Na^+ to flow into the cell to reverse the membrane's polarity by 90 to 100 mV. Thus, when Na^+ channels open under the influence of electrical stimulation generating an action potential, sodium ions move down their chemical concentration gradient into neurons through voltage-gated channels. This is followed by movement of potassium ions out of neurons. The Na^+/K^+-exchanging ATPase eventually reestablishes the ionic gradients and restores the resting state.

An electrical impulse is generated and propagated down the axon by a process of depolarization of voltage-gated channels during which time Na^+ enters the cell. Channel proteins undergo a charge-dependent conformational change that triggers their opening when the electrical potential across the membrane reaches a threshold voltage of +20 to +30 mV. When the membrane becomes depolarized, Na^+, whose concentration is higher outside of the cell than inside, flows into the cell and K^+, whose concentration is higher inside the cell, flows out of the cell; both move down their respective concentration gradients. The channels are open in a defined region of the cell membrane for fractions of milliseconds (Figure 23.3). The localized depolarization (voltage changes due to Na^+ influx) causes a conformational change in the neighboring proteins of **voltage-gated ion channels** (p. 481). These adjacent channels open momentarily in response to the localized depolarization and allow the process to continue down the axon. Since there is a finite recovery time greater than the resident time of Na^+ within that region during which time the signal for reopening diminishes, charge propagation proceeds in one direction. This recovery time for channels to reopen is related to the time required to reestablish a membrane potential below the excitation threshold value (by action of the Na^+/K^+ exchanging ATPase) and protein conformational changes required to close and reset the channel gate. Thus, progressive depolarization and repolarization along the length of the axon allows electrical impulses to be propagated undiminished in amplitude and direction. A cartoon of how a sensor for a voltage-gated potassium channel may appear and operate in a membrane is shown in Figure 23.3*c*. When the inside of the cell becomes more positive due to a depolarization event, the channel protein undergoes a conformation change, opens the gate, and K^+ is permitted to flow out of the cell down its concentration gradient. This helps to minimize the extent to which that localized region of the membrane stays above the excitation threshold voltage.

Voltage-gated ion channels of primary concern are Na^+, K^+, and Ca^{2+}. They show varying degrees of overall structural diversity, but a high degree of conservation within the pore-forming regions. Each has a selectivity filter that determines which ion will be permitted to flow through its pore (Figure 23.4, p. 944). The selectivity filter uses chemical features of the protein's structural components to mimic the hydration sphere of the ions leading to dehydration; rehydration occurs as the ions exit the filter.

Neuron–Neuron Interaction Occurs through Synapses

Neuron–neuron interaction occurs through **electrical synapses** or through **chemical synapses**. Electrical synapses permit the more rapid transfer of signals from cell to cell. Chemical synapses allow for a greater degree of chemical versatility in neuron–neuron communication. Pathological events that affect proper functioning of chemical synapses are also more accessible to therapeutic drug interventions.

Chemical synapses are of two types: those where the neurotransmitter binds directly to an ion channel (neuron–neuron) and causes it to open or to close and those where the neurotransmitter binds to a receptor that leads to generation of a second messenger (smooth muscles, for example) that reacts with ion channels causing them to open or to close. Note that propagation of an impulse down an axon occurs by the operation of voltage-gated channels and that the chemical transmission of an impulse across the synapse is by ligand-gated channels.

Chemical neurotransmitters are found in presynaptic axon termini and so are enzymes for their syntheses. Electrical or physiological stimulation of the presynaptic axon results in their release. Mechanisms exist within the synaptic junction for rapid termination of their action. Direct application of appropriate neurotransmitters to the postsynaptic terminal mimics in that neuron the action of nervous stimulation. Drugs that modify the metabolism of neurotransmitters have physiological effects consistent with *in vivo* modification of actions of the neurotransmitters.

Chemical neurotransmitters are of two general types: excitatory and inhibitory. **Excitatory neurotransmitters** include acetylcholine and the catecholamines. **Inhibitory neurotransmitters** include **γ-aminobutyric acid** (**GABA** or 4-aminobutyric acid), glycine, and taurine (Table 23.1). Glycine acts predominantly in the spinal cord and the brain stem; GABA acts predominantly in other parts of the brain. **Strychnine** (Figure 23.5), a highly poisonous alkaloid obtained from *Nux vomica* and related plants of the genus *Strychnos,* binds to **glycine receptors**. It has been used in very small doses as a CNS stimulant. Can you propose how it works? **GABA receptors** also react with a variety of pharmacologically significant agents such as **benzodiazepines (Valium)** (Figure 23.6) and barbiturates. There is little structural similarity between GABA and benzodiazepines.

Genes for some of the receptors have been cloned, including those for **nicotinic/acetylcholine**, glycine, glutamate, and GABA and X-ray crystallographic structures of some have been determined.

A model of the GABA receptor is shown in Figure 23.7. This receptor has an $\alpha_2\beta_2\gamma_2$ composition. This model shows areas where GABA binds and where some pharmacological agents such as benzodiazepines (Bz), an antagonist, bind. The subunits of the receptor form channels through which small negative ions (Cl^-) flow into the cell under normal stimulation by GABA making the inside of the cell more negative. Thus, inhibitory neurotransmitters make depolarization more difficult because enough Na^+ must flow into the neuron to overcome the increased negative charges of excess Cl^- as well as create a polarization value above the threshold potential.

Chloride ion (Cl^-) channels differ significantly from cation channels (Na^+, K^+, and Ca^{2+}). The Cl^- channel is a two-barrel antiparallel structure in which the ion selectivity filter is formed mostly by the charged polarized ends of helices. These are shown in Figure 23.8*a*, p. 945, in a 2-D linear conformation. A 3-D conformational arrangement with a Cl^- within the filter is shown in Figure 23.8*b*. It is assumed that this selectivity filter does not use more positively charged amino acid residues because the stronger ionic interaction would impede Cl^- movement through the channel.

Excitatory neurotransmitters are released after stimulation of the neuron, traverse the synapse, and bind to specific receptors on the postsynaptic junction to elicit a response in its targeted postsynaptic cell. They cause depolarization of the membrane by opening channels permitting the influx of Na^+. They interact with ligand-gated receptors (p. 478). When no ligand is bound, the receptor is at rest and the ion channel is closed. Binding of ligand causes conformational changes in the membrane helices that open the ion channel. The channel becomes desensitized and closes as the ligand begins to dissociate, and the channel returns to its resting state.

Synthesis, Storage, and Release of Neurotransmitters

Nonpeptide neurotransmitters may be synthesized in almost any part of the neuron, in the cytoplasm near the nucleus, or in the axon. Most nonpeptide neurotransmitters are amino acids or derivatives of amino acids.

Released neurotransmitters travel rapidly across the **synaptic junction** (which is about 20 nm across) and bind to receptors on the postsynaptic side. On binding, they initiate the process of electrical impulse propagation in the postsynaptic neuron as described above. Storage and release of neurotransmitters are multistep processes, many of which have been defined. Some neurons appear to contain more than one chemical type of neurotransmitter. The physiological significance of this observation is not clear. Release of neurotransmitters is a quantal event. A nerve impulse reaching the presynaptic terminal causes release of transmitters from a fixed number of **synaptic vesicles**. An important step in the process involves attachment of synaptic vesicles to the presynaptic membrane and **exocytosis** of their content into the synaptic cleft.

Storage of neurotransmitters occurs in large or small vesicles in the presynaptic terminal. Small vesicles predominate and exist in two pools; free and attached to cytoskeletal proteins, mainly actin. They contain nonpeptide small-molecule-type transmitters. A schematic diagram of a small synaptic vesicle is shown in Figure 23.9*a*. Large vesicles may contain both nonpeptide- and peptide-type neurotransmitters. Some may also contain enzymes for synthesis of norepinephrine from dopamine. A list of some proteins in synaptic vesicles is presented in Table 23.2. Figure 23.10, p. 947, shows schematically how some of the proteins may be arranged on the synaptic vesicle and how they may interact with the plasma membrane of the presynaptic neuron.

Synapsin has a major role in determining whether the small synaptic vesicles are free and available for binding to the presynaptic membrane (Figure 23.11, p. 947) or whether they are attached to cytoskeletal proteins. There is a family of synapsin proteins, encoded by two genes that differ primarily in the C-terminal end (see Figure 23.9*b*). Synapsins constitute about 9% of the total protein of the synaptic vesicle membrane. All can be phosphorylated near their *N*-termini by either **cAMP-dependent protein kinase** and/or **calcium-calmodulin (CaM) kinase I**. Synapsins Ia and Ib can also be phosphorylated by **CaM kinase II** near their C-termini, a region that is missing in synapsins IIa and IIb.

Nerve stimulation leads to the entry of Ca^{2+} into the presynaptic neuron (see Clin. Corr. 23.2, p. 948), where it binds to calmodulin and activates CaM kinases I and CaM kinases II (producing Ca^{2+}-CaM kinases I and II), which phosphorylate synapsin. This causes release of synaptic vesicles from the cytoskeletal protein matrix and/or prevents free phosphorylated vesicles from binding to those matrices. The result is an increase in the free pool of synaptic vesicles. **Calcium-calmodulin** (p. 493) can also bind synapsin directly and competitively block its interaction with actin and presumably other cytoskeletal proteins. Calcium-calmodulin and the phosphorylation of synapsin, therefore, regulate the number of synaptic vesicles that are in the free state.

Following is a brief summary of some properties of other synaptic vesicle proteins:

Synaptophysin is an integral membrane protein of synaptic vesicles that is structurally similar to gap junction proteins. It may be involved in formation of a channel from the synaptic vesicle through the presynaptic membrane to permit passage of neurotransmitters into the synaptic cleft.

Synaptotagmin is also an integral membrane protein of synaptic vesicles. It interacts in a Ca^{2+}-dependent manner with specific proteins localized on the presynaptic membrane. It is probably involved in docking of synaptic vesicles to the membrane.

Syntaxin is an integral protein of the plasma membrane of presynaptic neurons. It binds synaptotagmin and mediates its interaction with Ca^{2+} channels at the site of release of the neurotransmitters. It also appears to have a role in exocytosis.

Synaptobrevin/VAMP (vesicle associated membrane protein) consists of a family of two small proteins of 18 and 17 kDa that are anchored in the cytoplasmic side of the membrane through a single C-terminal domain. It appears to be involved in **vesicle transport** and/or **exocytosis**. VAMPs appear to be involved in the release of synaptic vesicles from the plasma membrane of the presynaptic neuron. **Tetanus toxin** and **botulinum toxin**, a zinc-dependent endoprotease, bind and cleave VAMPs, resulting in a slow and irreversible inhibition of transmitter release.

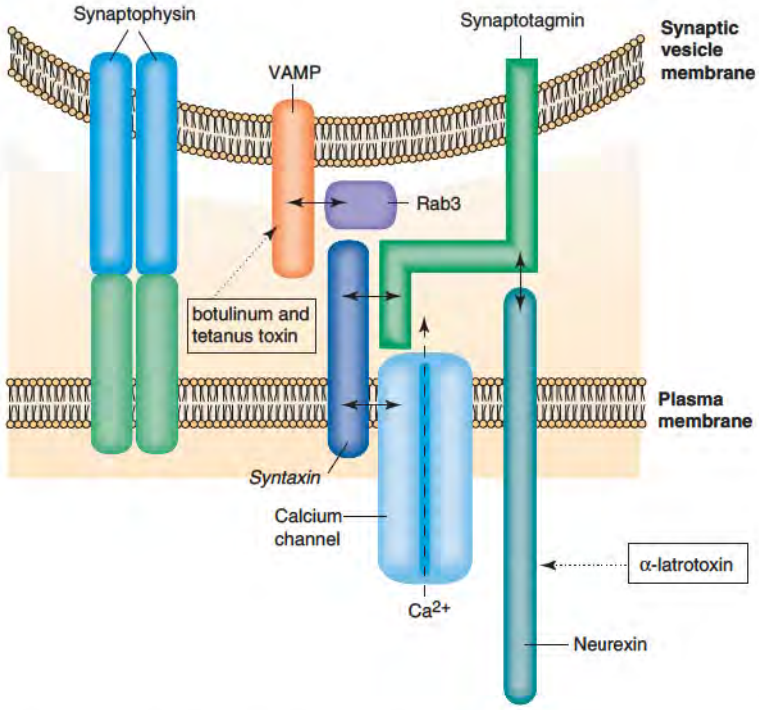

Figure 23.10 Schematic diagram showing how some synaptic vesicle proteins may interact with plasma membrane proteins.
Redrawn from Bennett, M. K., and Scheller, R. H. *Proc. Natl. Acad. Sci. USA* 90:2559, 1993.

Rab3 belongs to the large rab family of **GTP-binding proteins**. Rab3 is specific for synaptic vesicles and is involved in docking and fusion of vesicles for exocytosis. Rab3 is anchored to the membrane through a polyprenyl side chain near its C-terminal.

SV-2 is a large glycoprotein with 12 transmembrane domains. Its function is unclear.

Vacuolar proton pump (p. 491) functions to transport neurotransmitters back into the synaptic vesicles after their reformation and release from the presynaptic membrane.

CSPs are cysteine string proteins and members of a family of chaperones (p. 231) that function during latter stages of Ca^{2+}-regulated exocytosis.

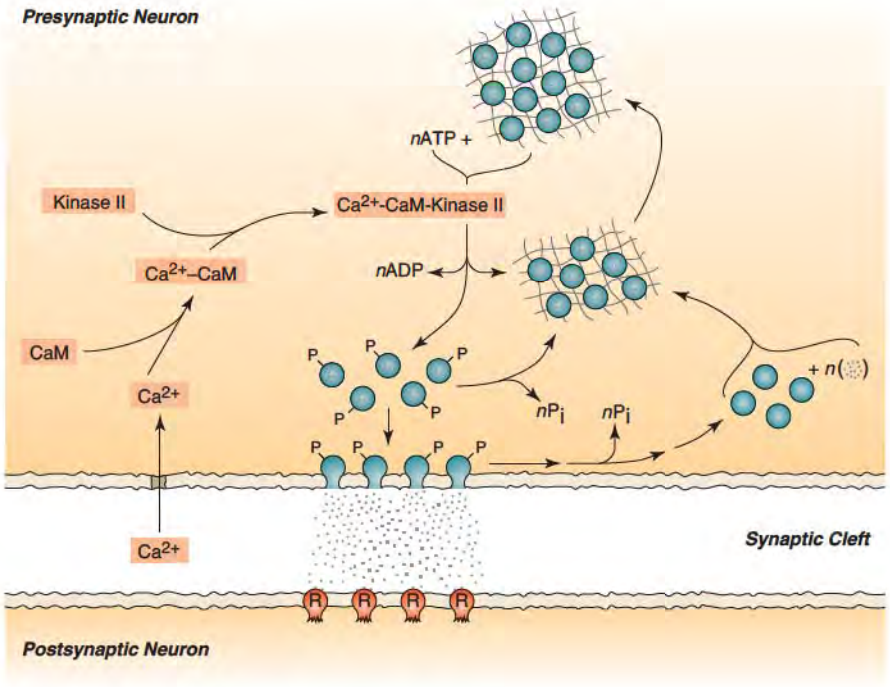

Figure 23.11 A model of the mechanism of regulation of synaptic vesicles function by calcium ions and calmodulin kinase II. Green circles within the skeletal mesh represent bound, nonphosphorylated synaptic vesicles. Green circles with P attached have been freed from the mesh (bound pool) after phosphorylation of synapsin. These phosphorylated synaptic vesicles can now interact with the presynaptic membrane and release neurotransmitters into the synaptic cleft. Receptors on the postsynaptic membrane (red) will bind to some of those neurotransmitters. The recovery of synaptic vesicles and repackaging with neurotransmitters is also illustrated schematically.

CLINICAL CORRELATION 23.2

Lambert–Eaton Myasthenic Syndrome

Lambert–Eaton myasthenic syndrome (LEMS) (OMIM 600003) is an autoimmune disease in which the body raises antibodies against voltage-gated calcium channels (VGCC) located on presynaptic nerve termini. On depolarization of presynaptic neurons, these calcium channels open permitting the influx of Ca^{2+}. This increase in Ca^{2+} concentration initiates events of the synapsin cycle resulting in release of neurotransmitters into synaptic junctions. When autoantibodies against VGCC react with neurons at neuromuscular junctions, Ca^{2+} cannot enter and the amount of acetylcholine released into the synaptic junction is diminished. Since action potentials to muscles may not be induced, the effect mimics that of classic myasthenia gravis.

LEMS has been observed in conjunction with other conditions such as small-cell lung cancer. Some patients manifest subacute cerebellar degeneration (SCD). Plasma exchange (removal of antibodies) and immunosuppressive treatments have been effective for LEMS, but the latter treatment is less effective on SCD.

Diagnostic assays for LEMS depend on the detection of antibodies against VGCC in serum. There are at least four subtypes of VGCC, T, L, N, and P. The P-subtype may be the one responsible for initiating neurotransmitter release at the neuromuscular junction in mammals. A peptide toxin produced by a cone snail (Conus magnus) binds to P-type VGCC in cerebella extracts. This small peptide, labeled with ^{125}I, binds VGCC in cerebella extracts. Precipitation of this radiolabeled complex with sera of patients confirms LEMS in those who have clinical and electrophysiological symptoms of the condition. This assay may prove useful not only in detecting LEMS but also in providing a means of finding out more about the antigenicity of the area(s) on the VGCCs to which antibodies are raised.

LEMS patients have been subjected to several clinical trials in attempts to find effective treatments, but there is insufficient data to quantify any of them as being effective. Plasma exchange, steroids, and immunosuppressive agents have been tested. There is no cure and clinical trials looking for effective therapy continue.

Chichester, UK: Wiley, 2004.

Termination of Signals at Synaptic Junctions

Neurotransmitter action may be terminated by reuptake into the presynaptic neurons, metabolism, or uptake into other cell types. One or more of these mechanisms function for inactivation of neurotransmitters. Here are examples of some pathways involved in synthesis and degradation of some representative neurotransmitters.

Acetylcholine

Reactions involving acetylcholine at the synapse are summarized in Figure 23.12. Acetylcholine is synthesized by condensation of choline and acetyl CoA catalyzed by **choline acetyltransferase** in the cytosol of the neuron This reaction is

$$\underset{\text{Choline}}{(CH_3)_3\overset{+}{N}CH_2CH_2OH} + CH_3CO{-}SCoA \longrightarrow \underset{\text{Acetylcholine}}{(CH_3)_3\overset{+}{N}CH_2CH_2OCOCH_3} + CoASH$$

Choline is derived mainly from the diet; however, some may come from reabsorption from the synaptic junction or other metabolic sources (p. 778). The major source of acetyl CoA is decarboxylation of pyruvate by pyruvate dehydrogenase in mitochondria. The mechanism for getting acetyl CoA across the inner mitochondrial membrane as citrate (see Figure 17.11, p. 684) operates in presynaptic neurons.

Acetylcholine is released, and it reacts with the nicotinic–acetylcholine receptor embedded in the postsynaptic membrane (Clin. Corr. 23.3). Its action is terminated by the action of **acetylcholinesterase**, which hydrolyzes it to acetate and choline (A Closer Look 23.1).

$$\text{Acetylcholine} + H_2O \rightarrow \text{acetate} + \text{choline}$$

Acetate is probably taken up and metabolized by other tissues.

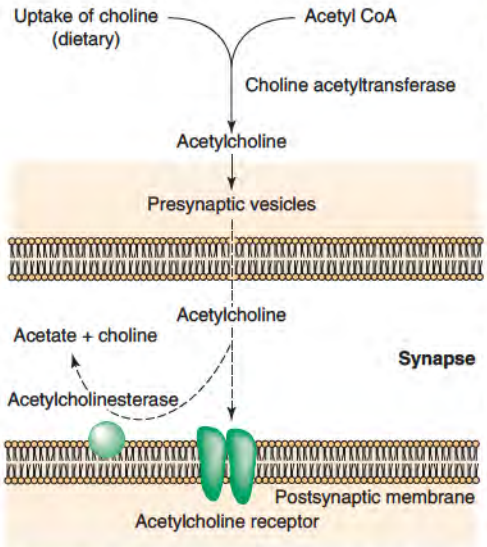

Figure 23.12 Summary of reactions of the neurotransmitter acetylcholine at the synapse. Abbreviations: AcCoA, acetylcoenzyme A, and AcChEase, acetylcholinesterase.

CLINICAL CORRELATION 23.3

Myasthenia Gravis: A Neuromuscular Disorder

Myasthenia gravis (OMIM 254200) is an acquired autoimmune disease characterized by muscle weakness due to decreased neuromuscular signal transmission. The neurotransmitter involved is acetylcholine. The sera of more than 90% of patients with myasthenia gravis have antibodies to the nicotinic–acetylcholine receptor (AChR) located on the postsynaptic membrane of the neuromuscular junction. Antibodies against the AChR interact with and inhibit either its ability to bind acetylcholine or its ability to undergo conformational changes necessary to affect ion transport. The number of functional AChRs is reduced in patients with the disease. Experimental models of myasthenia gravis have been generated either by immunizing animals with the AChR or by injecting them with antibodies against it.

Events that trigger the onset of the disease are unknown. Some environmental antigens have epitopes resembling those on the AChR. A rat monoclonal IgM antibody prepared against AChRs reacts with two proteins obtained from the intestinal bacterium *E. coli*. Both are membrane proteins of 38 and 55 kDa, the smaller of which is located in the outer membrane. This does not suggest that exposure to *E. coli* proteins is likely to trigger the disease. The sera of both normal individuals and myasthenia gravis patients have antibodies against a large number of *E. coli* proteins. Some environmental antigens from other sources also react with antibodies against AChRs.

The thymus gland, which is involved in antibody production, is implicated in this disease. Antibodies have been found in thymus glands of myasthenia gravis patients that react with AChRs and with environmental antigens. The relationship between environmental antigens, thymus antibodies against AChRs, and onset of myasthenia gravis is not clear.

Myasthenia gravis patients may receive one or a combination of several therapies. Pyridostigmine bromide, a reversible inhibitor of acetylcholine esterase (AChE) that does not cross the blood–brain barrier, has been used. The inhibition of AChE within the synapse increases the half-time for acetylcholine hydrolysis. This leads to an increase in the concentration of acetylcholine, stimulation of more AChR, and increase in signal transmission. Other treatments include immunosuppressant drugs, steroids, and surgical removal of the thymus gland to decrease the rate of production of antibodies. Future treatment may include the use of anti-idiotype antibodies to the AChR antibodies, and/or the use of small nonantigenic peptides that compete with AChR epitopes for binding to the AChR antibodies.

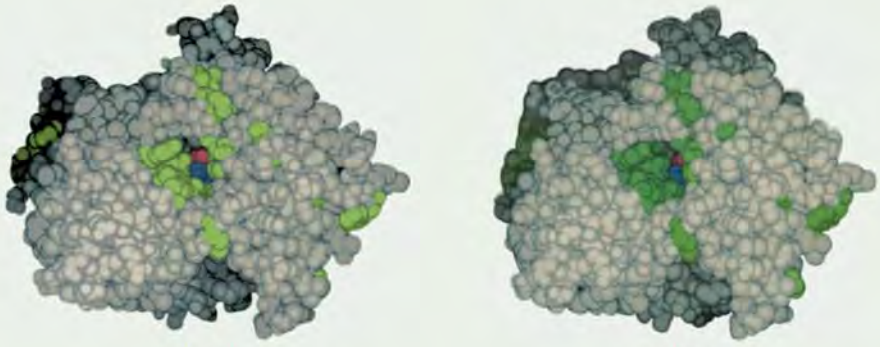
A CLOSER LOOK 23.1

Structure of Acetylcholine Esterase

An X-ray crystallographic structure of acetylcholine esterase is shown in the following figure. Its mechanism of action is similar to that of serine proteases (p. 343). It contains a **catalytic triad**, but the amino acids in that triad, from N- to C-termini, are in reverse order to those of serine proteases like trypsin and chymotrypsin; in addition, glutamate replaces aspartate. The serine that forms the covalent intermediate during catalysis is visible at the bottom of a hydrophobic channel. Glutamate, one of the other residues of the catalytic triad, is also visible within the channel of that structure.



RChE-L RChE-R

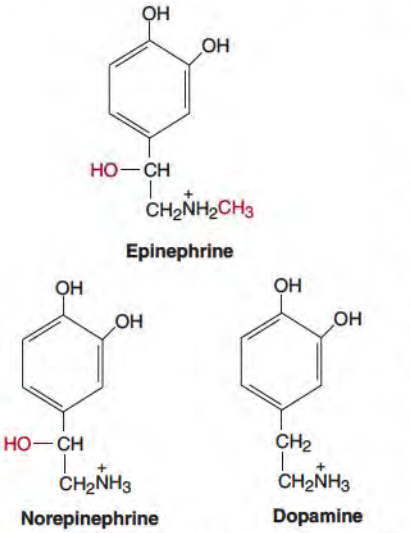

Figure 23.13 **Catecholamine neurotransmitters.**

Catecholamines

The **catecholamine neurotransmitters** are **dopamine** (3,4-dihydroxyphenylethylamine), **norepinephrine**, and **epinephrine** (Figure 23.13 and p. 781). Their action is terminated by reuptake into the presynaptic neuron by specific transporter proteins (A Closer Look 23.2). Cocaine, for example, binds specifically to the **dopamine transporter** and blocks dopamine reuptake. In the presence of cocaine, dopamine remains in the synaptic cleft for a prolonged period and stimulates excessively its receptors on the postsynaptic neuron. After reuptake, catecholamine neurotransmitters may be either repackaged into synaptic vesicles or metabolized by **catechol-*O*-methyltransferase** that catalyzes the transfer of a methyl group from *S*-adenosylmethionine to one of the phenolic OH groups, and **monoamine oxidase** (Figure 23.14) that catalyzes the oxidative deamination of these amines to aldehydes and ammonium ions. They are substrates for monoamine oxidase whether or not they have been altered by catechol-*O*-methyltransferase. The end product of dopamine metabolism is **homovanillic acid**, and that of epinephrine and norepinephrine is **3-methoxy-4-hydroxymandelic acid**.

5-Hydroxytryptamine (Serotonin)

Serotonin is derived from tryptophan (p. 785). Like dopamine, its action is terminated by **reuptake** by a specific transporter. Some types of depression are associated with low brain levels of serotonin; antidepressants such as Paxil (paroxetine hydrochloride), Prozac (fluoxetine hydrochloride), and Zoloft (sertraline hydrochloride) specifically inhibit serotonin reuptake. Once inside the presynaptic neuron, serotonin may be either repackaged in synaptic vesicles or oxidatively deaminated to the corresponding acetaldehyde by monoamine oxidase (Figure 23.15, p. 952). The aldehyde is further oxidized to 5-hydroxyindole-3-acetate by an aldehyde dehydrogenase.

γ-Aminobutyrate (GABA)

γ-Aminobutyrate, an inhibitory neurotransmitter, is synthesized and degraded through reactions commonly known as the **GABA shunt**. In brain tissue, GABA and glutamate, an excitatory neurotransmitter, may share common routes of metabolism (Figure 23.16, p. 952) where they are taken up by astrocytes and converted to glutamine, which is then transported back into presynaptic neurons. In excitatory neurons, glutamine is converted to glutamate and repackaged in synaptic vesicles. In inhibitory neurons, glutamine is converted to glutamate and then to GABA, which is packaged in synaptic vesicles.

It has been suggested that brain levels of GABA in some epileptic patients may be low. **Valproic acid** (2-propylpentanoic acid) can cross the blood–brain barrier and apparently increases brain levels of GABA. The mechanism by which it does so is not clear. Valproic

A CLOSER LOOK 23.2

LeuT–Desimpramine Structure: A Clue to the Mechanism of Neuronal Reuptake of Dopamine, Epinephrine, and Serotonin

Serotonin and catecholamine neurotransmitters are among those whose actions are stopped at the synapse by reuptake into the presynaptic neuron by transporters that are specific for each individual neurotransmitter. Pharmacological agents and some drugs of abuse generally effect their actions by blocking reuptake of neurotransmitters. The specifics of how these agents work is poorly understood because of a lack of mechanistic information at the molecular level.

Transporters for serotonin (SERT), norepinephrine (NET), and dopamine (DAT) are members of a family of proteins that have a high degree of homology with the bacterial leucine transporter (LeuT) whose structure has been determined at 2.9-Å resolution in a complex with desimpramine, a tricyclic inhibitor of LeuT's action. Desimpramine binds at a different site than leucine, and its binding at the inner end of the extracellular cavity of the transporter prevents conformational changes that would open the gate to permit leucine transport. This allows the speculation that inhibitors of SERT, NET, and DAT may function in a similar manner. Structural and other information are available in the cited article.

Zhou, Z., Zhen, J. Karpowich, J. K., Goetz, R. M., Law, C. J., Reith, M. E., and Wang, D.-N. LeuT–desipramine structure reveals how antidepressants block neurotransmitter reuptake. *Science* 317:1390, 2007.

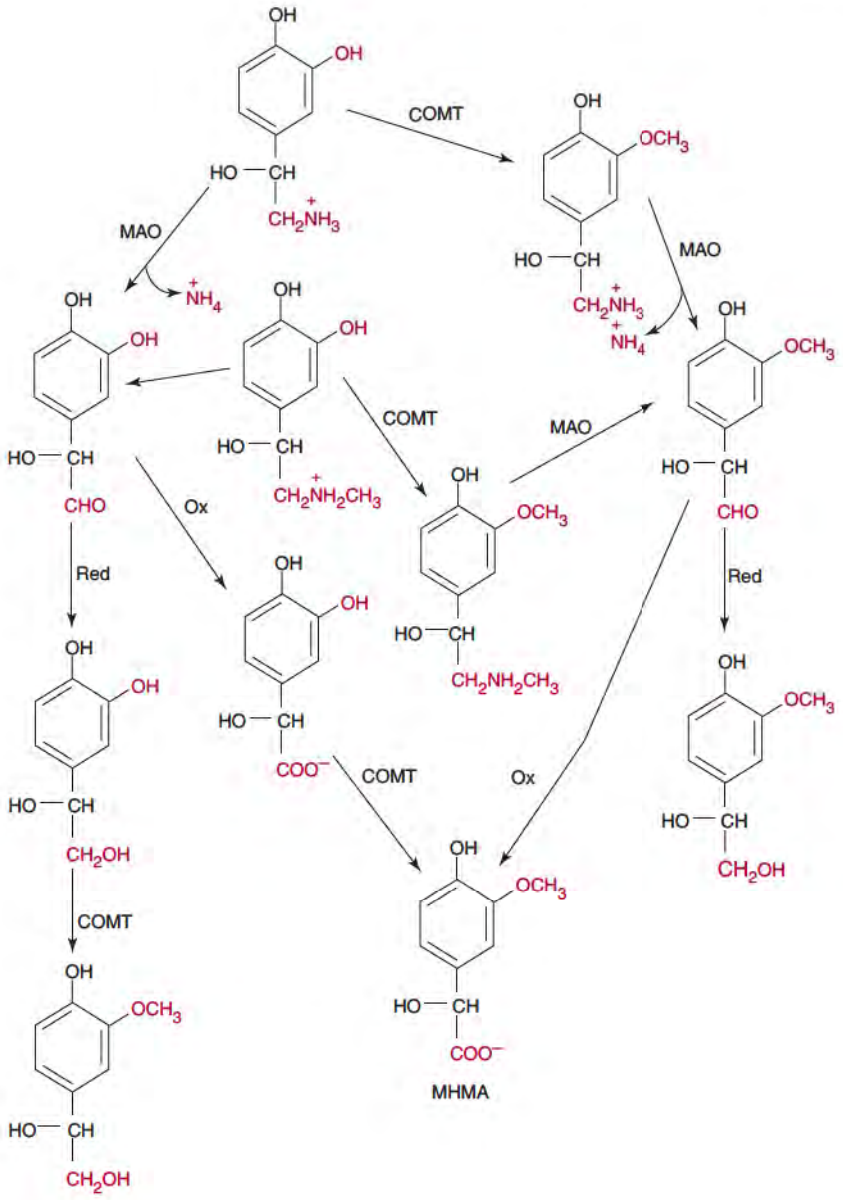

Figure 23.14 Reactions of catecholamine degradation. Abbreviations: COMT, catechol-*O*-methyl transferase (requires *S*-adenosylmethionine); MAO, monoamine oxidase; Ox, oxidation; and Red, reduction. The end product of epinephrine and norepinephrine metabolism is 3-methoxy-4-hydroxymandelic acid (MHMA).

acid is metabolized primarily in the liver by glucuronidation and urinary excretion of the glucuronides or by mitochondrial β-oxidation and oxidation by endoplasmic reticulum enzymes.

Neuropeptides Are Derived from Precursor Proteins

Peptide neurotransmitters are synthesized as larger proteins. Proteolysis of these larger proteins releases the neuropeptide molecules. Synthesis of the larger proteins takes place in the cell body and not the axon. The neuropeptides travel down the axon to the presynaptic region by one of two mechanisms: **fast axonal transport** at a rate of about 400 mm/day or **slow axonal transport** at a rate of 1–5 mm/day. Since axons may vary in length from 1 mm to 1 m in length, theoretically the transit time could vary from 150 ms to 200 days. It is unlikely that the latter transit time occurs under normal physiological conditions, and the upper limit is probably hours rather than days. There is experimental evidence that suggest that the faster transit time prevails. Kinesins and myosins, molecular motor proteins (p. 980), facilitate this transport process.

Neuropeptides mediate sensory and emotional responses such as those associated with hunger, thirst, sex, pleasure, pain, and so on. Included in this category are **enkephalins**,

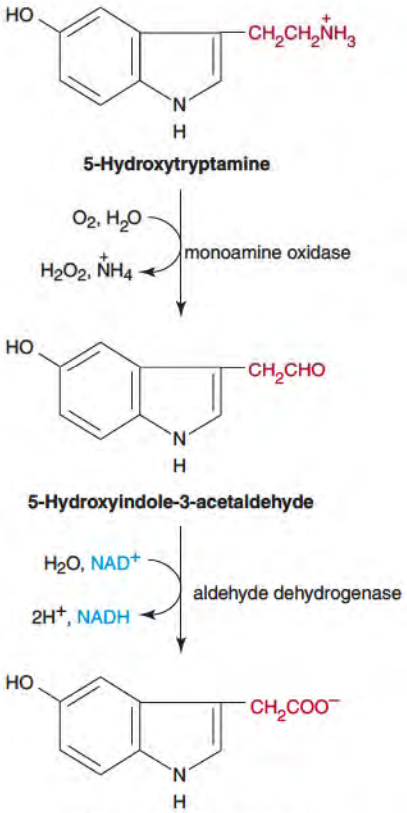

Figure 23.15 Degradation of 5-hydroxytryptamine (serotonin).

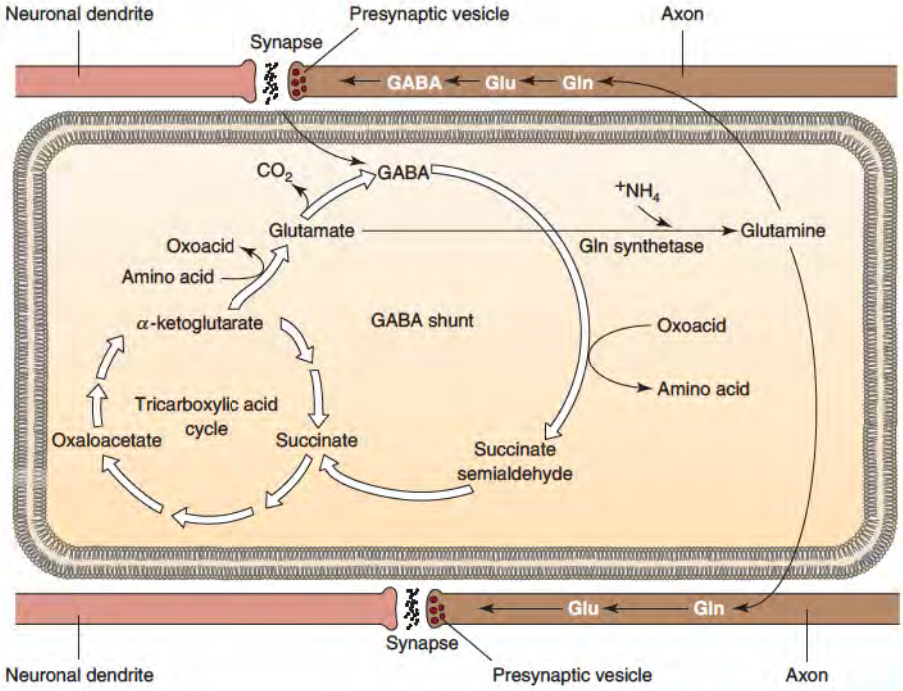

Figure 23.16 Involvement of astrocytes in the metabolism of GABA and glutamate.

endorphins, and **substance P**. Substance P is an excitatory neurotransmitter that has a role in pain perception. It is among a class of neuropeptides called **neurokinins**. Its receptor, **NK-1** (**n**euro**k**inin-**1**) is a G-type protein consisting of seven transmembrane helical elements. Endorphins and opioids bind to receptors that also have seven transmembrane helical elements. Endorphins and enkephalins have roles in eliminating the sensation of pain. Some of the peptides found in brain tissue are shown in Table 23.3. Note that Met-enkephalin is derived from the *N*-terminal region of β-endorphin. The *N*-terminal or both the *N*- and C-terminal amino acids of many of the neuropeptide transmitters are modified.

TABLE 23.3 • Peptides Found in Brain Tissue[a]

Peptide	*Structure*
β-Endorphin	Y G G F M T S E K S Q T P L V T L F K N A I I K N A Y K K G E

[a]Peptides with "p" preceding the structure indicate that the N-terminal is pyroglutamate. Those with NH_2 at the end indicate that the C-terminal is an amide.

23.2 • THE EYE: METABOLISM AND VISION

The eye, our window to the outside world, allows us to view the beauties of nature. A view through any window or any camera lens is clearest when unobstructed. The eye has evolved in such a way that a similar objective has been achieved. It is composed of live tissues that require continuous nourishment obtained through use of conventional metabolic pathways appropriate to their unique needs. Pigmented structures such as cytochromes of mitochondria are either not present in some structures or arranged and distributed so as not to interfere with the visual process. In addition, the brain has devised an enormously efficient filtering system that makes objects within the eye invisible that may otherwise appear to lead to visual distortion. A schematic diagram of a cross section of the eye is shown in Figure 23.17.

Light enters the eye; passes progressively through the **cornea**, the anterior chamber that contains aqueous humor, the lens, the vitreous body that contains vitreous humor; and finally focuses on the **retina** that contains the visual sensing apparatus. Tears bathe the exterior of the cornea while the interior is bathed by the aqueous humor, an isoosmotic fluid that contains salts, albumin, globulin, glucose, and other constituents. The aqueous humor brings nutrients to the cornea and to the lens, and it removes end products of metabolism from them. The vitreous humor is a gelatinous mass that helps maintain the shape of the eye while allowing it to remain somewhat pliable.

Cornea Derives ATP from Aerobic Metabolism

The eye is an extension of the nervous system and, like other tissues of the central nervous system, its major metabolic fuel is glucose. The cornea is not a homogeneous tissue. It consists of (1) an anterior corneal epithelium, (2) Bowman's membrane, (3) stroma (substantia propria) that is made up primarily of type 1 collagen and constitutes about 90% of the corneal thickness, (4) Descemet's membrane, and (5) endothelium (posterior corneal epithelium). The cornea is a clear tissue that, like the lens, diffracts light. Its clearness is due in part to the arrangement of collagen molecules of the stroma. The cornea is permeable to water and oxygen. The water content of the corneal stroma must be controlled for it to maintain clarity, and this is done by an ATP-driven water pump. Another reason for its clarity is the lack of blood vesicles in the epithelial layer. There is a large amount of the protein **VEGFR-3 (vascular endothelial growth factor receptor-3)** on the anterior epithelial layer of the cornea. VEGFR-3 prevents growth of blood vessels by binding to or neutralizing growth factors that are produced to stimulate growth of blood vessels.

The cornea obtains its ATP from aerobic glucose metabolism; glycolysis, and the TCA cycle. Lactate does not accumulate to any significant extent because of efficient use of pyruvate by oxidative metabolism. About 30% of the glucose it metabolizes is by glycolysis, and about 65% by the hexose monophosphate pathway. On a relative weight basis, the cornea has the highest activity of the hexose monophosphate pathway of any mammalian tissue. It also has a high activity of **glutathione reductase** that requires NADPH, a product

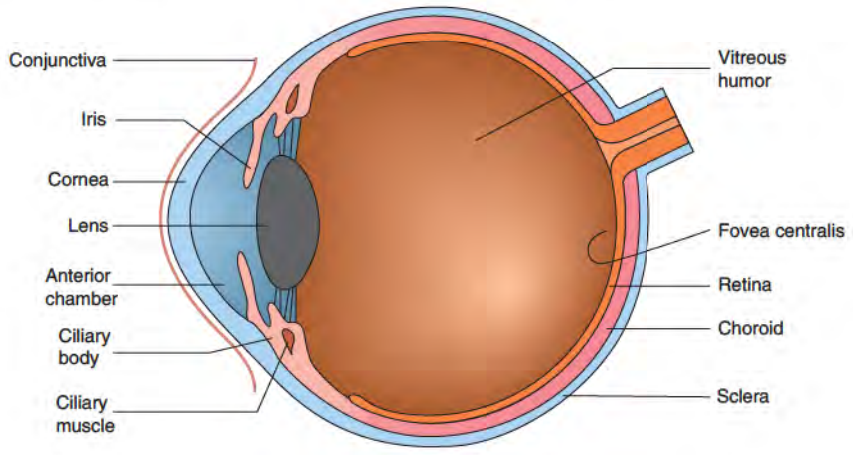

Figure 23.17 Schematic of a horizontal section of the left eye.

of the hexose monophosphate pathway. Corneal epithelium is permeable to atmospheric oxygen. Reactions of oxygen can lead to formation of various **active oxygen species** that are harmful to tissues, in some cases by oxidizing protein sulfhydryl groups to disulfides and by lipid peroxidation, mostly of cellular medium-chain lipids of six carbons or more (p. 583). Reduced glutathione (GSH) is used to reduce those disulfide bonds and lipid peroxides back to their original native states while GSH itself is converted to oxidized glutathione (GSSG). GSSG may also be formed directly by active oxygen species. Glutathione reductase uses NADPH to reduce GSSG to 2GSH.

$$GSSG + NADPH + H^+ \overset{\text{GSH reductase}}{\rightleftharpoons} 2GSH + NADP^+$$

The pentose phosphate pathway and glutathione reductase help protect the cornea by effectively neutralizing active oxygen species.

Some lipids that are subjected to peroxidation may spontaneously form active aldehydes that react with other tissue components and lead to various pathological conditions. The cornea also contains an isoform of aldehyde dehydrogenase (ALDH3A1), a member of a superfamily of enzymes that uses either NAD^+ or $NADP^+$ to inactivate these active aldehydes by oxidizing them to their corresponding acids.

Lens Consists Mostly of Water and Protein

The **lens** is bathed on one side by aqueous humor and supported on the other side by vitreous humor. It has no blood supply, but is metabolically active. It obtains nutrients from and eliminates waste into the aqueous humor. The lens is mostly water and proteins. The majority of vertebrate lens proteins are **α-, β-, and γ-crystallins** (Table 23.4). There are also albuminoids, enzymes, and membrane proteins that are synthesized in an epithelial layer around the edge of the lens. Other animals have different crystallins, some of which are enzymes that probably function as such in other tissues. The most important physical requirement of these proteins is that they maintain a clear crystalline state. They are sensitive to changes in oxidation–reduction, osmolarity, excessively increased concentrations of metabolites, and UV irradiation. Structural integrity of the lens is maintained: for osmotic balance by the Na^+/K^+ exchanging ATPase (p. 491); for redox-state balance by glutathione reductase and for growth and maintenance by protein synthesis and other metabolic processes that take place mostly in cells on the periphery of the lens.

The primary role of most lens proteins is to function as crystallins, but many are expressed in other tissues and serve other roles such as enzymes and/or have other functional roles. **α- and β-Crystallins** are **small heat shock proteins (sHSP)** or **chaperones** that function to help maintain lens proteins in their native, unaggregated states. Their highest expression is in eye lens, but they also occur in other tissues such as skeletal and cardiac muscle where they are involved in filament assembly. Mutations in crystallins, therefore, not only predispose an individual to cataract formation, but also to possible muscle weakness and heart failure.

TABLE 23.4 • Eye Lens Crystallins and Their Relationships with Other Proteins

Crystallin	*Distribution*	*[Related] or Identical*
α	All vertebrates	Small heat shock proteins (αB) [*Schistosoma mansoni* antigen]
β	All vertebrates	[*Myxococcus xanthus* protein S]
γ	(embryonic γ not in birds)	[*Physarum polycephatum* spherulin 3a]
Taxon-specific enzyme crystallins		
δ	Most birds, reptiles	Argininosuccinate lyase (δ2)
ε	Crocodiles, some birds	Lactate dehydrogenase B

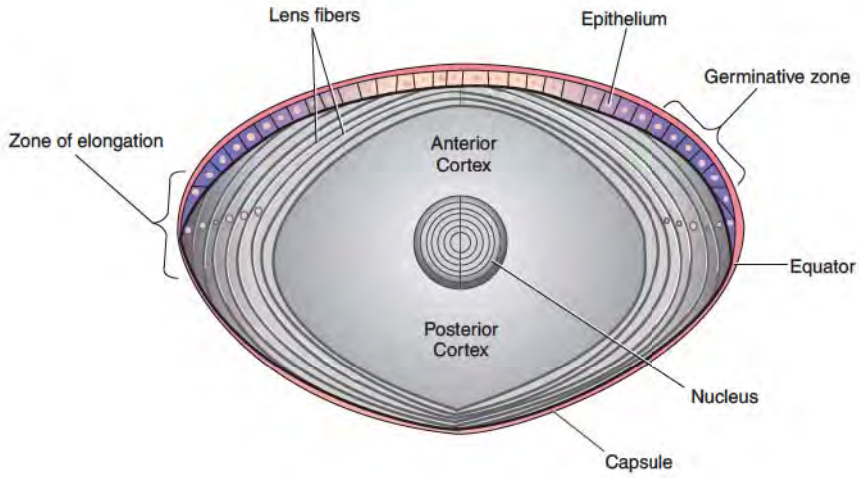

Figure 23.18 **Schematic representation of a meridional section of a mammalian lens.**

Energy for these processes comes from the metabolism of glucose. About 85% of glucose used by lens tissue is metabolized by glycolysis and about 3% by the TCA cycle, presumably by cells located at the periphery. Most of the remaining portion of glucose metabolized by lens goes through the pentose phosphate pathway.

The central area of the lens, the nucleus or core, consists of lens cells that were present at birth. The lens grows from the periphery (Figure 23.18) and in humans increases in weight and thickness with age and becomes less elastic. This leads to a loss of near vision (Table 23.5), a normal condition referred to as **presbyopia**. On average, the lens may increase threefold in size and approximately 12-fold in thickness from birth to about age 80.

Cataract, the only known disease of the lens, is an opacity of lenses brought about by many different conditions. The two most common types of cataracts are (1) **senile cataracts** in which changes in the architectural arrangement of the lens crystallins and other lens proteins are age related and due to such changes as breakdown of the protein molecules starting at the C-terminal ends, deamidation, and racemization of aspartyl residues and (2) **diabetic cataracts** which result from loss of control of osmolarity of the lens due to increased activity of **aldose reductase** and **polyol (aldose) dehydrogenase** of the polyol metabolic pathway. When glucose concentration in the lens is high, aldose reductase converts some of it to **sorbitol** (Figure 23.19) that may be converted to

TABLE 23.5 • Changes in Focal Distance with Age

Age (years)	*Focal Distance (in.)*
10	2.8
20	4.4
35	9.8
45	26.2
70	240.0

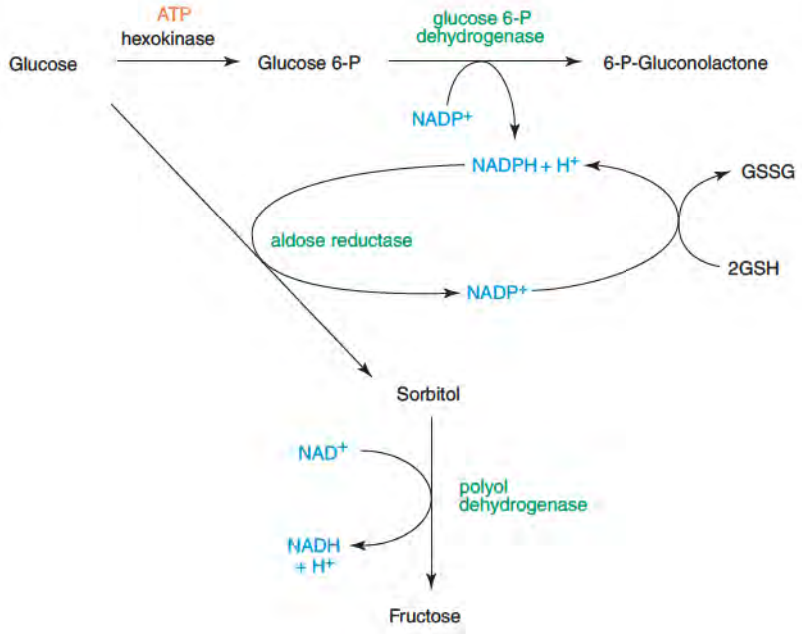

Figure 23.19 **Metabolic interrelationships of lens metabolism.**

fructose by polyol dehydrogenase. In human lens, the ratio of activities of these two enzymes favors sorbitol accumulation, especially; since sorbitol is not used by other pathways and it diffuses out of the lens rather slowly. Accumulation of sorbitol increases osmolarity of the lens, affects the structural organization of the crystallins, and enhances the rate of protein aggregation and denaturation. Areas where this occurs have increased light-scattering properties, which is the definition of cataracts. Normally, sorbitol formation is not a problem because the K_m of aldose reductase for glucose is about 200 mM and very little sorbitol would be formed. In diabetics, where circulating concentration of glucose is high, activity of this enzyme can be significant. Cataracts affect millions of people per year throughout the world, and there are no known cures or preventative measures, especially for the senile type. The most common remedy is lens replacement; a routine operation in many countries. A side effect of cataract and surgical treatment for it can be glaucoma; but this is rare. A third cause of cataracts, especially among young people, is due to inherited mutations in crystallins that function in lens as chaperones. When there are mutations in chaperones that interfere with their function, misfolded proteins can occur and result in cataract formation.

Retina Derives ATP from Anaerobic Glycolysis

The **retina**, like the lens, depends heavily on anaerobic glycolysis for ATP production. Unlike the lens, the retina is a vascular tissue. In its center is the macula, and in the center of the macula is the **fovea centralis**, an avascular concave area that contains only cones. This is the area of greatest visual acuity (Clin. Corr. 23.4). Mitochondria are present in retinal rods and cones but not in the outer segments where visual pigments are located.

CLINICAL CORRELATION 23.4

Macula Degeneration and Loss of Vision

Many diseases of the eye affect vision, but not all have clear, direct biochemical origins. The most serious eye diseases are those that result in blindness. Glaucoma is the most common and is often associated with diabetes mellitus, the biochemistry of which is fairly well known. Glaucoma is treatable and blindness does not have to be a result.

Macula degeneration leads to blindness and there is no cure. The macula is a circular area of the retina, the center of which is the fovea centralis, the area of greatest visual acuity, which contains the highest number of cones. Age-related macula degeneration (AMD) may be among the leading causes of blindness of people over the age of 50 and is of two types: dry and wet. The dry form develops gradually over time, whereas the wet form develops rapidly and can lead to blindness within days. It occurs when blood vessels invade and/or rupture under the macula leading to a rapid loss of vision.

One current therapy under assessment for neovascular age-related macular degeneration is intravitreal ranibizumab. Ranibizumab is a humanized monoclonal antibody fragment that inhibits VEGF (vascular endothelial growth factor) (p. 909). In 2006, a Phase 3 trial showed that this treatment is somewhat effective. Another therapy involves use of siRNA to inhibit expression of the gene for VEGF. VEGF promotes excessive blood vesicle growth behind the retina. These blood vesicles leak and cause blindness. siRNA treatment has been quite effective in treating AMD. This is the first siRNA therapy to be given to patients in clinical trials. Thus, advances in basic science and medical research continue to reveal better ways of treating and possibly preventing onset of AMD.

Rupture of blood vessels that obscure macula details and result in rapid onset of blindness may be temporary. Several cases of sudden visual loss associated with sexual activity, but not with a sexually transmitted disease, have been reported. Vision was lost in one eye apparently during, but most often was reported a few days after engaging in, highly stimulatory sexual activity. Blindness was due to rupture of blood vessels in the macula area. Most patients were reluctant to discuss with their ophthalmologist what they were doing when sight loss was first observed. Four patients recovered with restoration of vision on reabsorption of blood. In one case, blood was trapped between the vitreous humor and the retinal surface directly in front of the fovea. The hemorrhage cleared only slightly during the next month, but visual acuity did not improve. That patient did not return for a follow-up examination, but there was no indication during the initial examination that the condition was permanent. Since most of the victims of this phenomenon were over the age of 39, it may be a worry more to professors than to students. It also may give a new meaning to the phrase, "love is blind."

Visual Transduction Involves Photochemical, Biochemical, and Electrical Events

Figure 23.20*a* shows an electron micrograph and schematic of the retinal membrane. Light enters the eye, and when it reaches the retinal membrane, it passes the optic nerve fibers, the ganglion neurons, the bipolar neurons, and the nuclei of rods and cones before it reaches the outer segment of the rods and cones where the signal transduction process begins. The tips of the rods and cones penetrate the **pigmented epithelial** layer of the retina. The pigmented

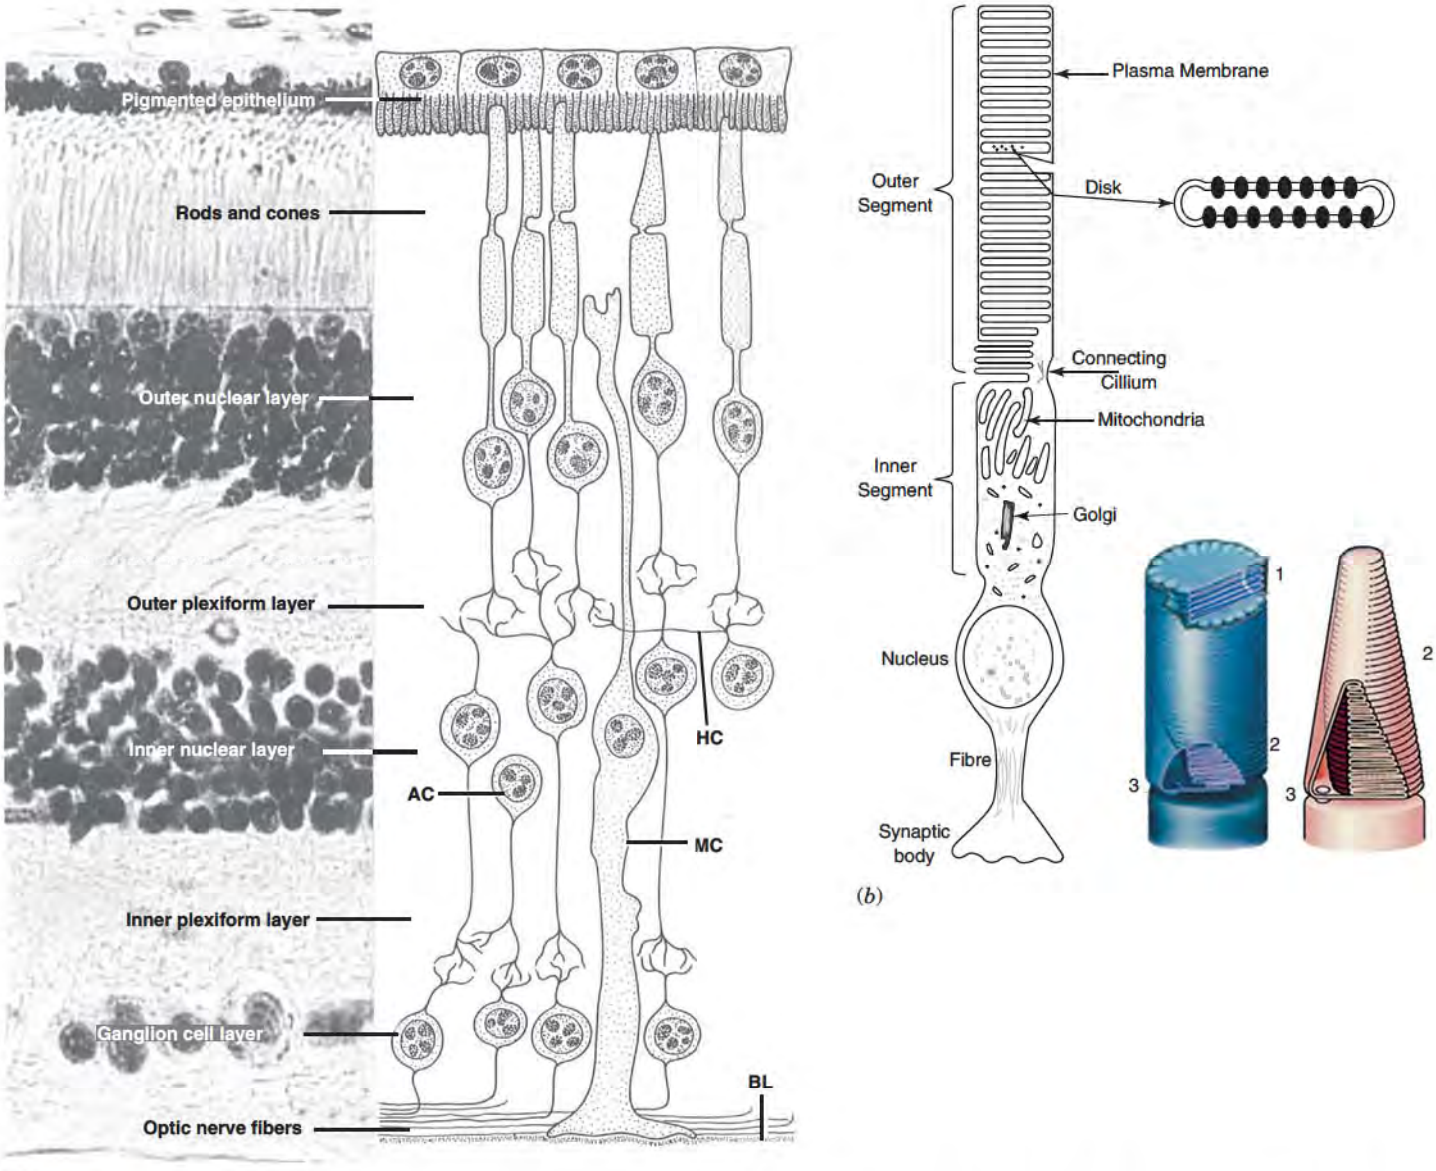

Figure 23.20 Layers of the human retinal membrane. (*a*) Electron micrograph and schematic representation of cells of the human retina. Tips of rods and cones are imbedded in the pigmented epithelium of the outermost layer. Rods and cones form synaptic junctions with many bipolar neurons that form synapses with cells in the ganglion layer. Cells in this layer send axons through the optic nerve to the brain. Synaptic interactions of rods and cones with many neurons are important for the integration of information. Abbreviations: HC, horizontal cells; AC, amacrine cell; MC, Muller cell; and BL, basal lamina. (*b*) More detailed structural features of rods and cones showing the relationships of disks to plasma membrane. Dots on the disk in the rod and in the enlarged diagram represent rhodopsin (Figure 23.21) that is imbedded in the disk membrane. The same relationship holds for cones and color pigments. Numbers next to the blue (rod) and tan (cone) inserts indicate structural areas of disk arrangements. Number 1 identifies disk in rods that are free floating and not directly attached to the plasma membrane, number 2 shows folding of outer cell membrane that is continuous with disk in both rods and cones, and number 3 is the connecting cilium of both rods and cones. CLINICAL CORRELATION 23.5

Niemann–Pick Disease and Retinitis Pigmentosa

There are central nervous system disorders associated with the Niemann–Pick group of diseases that can become evident by ocular changes. Some of these are observed as abnormal macula with gray discoloration and granular pigmentation or granule opacities about the fovea.

Acute type I Niemann–Pick disease (OMIM 257220), lipidosis with sphingomyelinase deficiency and primary sphingomyelin storage, may show a cherry red spot in the retina in up to 50% of these patients. Macula halo describes the crystalloid opacities seen in some patients with subacute type I disease. These halos are approximately one-half the disk diameter at their outer edge and are scattered throughout the various layers of the retina. They do not interfere with vision.

An 11-year-old girl with type II disease had more extensive ocular involvement. There was sphingomyelin storage in the keratocytes of the cornea, the lens, the retinal ganglion cells, the pigmented epithelium, the corneal tract, and the fibrous astrocytes of the optic nerve.

Thus, retinitis pigmentosa may also be a secondary effect of the abnormal biochemistry associated with Niemann–Pick disease.

Spence, M. W., and Callahan, J. W. Sphingomyelin-cholesterol lipidoses: The Niemann–Pick group of diseases. In Schriver, C. R., Beaudet, A. L., Sly, W., and Valle, D. (Eds.), *The Metabolic Bases of Inherited Disease*. New York: McGraw Hill, 1989, 1656.

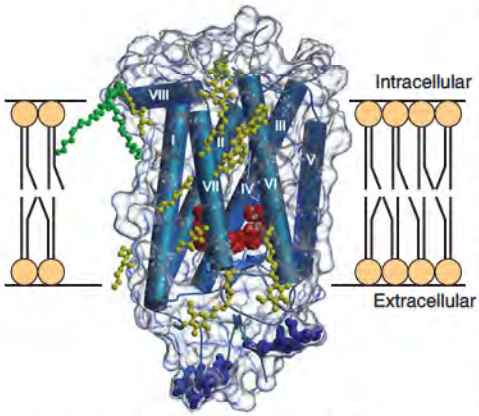

Figure 23.21 Crystal structure of bovine rhodopsin at 2.8-Å resolution. Rhodopsin is a transmembrane protein. The width of the disk membrane into which it is imbedded is approximately equivalent to the length of its helices (blue rods). The intracellular side of the membrane approximately transects helix VIII. β-Strands are shown as blue arrows. Structures in green on the intracellular side are two palmitoyl groups oriented such that the hydrophobic groups can interact with hydrophobic regions of the membrane. The blue ball-and-stick structures at the bottom (extracellular side) of the molecule are carbohydrates. The yellow structures located near the hydrophobic surface of the protein are nonylglucoside and heptanol molecules. Reproduced with permission from Teller, D. C., Okada, T., Behnke, C. A., Palczewski, K., and Stenkamp, R. E. *Biochem.* 40: 7761, 2001. Copyright, (2001) American Chemical Society. Figure generously supplied by Dr. K. Palczewski and Dr. C. A. Behnke.

epithelial layer of the retina is involved in the *trans*- to *cis*-retinal recycling phase of the visual cycle, and it also absorbs excess light and prevents reflections back into rods and cones where it may cause distortion or blurring of images (Clin. Corr. 23.5). The choroid lies behind the retina and contains blood vesicles that supply nutrients to the retina.

The eye may be compared to a video camera, which collects images, converts them into electrical pulses, records them on magnetic tape, and allows their visualization by decoding the taped information. The eye focuses on an image by projecting that image onto the retina. A series of events begins, the first of which is photochemical, followed by biochemical events that amplify the signal, and finally electrical impulses are sent to the brain where the image is reconstructed—"in the mind's eye." In effecting this process, the initial event is transformed from a physical event to a chemical event through a series of biochemical reactions, to an electrical event, to a conscious acknowledgment of the presence of an object in the environment outside of the body.

Photons (light) are absorbed by photoreceptors in the **outer segments** of **rods** or **cones**, where they cause isomerization of the visual pigment, **retinal**, from the 11-*cis*-form to the all-*trans*-form. This isomerization causes a conformational change in the protein moiety of the complex and affects the resting membrane potential of the cell, resulting in an electrical signal being transmitted by way of the optic nerve to the brain.

Rods and Cones Are Photoreceptor Cells

Photoreceptor cells of the eye are the **rods** and the **cones** (Figure 23.20*b*, p. 957). Each type has flattened disks that contain a photoreceptor pigment that consists of a protein and a prosthetic group, 11-*cis*-retinal. The pigment is **rhodopsin** in rod cells, and they are red (long), green (medium), or blue (short) pigments in cone cells. Rhodopsin, as are other photoreceptor pigments, is a transmembrane protein containing **11-*cis*-retinal**, the protein moiety of which is called **opsin**. The three proteins that form the red, green, and blue pigments of cone cells are different from each other and from the opsin of rhodopsin; but the prosthetic group for all visual pigments is the same.

Rhodopsin (~40 kDa) contains seven transmembrane α-helices. An 11-*cis*-retinal molecule is attached through a protonated Schiff base to the ε-amino group of Lys^{296} on the seventh helix and lies about midway between the two faces of the membrane (Figure 23.21; Clin. Corr. 23.6, p. 960).

A schematic of the formation of 11-*cis*-retinal from **β-carotene** and rhodopsin formation from opsin and 11-*cis*-retinal are shown in Figure 23.22. 11-*Cis*-retinal is derived from **vitamin A** and/or β-carotene of the diet. Cleavage of β-carotene yields two molecules of **all-*trans*-retinol**, which is isomerized by an enzyme in the pigmented epithelial cell layer of the retina to **11-*cis*-retinol**. Oxidation of 11-*cis*-retinol to 11-*cis*-retinal and its binding to opsin occur in the rod outer segment.

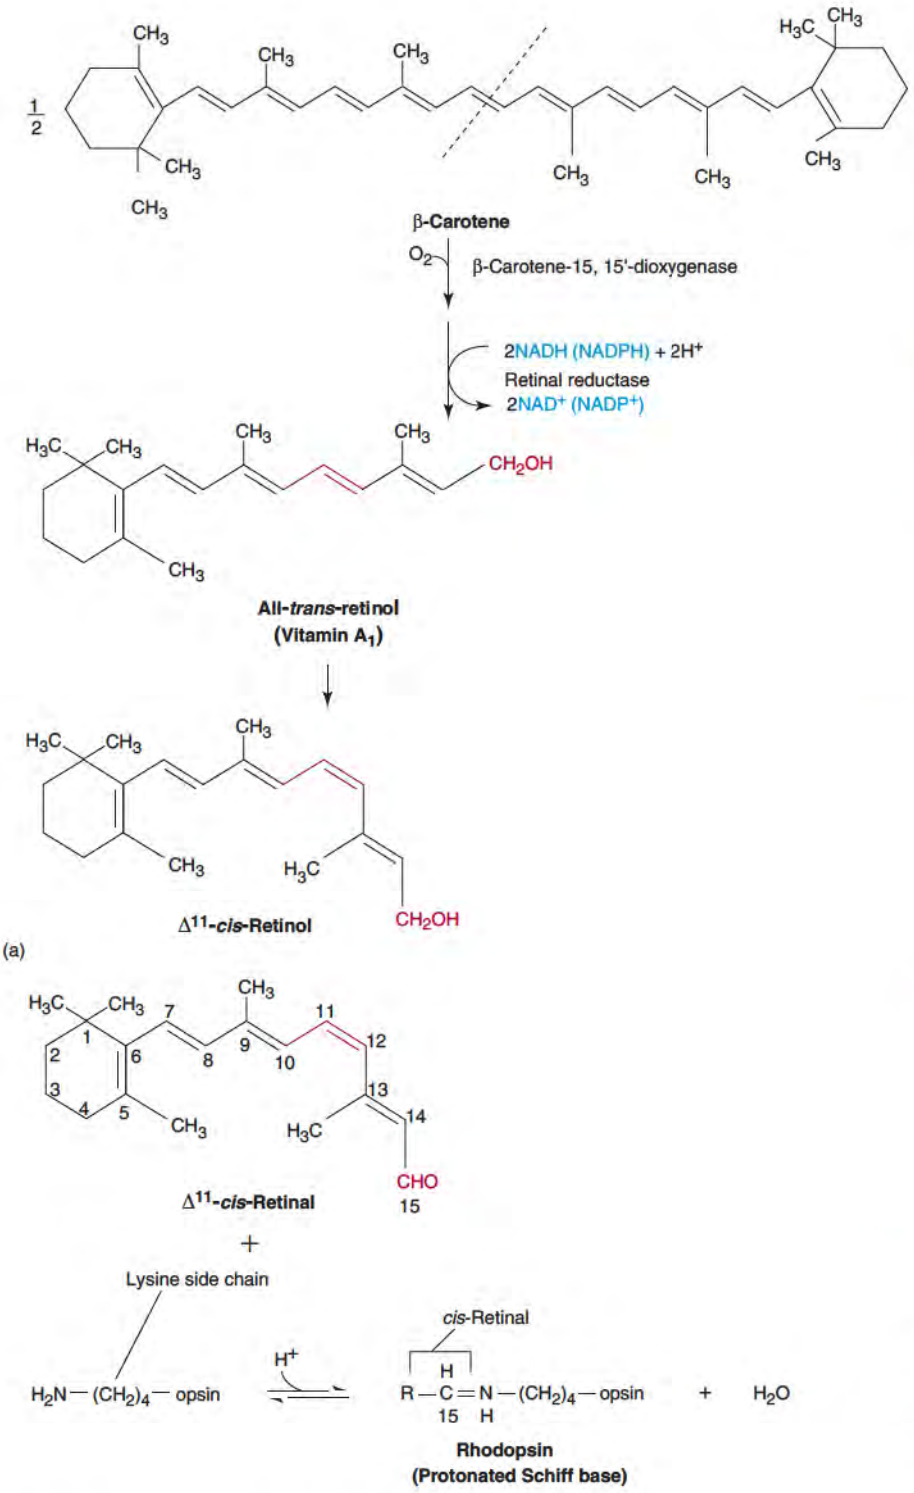

Figure 23.22 **Formation of 11-*cis*-retinal and rhodopsin from β-carotene.**

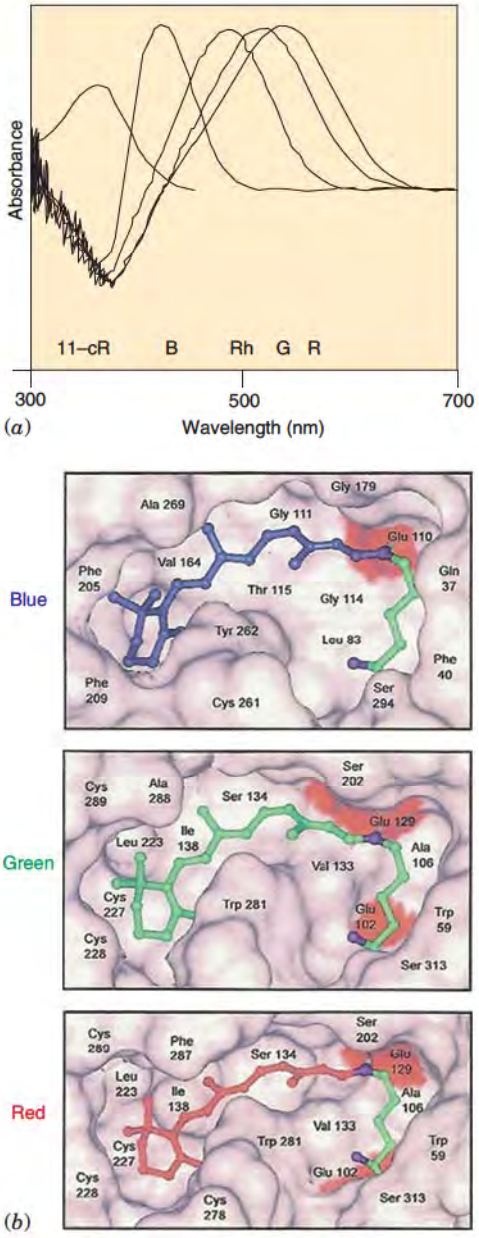

Figure 23.23 **Absorption spectra of 11-*cis*-retinal and the four visual pigments.** (*a*) Absorbance is relative and represents difference spectra obtained by subtracting the spectra for the recombinant apoproteins. The spectrum for 11-*cis*-retinal (11cR) is in the absence of protein. Other abbreviations: B, blue pigment; Rh, rhodopsin; G, green; and R, red. (*b*) Some of the amino acids in the vicinity of 11-*cis*-retinal in the blue, green, and red pigments.

Modified from Nathans, J. *Cell* 78: 357, 1994.

The absorption spectra of 11-*cis*-retinal and the four visual pigments are shown in Figure 23.23*a*. The wavelength of maximum absorption of 11-*cis*-retinal is different when it is bound to opsin (λ_{max} = 498 nm) or to the protein moieties of the other visual pigments. Spectral differences are due to subtle differences in the chemical environments in which the 11-*cis*-retinal resides (Figure 23.23*b*). Absorption bands for the pigments reflect spectral areas of their light sensitivity.

CLINICAL CORRELATION 23.6

Retinitis Pigmentosa from a Mutation in the Gene for Peripherin

Retinitis pigmentosa (RP) (OMIM 268000) is a slowly progressive condition associated with loss of night and peripheral vision. It is a group of heterogeneous diseases of variable clinical and genetic origins; several are associated with abnormal lipid metabolism. This disease affects approximately 1.5 million people throughout the world. It is inherited through an autosomal dominant, recessive, or X-linked mode. RP has been associated with mutations in the protein moiety of rhodopsin and in a related protein, peripherin/RDS (retinal degeneration slow), both of which are integral membrane proteins. Peripherin contains 344 amino acid residues and is located in the rim region of the disc membrane. Structural models of these two proteins are shown in the following figure. Filled circles and other notations in the figure mark residues or regions that have been correlated with RP or other retinal degenerations.

A *de novo* mutation in exon 1 of the gene coding for peripherin resulted in the onset of RP. It caused a C-to-T transition in the first nucleotide of codon 46. This resulted in changing an arginine to a stop codon (R46X). The pedigree of this family is shown in the adjacent figure. Neither parent had the mutation and genetic typing analysis (20 different short tandem repeat polymorphisms) showed that the probability that the proband's parents are not his actual biological parents is less than one in 10 billion, establishing with near certainty that the mutation is *de novo*.

This R46X mutation has been observed in another unrelated patient. This demonstrates the importance of DNA analysis to establish the genetic basis for RP, as opposed to that associated with other abnormal metabolic conditions.

The magnitude of change in the electrical potential of photoreceptor cells following exposure to a light pulse differs from that of neurons during depolarization. The **resting potential** of rod cell membrane is approximately −30 mV compared to −70 mV for neurons. Excitation of rod cells by a light pulse causes **hyperpolarization** of the membrane; from about -30 mV to about -35 mV (Figure 23.24). It takes hundreds of milliseconds for the potential to reach its maximum state of hyperpolarization, during which time a number of biochemical events occur.

Absorption of photons of light and isomerization of 11-*cis*-retinal in rhodopsin, are rapid, requiring only picoseconds. Following this, rhodopsin undergoes a series of conformation changes to accommodate the structural change of the 11-*cis*- to all-*trans*-retinal (Figure 23.25). One of these species, **metarhodopsin II**, has a half-life of approximately 1 min and is *active rhodopsin* (R*) that is involved in the more important biochemical phase of the visual cycle (A Closer Look 23.3, p. 964).

Structural changes are all kinetic events; that is, one does not have to be completed before the other begins, and metarhodopsin II will have begun to form within hundredths of microseconds of the initial event. Finally, dissociation of metarhodopsin to opsin and all-*trans*-retinal occurs. All-*trans*-retinal is enzymatically converted to all-*trans*-retinol by **all-*trans*-retinol dehydrogenase** in the rod outer segment. All-*trans*-retinol is transported into the pigmented epithelium where a specific isomerase converts it to 11-*cis*-retinol that is then oxidized to the aldehyde and transported back into the rod outer segment. After the aldehyde is transported back into the rod outer segment, it can recombine with opsin to form rhodopsin and the cycle can begin again. A diagrammatic representation of these events is shown in Figure 23.26 (see also Clin. Corr. 23.7, p. 965). Similar events occur in the cones with the three proteins of the red, green, and blue pigments.

There are three interconnected biochemical cycles of events that occur in the conversion of light energy to nerve impulses (Figure 23.27). These cycles describe the reactions of rhodopsin, **transducin**, and **phosphodiesterase**, respectively. The net result is a hyperpolarization of the plasma membrane of the rod (or cone) cells from −30 mV to approximately −35 mV. Maintenance of a steady-state potential of the plasma membrane of rod and cone cells at −30 mV is an important function of this series of reactions.

Rod cells of a fully dark-adapted human eye can detect a flash of light that emits as few as five photons. The rod is a specialized type of neuron in that the signal generated does not depend on an all-or-none event. The signal may be graded in intensity and reflect the extent that the mV potential changes from its steady-state value of −30 mV as well as the number of photoreceptor cells stimulated. The **steady-state potential** of −30mV is maintained at this more positive value because **Na^+ channels** of the photoreceptor cells are **ligand-gated**, and a fraction of them responsible for the influx of Na^+ are maintained in an open state. The ligand responsible for keeping some of the Na^+ channels open is **cyclic GMP (cGMP)**, which binds to them in a concentration-dependent, kinetically dynamic manner. Biochemical events that affect the concentration of cGMP within rod and cone cells also affect the number of Na^+ channels open, the concentration of Na^+ within the cells, and hence, the membrane potential (Figure 23.27).

Active rhodopsin (R*, namely, **metarhodopsin II**) forms a complex with transducin. **Transducin** is a classic trimeric **G protein** and functions in a manner very similar to that described on page 522. In the R*-transducin complex (R*-$T_{\alpha,\beta,\gamma}$), transducin undergoes a conformational change that facilitates exchange of its bound GDP with GTP. When this occurs, the α-subunit (T_α) dissociates from the β-,γ-subunits. T_α activates **phosphodiesterase (PDE)**, which hydrolyzes cGMP to 5′-GMP. This decreased concentration of cGMP decreases the amount of cGMP available to bind to Na^+ channels and, therefore, decreases the number of open Na^+ channels. The influx of Na^+decreases, but the efflux of Na^+ is not affected by these events and Na^+ concentration inside the cells decreases causing the membrane potential to become more negative, that is, hyperpolarized.

The diagram of Figure 23.27 shows in cartoon form two such channels in the plasma membrane, one of which has cGMP bound to it and is open. The other does not have cGMP bound to it and is closed. By this mechanism, the concentration of Na^+ in the cell is directly linked to the concentration of cGMP and, thus, also the membrane potential.

PDE in rod cells is a **heterotetrameric protein** consisting of one each α and β catalytic subunits and two γ regulatory subunits. T_α-GTP forms a complex with the γ-subunits of PDE effecting dissociation of the catalytically active α,β-dimeric PDE subunit complex. T_α-GTP has GTPase activity that hydrolyzes bound GTP to GDP and inorganic phosphate (P_i). This results in dissociation of T_α-GDP from the regulatory γ-subunits of PDE permitting them to reassociate with the catalytic subunits to reestablish the α,β,γ_2 structure of PDE—its inactive form. The same reactions occur in cone cells, but the catalytic subunits of cone cells PDE differ from those of rods in that cone cells PDE consists of two α catalytic subunits (α_2) instead of an α and a β catalytic subunit ($\alpha\beta$).

cGMP concentration is regulated by intracellular Ca^{2+}. Ca^{2+} enters rod cells in the dark through sodium channels increasing its concentration to the 500-nM range. At

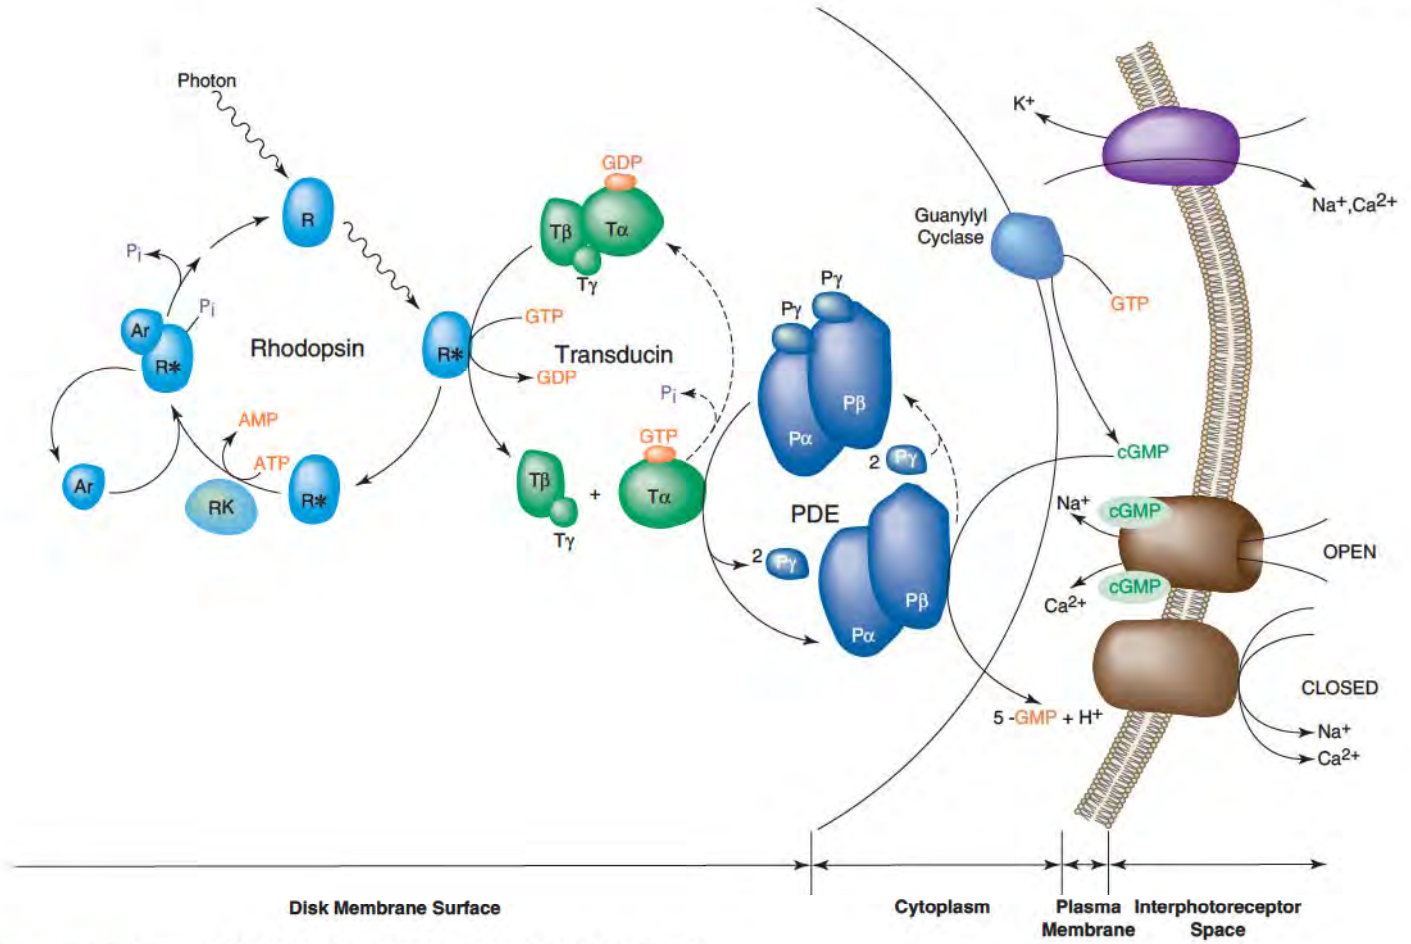

Figure 23.27 Cascade of biochemical reactions involved in the visual cycle.
Redrawn from Farber, D. B. *Investigative Ophthalmology & Vis. Sci.* 36: 263, 1995.

these concentrations, activity of **guanylate cyclase** is low. When sodium channels are closed, Ca^{2+} entry is inhibited also, but efflux of Ca^{2+} by the sodium/calcium–potassium exchanger is unchanged (top complex of the plasma membrane in Figure 23.27). This decreases the intracellular Ca^{2+} concentration resulting in activation of guanylate cyclase and increased production of cGMP from GTP. Resynthesis of cGMP and the hydrolysis of GTP of the T_α-GTP complex play important roles in stopping reactions of the visual cycle.

Inactivation of activated rhodopsin R* is also important in stopping this cascade of events. Activated rhodopsin R* is phosphorylated by an ATP-dependent **rhodopsin kinase** (Figure 23.27). The R*-P_i has high binding affinity for the cytosolic protein, **arrestin**. The arrestin-R*-P_i complex is no longer capable of interacting with transducin. The kinetics of binding of arrestin to the activated-phosphorylated rhodopsin is sufficiently rapid *in vivo* to stop the cascade of reactions. When rhodopsin is regenerated, the cycle can be initiated again by photons of light.

Mutations can occur in any of the major proteins involved in the visual cycle, some of which are listed in Table 23.6, and result in visual impairment (Clin. Corr. 23.7).

Color Vision Originates in Cones

Even though photographic artists, such as the late Ansel Adams, make the world look beautiful in black and white, the intervention of colors in the spectrum of life's pictures brings another degree of beauty to the wonders of nature and the beauty of life, even the ability to make a distinction between tissues from histological staining. The ability of humans to distinguish colors resides within a relatively small portion of the visual system, the cones. The number of cones within the human eye (6 to 7 million) is few compared with the number

A CLOSER LOOK 23.3

Conformation Changes during Formation of "Active Rhodopsin"

The conformation changes leading to formation of "active rhodopsin" are stepwise events with some of the species being very short lived as evident by the data shown in Figure 23.25, p. 961. The exact structures for these intermediates are not known, but it is clear that they result from changes in the neighboring group environment of retinal after its isomerization. Panel *a* of the following figure is a schematic from the 3D structure of rhodopsin showing the amino acid side chains surrounding 11-*cis*-retinal as viewed from the cytoplasmic side. When 11-*cis*-retinal undergoes isomerization to the all-*trans*-retinal at the position within the red circle of panel *b*, the β-ionone ring of all-*trans*-retinal reaches Ala^{169} in helix IV. Ala^{169} is not within the range of interactions shown in panel *a*. The intermediate species listed in Figure 23.25 represent some of the conformations rhodopsin undergoes before it finally dissociates to opsin and all-*trans*-retinal. At 37°C, activated rhodopsin decays in slightly more than 1 ms through several intermediates to **metarhodopsin II**, which has a half-life of approximately 1 min.

CLINICAL CORRELATION 23.7

Leber Congenital Amaurosis: Retinal Dystrophy Leading to Blindness

Leber congenital amaurosis (LCA) is one of the more serious conditions leading to congenital blindness. Leber first described LCA in 1869. Clinical heterogeneity in LCA was recognized early but essentially ignored. Genetic heterogeneity has been accepted since 1963 and three genes have been shown to account for about 27 % of the dystrophy. (1) retGC1 (aka GUCY2D) on chromosome 17p13 codes for the photoreceptor specific guanylate cyclase. (2) CRX on chromosome 19q13.3 codes for a homeobox protein essential for photoreceptor maintenance and outer rod/cone segment biogenesis. RPE65 on chromosome 1p31 codes for a specific retinal pigment epithelium (RPE) protein involved in vitamin A metabolism, specifically, retinol *trans/cis* isomerase. Structural representation of the human RPE65 gene and positions of mutations that have been identified in LCA is shown.

A canine model of LCA has been treated by gene replacement therapy in which a normal RPE65 gene was delivered intraocularly to one eye of each test animal and vision was restored in that eye to near normal. The function of this enzyme in vision is evident from Figures 23.25 and 23.26. Gene therapy to restore vision of humans affected by this mutation is now in progress.

LCA has been linked to mutations in the gene encoding another protein, the photoreceptor-specific gene Aryl hydrocarbon interacting protein like AIPL 1 . The protein, AIPL 1, enhances protein farnesylation. Retinal proteins known to be farnesylated are cGMP phosphodiesterase, transducin, and rhodopsin kinase. Mutationally defective AIPL 1 affects cGMP phosphodiesterase localization and amount in rods and cones prior to their degeneration and loss of vision.

Schematic representation of the human RPE65 gene.

of rods (120 million). Some animals (e.g., dogs) have even fewer cones, and other animals (e.g., birds) have many more.

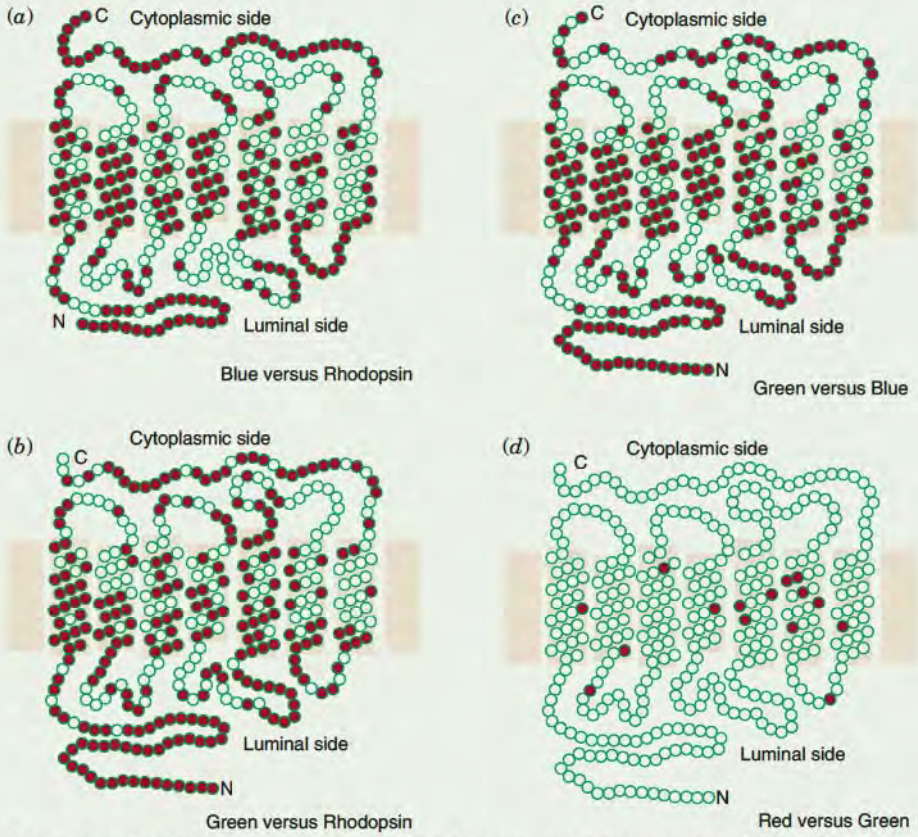
The mechanism by which light stimulates cone cells is the same as it is for rod cells. The initial event in all cases is the photo-induced isomerization of 11-*cis*-retinal. There are three types of cone cells, defined by whether they contain the blue, green, or red visual pigments (see Figure 23.23*b*, p. 959). They are also referred to in medical literature as short (S), medium (M), or long (L) wavelength-specific opsins, respectively. Color discrimination by cone cells is an inherent property of the proteins of the visual pigments to which the 11-*cis*-retinal is attached. The 11-*cis*-retinal is attached to each of the proteins through a protonated Schiff base as in rhodopsin. The absorption spectrum produced by the conjugated double-bond system of 11-*cis*-retinal is influenced by its chemical environment (see Figure 23.23*b*). When 11-*cis*-retinal is bound to different visual proteins, amino acid residues in the local areas around the protonated base and the conjugated π-bond system influence the energy level and give different absorption spectra with absorption maxima that are characteristic of the different color pigments: approximately 420 nm for blue, 535 nm for green, and 565 nm for red (A Closer Look 23.4).

Normally, only one type of visual pigment occurs per cell. During fetal development, however, multiple pigments may occur in the same cell. During development the blue pigment seems to appear first, followed by green and then red pigments. The number of cones containing these multiple pigments decreases after birth and is

A CLOSER LOOK 23.4

Sequence Homology of Visual Pigments

Significant homology exists among the amino acid sequences of the visual pigments (figure follows). Open circles represent amino acids that are the same, and closed circles those that are different. A string of closed circles at either end represents an extension of the chain of one protein relative to the other. The red and the green pigments show the greatest degree of homology, about 96% identity, whereas the degree of homology between different pairs of the others is between 40% and 45%.



Comparisons of the amino acid sequences of the human visual pigments. Each filled dot indicates an amino acid difference.
Adapted from Nathans, J. *Annu. Rev. Neurosci.* 10:163, 1987.

insignificantly small or nonexistent in adults. Cones containing the blue pigment constitutes only about 2% of the total number of cones, and they are outside of the fovea. Cones containing the green and red pigments are approximately 32% and 64% of the total, respectively.

Color Vision Is Trichromatic

Genes encoding the visual pigments have been mapped to specific chromosomes. The rhodopsin gene resides on **chromosome 3**, the gene encoding the blue pigment resides on **chromosome 7**, and genes for the red and green pigments are on the **X chromosome**. In spite of the great similarity among the red and green pigments, they are distinctly different proteins. Individuals have been identified with inherited variations that affect one but not both pigments simultaneously. There may be more than one gene for the green pigment, but it appears that only one is expressed. Colors other than those reflected by the absorption maxima of the visual pigments are distinguished by graded stimulation of the different cones and comparative analysis by the brain (A Closer Look 23.5 and 23.6).

A CLOSER LOOK 23.5

Diagnosis of John Dalton's Color Blindness

John Dalton (1766–1844), who developed the atomic theory of chemistry, was color blind. He first described his visual problem in a lecture in 1794 and published his observation in 1798. He thought his color blindness was due to the vitreous humor being tinted blue, selectively absorbing longer wavelengths of light. He instructed that after his death his eyes be examined to determine whether his theory was correct. An autopsy revealed that the vitreous humor was *perfectly pellucid*, or normal. Using DNA analysis on Dalton's preserved eyes, obtained from the British Museum, it has now been shown that Dalton was missing the green pigment. Thus, instead of having trichromatic vision, he was dichromatic with a vision type known as **deuteranopia** or "Daltonism" since his publication was the first recognized account of red-green color-blindness. The type color blindness of one who is missing the red pigment is called **protanopia**.

23.3 • MOLECULAR MOTORS AND ASSOCIATED PROTEINS

There are three families of molecular motors: myosin, kinesin, and dynein. Myosin is an actin-based motor, and the other two are microtubule-based motors. Actin-based motors include those involved in muscle contraction, and the latter two include those involved in intracellular trafficking—moving cargo or arranging intracellular structures. There are *unconventional myosins* (actin-based motors) that also move cargo. Motors involved in trafficking function as single units and do not form fibers as those involved in muscle contraction do. This includes also cargo-carrying actin-based myosins. Fuel for all of these motors is ATP. The mechanism for ATP use in myosin- and kinesin-based motors to affect their function is similar and well known. Dynein is structurally very different from myosin and kinesin, and the mechanisms of its load-dependent cargo movement and multiple ATP use are currently not well defined. Protein conformation changes on binding ATP, its hydrolysis, and release of products are common to the mechanics of action of all of them.

Muscle Contraction

There are three types of muscles in the human body: skeletal, cardiac, and smooth. Skeletal muscles are striated in appearance—they have discrete bands and filaments—and the individual controls their actions voluntarily. Cardiac muscles are striated also, but their contractile units are not arranged in a linear manner as are skeletal muscles and their contraction is not voluntary. Smooth muscles are not striated, their thick and thin filaments do not show a visibly discrete organizational pattern, and they, like cardiac muscle, are not under voluntary control. Common to the contraction of each of these classes of muscle is the *sliding filament model*, that is, movement of the actin filament over the myosin filament and use of ATP as the energy source to effect contraction.

Skeletal Muscle: Structural Organization of Its Components

A schematic diagram of the structural organization of skeletal muscle is shown in Figure 23.28. Skeletal muscle consists of bundles of fibers (panel *c*). Each bundle is called a fasciculus (panel *b*). The fibers are made up of myofibrils (panel *d*), and each myofibril is a tandem series of muscle cells or units called **sarcomeres**. The muscle cell is multinucleated and is not capable of division. Most muscle cells survive for the life of the animal, but they can be replaced when lost or lengthened by fusion of **myoblast cells**.

A muscle cell is shown diagrammatically in Figure 23.29. Note that the myofibrils are surrounded by a membranous structure called the **sarcoplasmic reticulum**. At discrete intervals along the fasciculi and connected to the terminal cisterna of the sarcoplasmic reticulum are transverse tubules. These are connected to the external plasma membrane that surrounds the entire structure. Nuclei and mitochondria lie just inside the plasma membrane.

A CLOSER LOOK 23.6

Other Differences between Rods and Cones

Sensitivity and response time of rods differs from those of cones. Absorption of a single photon by photoreceptors in rods generates a current of approximately 1–3 picoAmps ($1–3 \times 10^{-12}$), whereas the same event in the cones generates a current of approximately 10 femtoAmps (10×10^{-15}), about 1/100th of the rod response. The response time of cones, however, is about four times faster than that of rods. Thus, the cones are better suited for discerning rapidly changing events and the rods are better suited for low-light visual sensitivity.

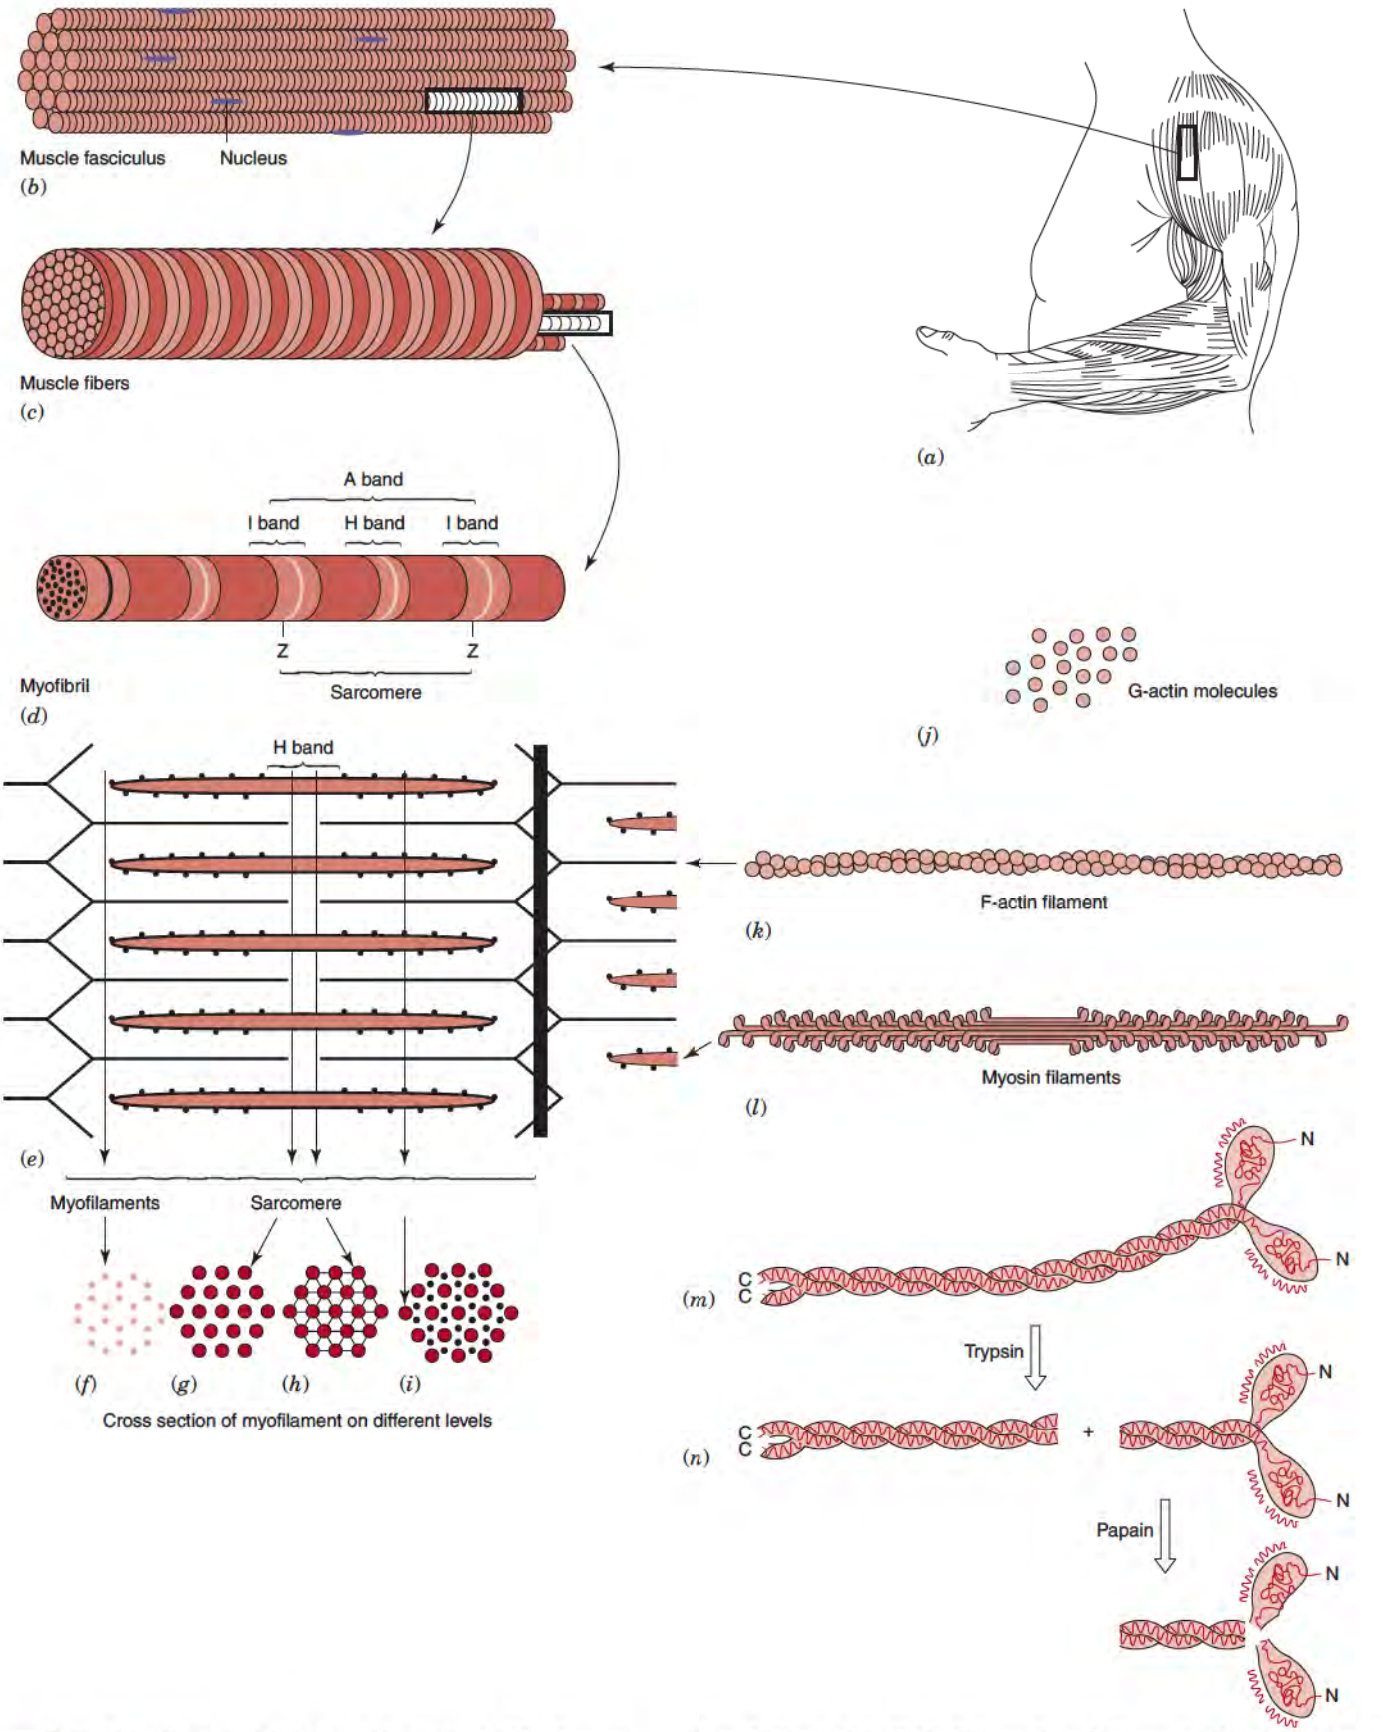


Figure 23.28 **Structural organization of skeletal muscle.** The diagram shows schematically the aggregation of G-actin to F-actin and the relative positions of cleavage of myosin by trypsin and papain.
Redrawn from Bloom, W. D., and Fawcett, D. W. *Textbook of Histology,* 10th ed. Philadelphia: Saunders, 1975. Sections *m* and *n* redrawn from Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K., and Watson, J. *Molecular Biology of the Cell,* 2nd ed. New York: Garland, 1983.

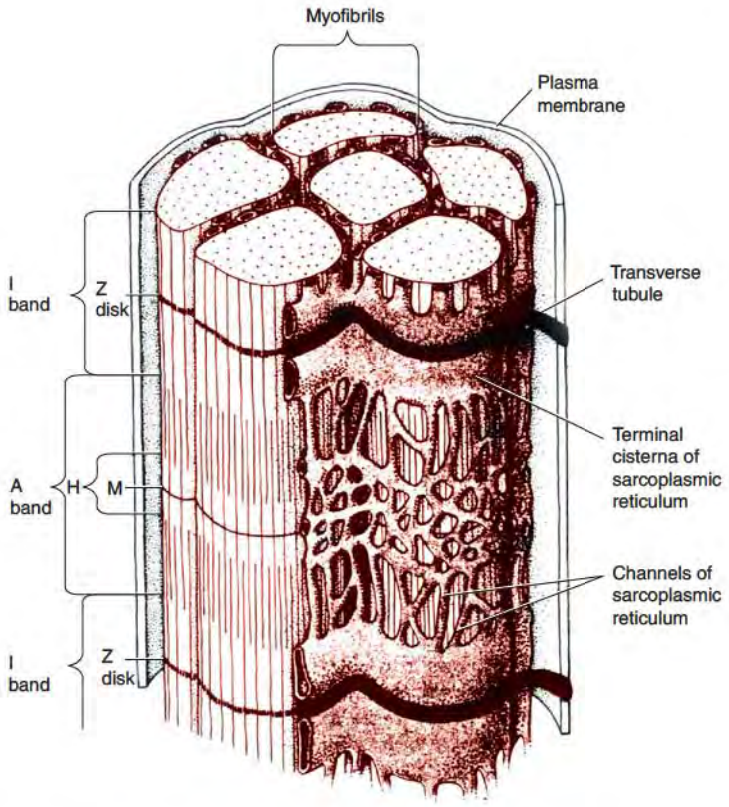

Figure 23.29 A schematic representation of a bundle of six myofibrils. The lumen of the transverse tubules connects with the extracellular medium and enters the fibers at the Z disk. Reprinted with permission from Darnell, J., Lodish, H., and Baltimore, D. *Molecular Cell Biology.* New York: Scientific American, 1986, 827.

The single contractile unit, the sarcomere, consists of all structural components between Z bands (or Z disk) (see Figures 23.28*d* and 23.29). Bands in the sarcomere are due to the arrangement of specific proteins (see Figure 23.28*e*). Two types of fibers are apparent: long thick fibers with protrusions on both ends are anchored at the center of the sarcomere, and long thin fibers that are attached to proteins within the **Z disk**. **I (isotropic) bands** extend for a short distance on both sides of the Z disk (two adjacent sarcomeres) and contain only **thin filaments**. The **H band** is in the center of the sarcomere and contains thick or heavy filaments but no thin filaments. In the middle of the H band, there is a somewhat diffuse **M band** which contains additional proteins that assist in anchoring fibers of the **heavy filaments** (Figure 23.28*h*) to the center of the sarcomere. The **A (anisotropic) band** contains both thin and heavy filaments and is located between the inner edges of the I bands. When a muscle contracts, the H and I bands shorten, but the distance between the Z disk and near edge of the H band remains constant. The distance between the innermost edges of I bands on both ends of the sarcomere also remains constant indicating that the length of thin filaments and of thick filaments does not change during contraction. Contraction, therefore, results when these filaments "slide" past each other.

Sarcomeres consist of many different proteins, eight of which are listed in Table 23.7. The two most abundant are myosin and actin. Approximately 60%–70% of the muscle protein is myosin and 20%–25% is actin. Thick filaments consist mostly of myosin and thin filaments consist mostly of actin. Thin filaments are formed from end-to-end polymerization of globular actin subunit monomers. After monomer polymerization, thin filaments are referred to as F-actin, fibrous actin (Figure 23.28*k*). Tropomyosin and troponin are associated with F-actin and have major roles in regulation of contraction. Other proteins listed are mostly associated with formation and/or maintenance of structural integrity of the contractile unit.

TABLE 23.7 • Approximate Molecular Masses (kDa) of Some Skeletal Muscle Proteins

Myosin	500
Heavy chain	200
Light chain	20

M-protein	100

Myosin Forms Thick Filaments of Muscle

Myosin, a long fibrous molecule with two globular heads on one end, consists of two heavy chains of about 230 kDa each. Bound near each head group is a dissimilar pair of light chains, each of which is approximately 20 kDa. The light chains are "calmodulin-like" proteins and are involved in various aspects of regulation of the process, not all of

A CLOSER LOOK 23.7

Experimental Evidence for Hinge Regions and for the Section of the Molecule That Promotes Aggregation

Structural analyses show that the carboxyl end of each myosin chain is located in the tail section, where the two heavy chains are held together in a coil–coil arrangement (Figure 23.28*m*). *In vitro* experiments show that **trypsin** cleaves the tail at about one-third of its length from the head to produce **heavy meromyosin** (the head group and a short tail) and **light meromyosin** (the remainder of the tail section). Only light meromyosin can aggregate under physiological conditions *in vitro*, suggesting that effecting aggregation is one of the roles of this part of the tail section in heavy-chain formation *in vivo*.

which have been clearly defined. They bind to IQ motifs (distinctive amino acid sequence patterns) in myosin. These IQ motifs are located near the head groups and have the consensus sequence IQXXXRGXXXR (Ile-Gln-X-X-X-Arg-Gly-X-X-X-Arg, where X is any amino acid).

The head section can be cleaved from the remainder of the tail section by **papain** (Figure 23.28*n*), resulting in a head-group fragment referred to as **Subfragment 1** or **S-1**. Action of papain and trypsin demonstrates that myosin has at least two hinge regions near the head–tail junction (A Closer Look 23.7).

Heavy chains are formed by **symmetrical tail-to-tail aggregation** of myosin centered around M lines of H zones in sarcomeres. Tail sections are aligned in a parallel manner on both sides of the M line with the head groups pointing toward the Z line. Each thick filament contains about 400 molecules of myosin. The C protein (Table 23.7) is involved in their assembly. The M protein is also involved, presumably to hold the tail sections together and to anchor them to the M line.

The myosin head contains **ATPase** activity that provides energy for contraction and **actin binding**. The S-1 fragment also contains binding sites for the **essential light chain** and the **regulatory light chain** that bind at IQ motifs as mentioned. A model of the three dimensional structure of the myosin S-1 fragment is shown in Figure 23.30. The actin-binding region is located at the lower right-hand corner in the region of the visible cleft. The S-1 fragment has several structural domain-like regions with masses of 25, 50, and 20 kDa colored green, red, and blue, respectively. The essential light chain (ELC) and the regulatory light chain (RLC) are shown in yellow and magenta, respectively (Clin. Corrs. 23.8 and 23.9).

The ATP binding site, just above the visible cleft, is also an open cleft about 13 Å deep and 13 Å wide. It is separated from the actin-binding site by approximately 35 Å. Myosin binds to actin in a stereospecific manner. The ELC and the RLC are associated with a single long helix that connects the head region with the tail section. There is room for flexibility between the ELC and the connecting single helix. The conformation of myosin–ATP complex has an affinity for actin that is 1/10,000th that of the conformation of myosin that contains ADP or no ADP. Thus, the transduction of chemical energy to mechanical work depends on protein conformational changes that occur on binding of ATP, its hydrolysis, and product dissociation—initially inorganic phosphate followed by ADP (A Closer Look 23.8).

Actin, Tropomyosin, and Troponin Are Thin-Filament Proteins

Actin is the major protein of thin filaments and constitutes about 20%–25% of muscle protein. It is synthesized as a 42-kDa globular protein called G-actin, which aggregates to form fibrous actin or F-actin (see Figure 23.28*k*). More than 90% of its amino acid sequence is conserved among a variety of species (Table 23.8, p. 972). For these examples, differences are observed in about seven positions. Sequences of more than 30 actin isotypes,

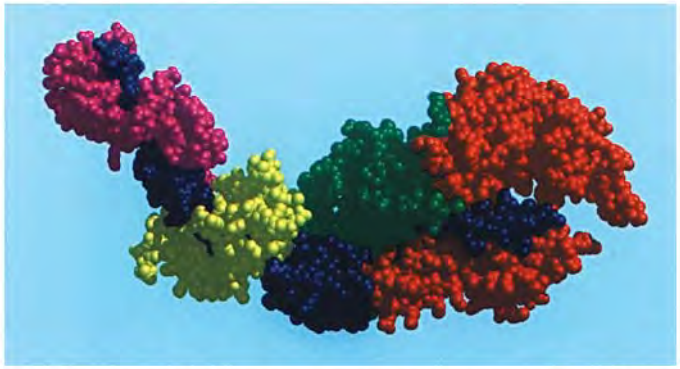

Figure 23.30 A space-filling model of the three-dimensional structure of the S-1 fragment of myosin. 25−, 50−, and 20-kDa domains of the heavy chain are green, red, and blue, respectively. Essential and regulatory light chains are yellow and magenta, respectively.

CLINICAL CORRELATION 23.8

Voltage-Gated Ion Channelopathies

There are three important types of voltage-gated cation channels: Na^+, Ca^{2+}, and K^+. Each is a heterogeneous protein consisting of various numbers of α- and β-subunits. In membranes, they are arranged in a more-or-less circular manner with a funnel-like channel formed through the middle of α-subunits. Roles of β-subunits are still being elucidated, but they appear to help stabilize and/or regulate activity of α-subunits.

Voltage-gated channels from nerve and muscle tissue show high sequence homology in many transmembrane domains, but are less conserved in the intracellular connecting loops. A common effect of mutations in Na^+ channels is muscle weakness or paralysis. Some inherited Na^+ voltage-gated ion channelopathies are listed following. Each of these is reported to result from a single amino acid change in the α-subunit and is transmitted as autosomal dominant.

It has been suggested that if the membrane potential is slightly more positive (i.e., changes from –70 to –60 mV) the myofiber can reach the threshold more easily and the muscle becomes hyperexcitable. If the membrane potential becomes even more positive (i.e., up to –40 mV) the fiber cannot fire an action potential leading to paralysis.

Disorder	*Unique Clinical Feature*
Hyperkalemic periodic paralysis	Induced by rest after exercise, or the intake of K^+
Paramyotonia congenita	Cold-induced myotonia
Sodium channel myotonia	Constant myotonia

CLINICAL CORRELATION 23.9

Familial Hypertropic Cardiomyopathies and Mutations in Muscle Proteins

Hypertropic cardiomyopathies are characterized by enlargement/thickening of the left and/or right ventricle. Arrhythmias and premature death can result from these conditions. Familiar hypertrophic cardiomyopathy results from mutations involving genes coding for β-myosin heavy chain, ventricular myosin regulatory light chain, cardiac troponin T, cardiac troponin I, α-tropomyosin, and cardiac myosin-binding protein C. Some of these genes express isoforms that may be expressed only in cardiac tissue. Thus, some of the effects are not applicable to other types of muscle. Mutations can alter structure and function of the sarcomere and lead to changes in cardiac function. Alteration in cardiac function may include decrease in force generated from myosin–actin interaction, faulty anchoring of myosin (protein C) within the sarcomere, and/or interference with any of the functions of tropomyosin and troponin subunits.

Bonne, C., Carrier, L., Pascal, R., Hainque, B., and Schwartz, K. Familiar hypertropic cardiomyopathy: from mutations to functional defects. *Circ. Res.* 83: 580, 1998.

the longest consisting of 375 amino acid residues, reveal that no more than 32 residues have been substituted (Clin. Corr. 23.10). A significant number of these substitutions occur at the *N*-terminal where essentially all actin molecules are posttranslationally modified. The *N*-terminal amino acid residue may be acetylated and hydrolyzed one or two times before the final acetylated product is achieved.

A crystal structure of G-actin is shown in Figure 23.31. Actin has two distinct domains of approximately equal size; however, one has been designated large (left) and the other small (right). Each of them consists of two subdomains. The *N*-terminal and the C-terminal residues are located within subdomain 1 of the small domain.

The molecule has polarity, and aggregation to **F-actin** can occur from either end. *In vitro* kinetic data indicate that the preferred direction of aggregation is by addition of monomers to the large end of the molecule and that the rate of addition to this end is diffusion controlled, that is, at a rate as fast as the monomer can diffuse to that end. Each G-actin contains a specific binding site between the two major domains for ATP and a

A CLOSER LOOK 23.8

Homology among Myosin from Different Sources

cDNA analyses of myosins from many different species and types of muscle indicate that there is a very high degree of homology among myosins from different sources, particularly within the head region. There is somewhat less sequence homology within the tail region, but functional homology exists to an extraordinarily high degree regardless of length, which ranges from about 86 to about 150 nm for different species. The myosin head contains nearly one-half (about 839 to about 850) of the amino acid residues in the entire molecule in mammals (Clin. Corr. 23.8, p. 971).

TABLE 23.8 • Summary of the Amino Acid Differences Among Chicken Gizzard Smooth Muscle Actin, Skeletal Muscle Actin, and Bovine Cardiac Actin

	Residue Number						
Actin Type	*1*	*2*	*3*	*17*	*89*	*298*	*357*
Skeletal muscle[a]	Asp	Glu	Asp	Val	Thr	Met	Thr
Cardiac muscle[b]		Asp	Glu			Leu	Ser
Smooth muscle[c]	Absent		Glu	Cys	Ser	Leu	Ser

divalent metal ion, Mg^{2+}, but Ca^{2+} competes with Mg^{2+} for the same binding site. The **G-actin–ATP–$Mg2^{+}$ complex** aggregates faster to form **F-actin**. Subdomains 1 and 2 of G-actin molecules in F-actin are to the outside where myosin binding sites are located. The conformational form of F-actin is helical. F-Actin may be viewed as either (1) a single-start, left-handed single-stranded helix with rotation of the monomers through an approximate 166° with a rise of 27.5 Å or (2) a two-start, right-handed double-stranded helix with a half pitch of 350–380 Å.

***β*-Actinin** binds to F-actin and assists in limiting the length of the thin filaments. ***α*-Actinin**, a homodimer of 90 to110 kDa subunits, binds adjacent actin monomers of F-actin at positions 86–117 of one and 350–375 of the other and strengthens the fiber. It also helps to anchor the actin filament to the Z disk. Other major proteins associated with the thin filament are **tropomyosin** and **troponin**.

Tropomyosin is a rod-shaped protein consisting of two dissimilar subunits, each of about 35 kDa. It forms aggregates in a head-to-tail configuration. It interacts in a flexible manner with the thin filament throughout its entire length. It fits within the groove of the helical assembly of the actin monomers of F-actin. Each tropomyosin molecule interacts with about seven actin monomers between subdomain one and three. Tropomyosin helps to

CLINICAL CORRELATION 23.10

Dilated Cardiomyopathy and Mutations in Actin

Thin walls of the heart and inability to pump blood effectively are characteristics of dilated cardiomyopathy. A genetic cause of this condition can be defective actin. Although the amino acid sequence of actin is highly conserved, there are several isoforms expressed by different genes; five of six are expressed in skeletal and cardiac myocytes. In adult cardiac myocytes, approximately 80% of actin results from expression of specific cardiac isoforms. Mutations in the invariant regions of these cardiac isoforms can result in serious health effects. An inherited single amino acid substitution (see following), Arg312His in one patient and Glu361Gly in another patient, resulted in dilated cardiomyopathy, a condition in which cardiac transplant is the only definitive treatment for end-stage disease.

Comparison of the positions of those substitutions with the structure of actin shown in Figure 23.31 reveals that they occur in two different functional regions of actin.

stabilize the thin filament and to transmit signals for conformational change to other components of the thin filament when Ca^{2+} binds to troponin that is attached to tropomyosin.

Troponin consists of three dissimilar subunits designated TnC, TnI, and TnT with molecular mass of about 18 kDa, 23 kDa, and 37 kDa, respectively. The TnT subunit binds to tropomyosin. The TnI subunit inhibits binding of actin to myosin. The TnC subunit is a calmodulin like protein that binds Ca^{2+}.

The three-dimensional structure of TnC shows it to be dumbbell shaped and very similar to calmodulin. A structural model of the calcium-saturated TnC–TnI complex is shown in Figure 23.32. The TnI subunit fits around the central region of TnC as a helical

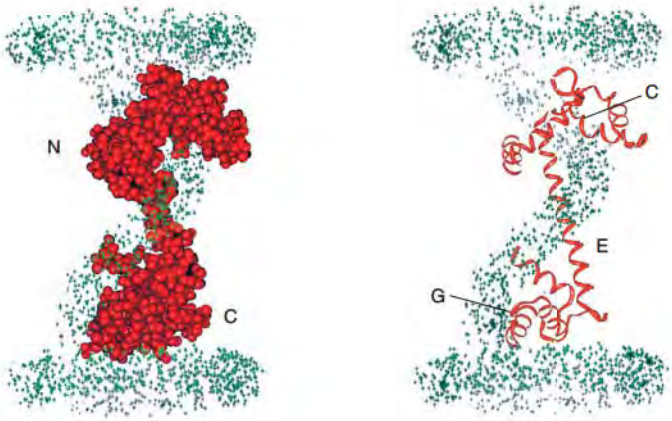

Figure 23.32 Best-fit model for the $4Ca^{2+}$–TnC–TnI complex. A model for the $4Ca^{2+}$–TnC–TnI complex based on neutron-scattering studies with deuterium labeling and contrast variation (Olah, C. CLINICAL CORRELATION 23.11

Troponin Subunits as Markers for Myocardial Infarction

Troponin contains three subunits (TnT, TnI, and TnC) and each is expressed by more than one gene. Two genes code for skeletal muscle TnI, one for fast and one for slow skeletal muscle, and one gene codes for cardiac muscle TnI. The genes that code for TnT have that same distribution pattern. The gene for the cardiac form of TnI appears to be specific for heart tissue. Two genes encode TnC, but neither gene appears to be expressed only in cardiac tissue.

The cardiac form of TnI in humans is about 31 amino acids longer than the skeletal muscle form. Serum levels of TnI increase within 4 h of an acute myocardial infarction and remain high for about seven days in about 68% of patients tested. Almost 25% of one group of patients showed a slight increase in the cardiac form of TnI after acute skeletal muscle injury indicating that it would not be a good and sensitive test for myocardial infarction.

Two isoforms of cardiac TnT, TnT_1 and TnT_2, are present in adult human cardiac tissue and two more isoforms are present in fetal heart tissue. These isoforms may result from alternative splicing of mRNA. Serum levels of TnT_2 increase within four hours of acute myocardial infarction and remain high for up to fourteen days. TnT_2 in serum is 100% sensitive and 95% specific for detection of myocardial infarction. TnT_2 assay is used to detect acute myocardial infarction. Myocardial infarcts are either undiagnosed or misdiagnosed in hospital patients admitted for other causes or in 5 million or more people who go to doctors for episodes of chest pain. This test is sufficiently specific to diagnose myocardial incidents in these patients and to help direct doctors to proper treatment for them.

Anderson, P. A. W., Malouf, N. N., Oakeley, A. E., Pagani, E. D., and Allen, P. D. Troponin T isoform expression in humans. *Circulation Res.* 69: 1226, 1991; and Ottlinger, M. E., and Sacks, D. B. *Clin. Lab. News,* 20: 33, 1994.

coil and forms caps over it at each end. The cap regions of TnI are in close contact with TnC when TnC is fully saturated with Ca^{2+}. TnC contains four divalent metal ion-binding sites. Two are in the C-terminal region, have high affinity for calcium ions (K_D of about 10^{-7} M), and are presumed to be always occupied by divalent metal ions (Ca^{2+} or Mg^{2+}) since the concentrations of these ions in resting cells are within the same order of magnitude as the K_D. Under resting conditions, TnI has a conformation that prevents proper orientation of tropomyosin and inhibits myosin binding to actin, thus, preventing contraction. On excitation, the calcium ion concentration increases to about 10^{-5}M, high enough to bind to sites within the *N*-terminal region of TnC. TnI now binds preferentially to TnC in a capped structural conformation as shown in Figure 23.32. This permits movement of tropomyosin, and myosin-binding sites on actin become exposed. The nature of the interaction of tropomyosin with actin permits it the flexibility to alter its conformation as a function of calcium ion concentration and to assist in blockage of the myosin binding sites on actin at low Ca^{2+} concentration (Clin. Corr. 23.11).

Figure 23.28*i*, p. 968, shows schematically a cross section of a sarcomere and the relative arrangement of thin and thick filaments. Six thin filaments surround each thick filament. The arrangement and flexibility of myosin head groups make it possible for each thick filament to interact with multiple thin filaments. When cross-bridges form between thick and thin filaments, they do so in patterns consistent with that shown in the colorized electron micrograph of Figure 23.33. This shows a two-dimensional view of thick filaments interacting with two thin filaments.

Skeletal Muscle Contraction

Skeletal muscle contraction is initiated by excitation of a motor neuron and propagation of an action potential to a neuromuscular junction (Figure 23.34). Note from an earlier section of this chapter on nerve transmission (p. 974) that when the impulse reaches the neuromuscular junction, Ca^{2+} channels open on the presynaptic neuron, Ca^{2+} enters those channels and initiates the process for release of acetylcholine into the neuromuscular junction (see Clin. Corr. 23.1, p. 941). Acetylcholine, on entering into the neuromuscular junction, binds to its (ligand-gated) receptors on the muscular side of the junction and initiates an impulse that travels along the sarcolemma, through the T-tubules, to sacs of the sarcoplasmic reticulum. Ca^{2+} is released into the cytosol (sarcoplasm) of the sarcomere resulting in an increase in its concentration of about 100-fold, from about 10^{-7} M to about 10^{-5} M. At this higher concentration, Ca^{2+} binds troponin; specifically, it binds to

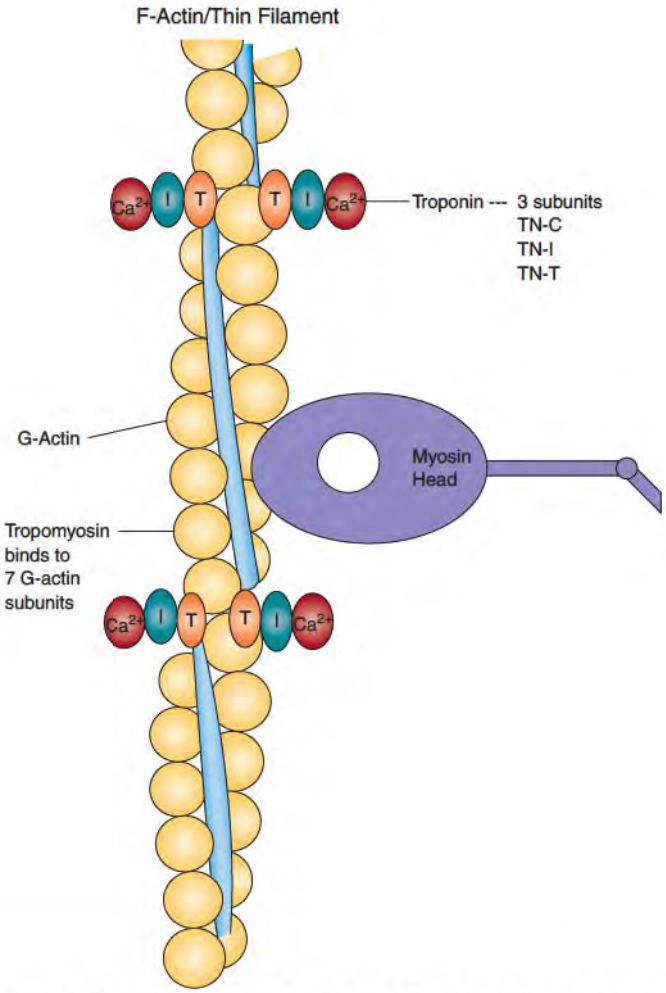

Figure 23.35 Diagram showing the relationship between the three subunits of troponin, tropomyosin, the actin filament, and a myosin head unit. TnC and TnI subunits are shown in Figure 23.32. These subunits interact with tropomyosin through TnT.

TnC subunits of the heterotrimeric troponin molecules (Figure 23.35). Binding of Ca^{2+} to TnC induces a conformation change that also affects other subunits of troponin. There is a change in TnI conformation and a conformational change is eventually transmitted through the TnT subunit of troponin to tropomyosin. Tropomyosin lies in the grove of the helical arrangement of the F-actin filament. Tropomyosin is forced into a rotational conformation that exposes myosin-binding sites on the F-actin filament permitting actin–myosin interaction.

Model for Skeletal Muscle Contraction: The Power Stroke

Myosin head groups undergo conformational changes on binding of ATP, hydrolysis of ATP, and release of products. ATP binding leads to closure of the active site cleft and opening of the cleft in the region of the actin binding site. Hydrolysis of ATP results in closure of the cleft in the actin-binding region that opens again on or for release of inorganic phosphate (A Closer Look 23.9).

Conformational changes in myosin that occur in conjunction with closing and opening of the cleft in the actin-binding region with release of inorganic phosphate (P_i) during ATP hydrolysis are associated with the **power stroke** (Figure 23.36). Actin filaments can be moved as much as 10 nm during this process. The open conformation of myosin is now in a position to bind ATP and start the cycle over again.

Individual myosin units functioning in an asynchronous manner, possibly like changes in the position of hands on a rope in the game of tug-of-war can maintain force or

A CLOSER LOOK 23.9

Evidence for Conformation Changes on P_i and ADP Release

This conformational change is evident by the movement of two cysteine-containing helices. The distance between Cys^{697} and Cys^{707} changes from about 19 Å to about 2 Å. Experimentally cross-linking of these two cysteines in the closed position traps ADP within its binding site. A stereo view of myosin showing the reactive cysteine pocket (cysteine residues that can react chemically with externally added cysteine reactive agents) is shown in the figure.

create maximum force. Thus, when some myosin head groups bind with high affinity, others have low affinity, and this binding, pulling, release, binding action of myosin shortens the sarcomere in an appropriately forceful manner.

Contraction is stopped by action of the Ca^{2+}-transporting ATPase (Ca^{2+}-ATPase) (see Figure 12.55, p. 992) that rapidly pumps Ca^{2+} from the sarcomere back into the sarcoplasmic reticulum where it is sequestered by calsequestrin.

Cardiac Muscle: Structure and Contraction

Cardiac muscle is striated but in a somewhat less pronounced way than skeletal muscle. A diagram of cardiac muscle structure is shown in Figure 23.37. Cardiac muscle is under control of the *autonomic nervous system* and its contraction is involuntary. The sarcomeres of cardiac muscle are not arranged in a linear manner but are branched and held together

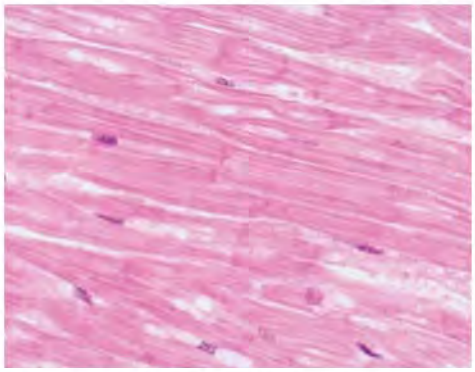

Figure 23.37 Cardiac muscle. Cardiac muscle cells are striated and connected to each other by intercalated discs; the dark red bands perpendicular to the fibers. Intercalated discs contain three types of membrane junctions – fascia adherens, macula adherens (desmosomes), and gap junctions. These membranes form a network (syncytium) ensuring that all cells work together as a unit. Darker areas are nuclei.
Photograph of human cardiac muscle was prepared and generously provided by Dr. Kate M. Baldwin, Department of Anatomy, Howard University College of Medicine, Washington, DC.

tightly by adheren junctions. These junctions are assembled from the association of a transmembrane protein, cadherin, a polymerized rodlike protein that crosses the membranes of adjacent cells and interacts with another protein, catenin, that binds to actin and α-actinin in adjacent sarcomeres.

Cardiac muscle contracts in a rhythmic manner originating from an impulse generated within the heart itself. Impulse transmission is electronic through gap junctions, which permit faster signaling between sarcomeres. There is a longer time period between each contractile cycle than usually occurs in skeletal muscle, but this can be altered by hormones or other agents.

The mechanism for contraction is the *sliding filament* model involving myosin–actin interaction as described for skeletal muscle. Other ions and ion channels play very important roles in control of cardiac muscle contraction. Some of these are discussed in Clin. Corrs. 23.9, p. 971, 23.10, p. 972, 23.11, p. 974, and 23.12, p. 978.

Smooth Muscle Contraction: Calcium Regulation

Smooth muscle contraction is generally slower than skeletal muscle contraction; but smooth muscle can contract to a greater extent and in more directions than skeletal muscle and can generate a greater contractile force (Figure 23.38). Actin filaments are attached to the dense bodies that contain α-actinin. α-Actinin is a Z-band protein in skeletal muscle that is also involved in anchoring F-actin. Presumably dense bodies of smooth muscle function as Z lines do in skeletal muscle. The ratio of thin to thick filaments is approximately 15:1 in smooth muscle compared to approximately 6:1 in skeletal muscle.

Smooth muscle contraction is also influenced by hormones. Among other proteins involved in smooth muscle contraction is **caldesmon**, which serves a function similar to troponin in skeletal muscle. Calcium-calmodulin binds to caldesmon, affects its release from actin, and permits contraction. Smooth muscle does not have a well-defined sarcoplasmic reticulum, and Ca^{2+} that is required for contraction comes from internal storage or from outside of the cell.

Calcium ions play another important role in smooth muscle contraction. A mechanism for calcium regulation of smooth muscle contraction is shown in Figure 23.39. Some key elements of this mechanism are (1) release of Ca^{2+} from intracellular stores or increased flux across the plasma membrane, (2) formation of a Ca^{2+}–CaM complex is dependent on the concentration of intracellular Ca^{2+}, (3) A Ca^{2+}–calmodulin (CaM) complex activates **myosin light-chain kinase (MLCK)**, (4) myosin light chain is phosphorylated by MLCK, (5) a phosphorylated myosin light chain stimulates myosin Mg^{2+}-ATPase, which supplies energy for the contractile process, and (6) contraction is stopped or decreased by a **myosin phosphatase** and/or transport of Ca^{2+} out of the cell. Many more biochemical steps are

CLINICAL CORRELATION 23.12

Ion Channels and Cardiac Muscle Disease

Voltage-gated ion channels in cardiac muscles, like those of other tissues, require a finite recovery time after excitation. The heart contracts and relaxes on a continuous basis and in a rhythmic manner that cannot be altered significantly without causing problems such as arrhythmias, fibrillation, and possibly death. The recovery time between contractions of cardiac muscle is measured on electrocardiograms as the QT interval. Initiating the excitation phase is the opening of Na^+ channels for a finite period. Na^+ moves into the cell causing depolarization. K^+ channels then open to permit K^+ to move out of the cell. Both ions flow down their respective chemical concentration gradients. Opening of the K^+ channels is important for shutting off the action potential. Inherited conditions referred to as long QT syndrome or LQTS, have been linked to genes that affect K^+ channels (KVLQT1, HERG, mink) and Na^+ channels (SCN5A). Defects in these channels in cardiac muscle can cause sudden death; particularly in young people who are physically active, have never had an electrocardiogram, and have no knowledge that they have LQTS. Prevalence of this condition is approximately 1 in 10,000.

Balser, J. R. Structure and function of the cardiac sodium channels. *Cardiovasc. Res.* 42: 327, 1999; Ackerman, M. J., Schroeder, J. J., Berry, R., Schaid, D. J., et al. A novel mutation in KVLQT1 is the molecular basis of inherited long QT syndrome in a near-drowning patient's family. *Pediatr. Res.* 44: 148, 1998; and Barinaga, M. Tracking down mutations that can stop the heart. *Science* 281: 32, 1998.

involved in the regulation of smooth muscle contraction, steps that can be regulated by hormones and other agents such as NO and cGMP. These diverse interactions give smooth muscles the ability to develop various degrees of tension and to retain it for prolonged periods.

Energy Reservoirs for Muscle Contraction

In normal muscle, the concentration of ATP remains fairly constant even during strenuous activity because of increased metabolic activity and the actions of **creatine phosphokinase** and **adenylate kinase**. Creatine phosphokinase catalyzes transfer of phosphate from phosphocreatine to ADP in an energetically favored manner.

$$\text{Phosphocreatine} + \text{ADP} \rightleftharpoons \text{ATP} + \text{Creatine}$$

If the metabolic activity is insufficient to keep up with the need for ATP, the creatine phosphokinase helps to maintain cellular levels relatively constant. Adenylate kinase provides additional ATP by catalyzing the reaction

$$2\text{ADP} \rightleftharpoons \text{ATP} + \text{AMP}$$

The most obvious pathological consequence of ATP depletion is development of a state of **rigor**. Effects of ATP depletion are (1) intracellular Ca^{2+} concentration is no longer controlled and (2) myosin will exist exclusively in the myosin–ADP complex and bound to actin, a condition called **rigor mortis**. Recall that ATP is required for dissociation of the actin–myosin complex.

Other Classes of Myosins and Molecular Motors

Eighteen classes of myosin have been identified in the human genome. They are generally written as Myosin- followed by [Roman numbers I-XVIII]. Skeletal, cardiac, and smooth muscle myosins are all in Class II and have gene designations MYH1–MYH8 for either skeletal or cardiac, whereas smooth muscle is designated MYH11. There are also some nonmuscle myosins in Class II.

Unconventional Myosins and Their Functions

Analyses of the human genome suggest that there are more than 20–30 myosins and/or myosin-like genes. Functions for some of their products are known and are listed here because they may be implicated in some disease states (Clin. Corr. 23.13).

CLINICAL CORRELATION 23.13

Mutations Affecting Pigmentation: Is There a Molecular Motor Connection?

Elejalde syndrome is characterized by silvery hair and severe dysfunction of the central nervous system. Large granules of melanin are unevenly distributed in the hair shaft, and abnormal melanocytes and melanosomes may be present in fibroblasts. These observations suggest that mechanisms for their movement and distribution might be defective.

Chediak–Higashi syndrome is characterized by enlarged lysosomes, melanosomes, and other cytoplasmic granules. Eyes of humans and animals with this condition are hypopigmented. Intraocular melanin granules vary in size and can become extremely large. Some of the manifestations of this condition suggest similarity in mechanism with Elejalde syndrome.

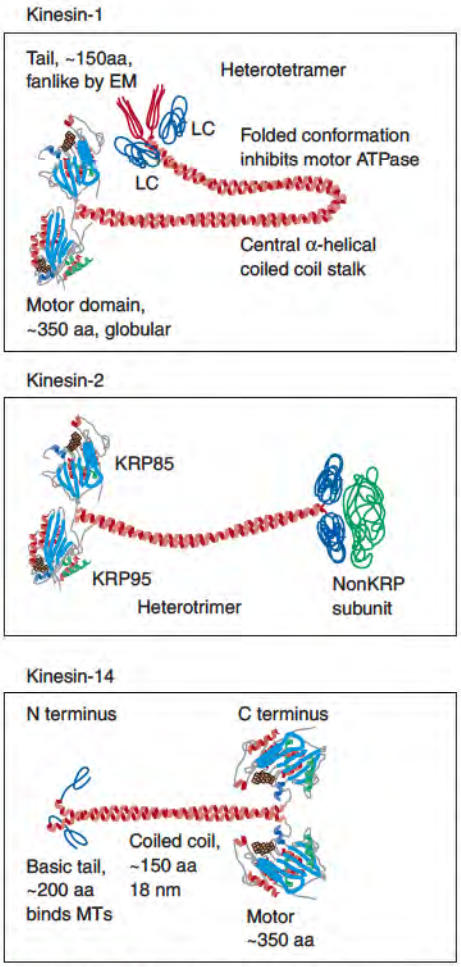

Figure 23.40 **Kinesin structures.** Representative structures of Kinesin-1, Kinesin-2, and Kinesin-14. All structures were taken from the Kinesin Home Page and associated links, http://www.proweb.org/kinesin/index.html.

Myosin I is a low-molecular-mass motor protein that is associated with cell membranes. It contains a tail section rich in basic amino acid residues and can associate with anionic phospholipids. There is a tail section domain rich in glycine, proline, and alanine (GPA domain) that facilitates binding to actin. The tail also contains an src homology 3 (SH3) domain that mediates protein–protein interactions. SH3 domains select peptides sharing the consensus motif LXXRPLXΨP, where Ψ is an aliphatic residue. This class of myosins appears to be involved in membrane–membrane interactions and to function in brush boarders of the small intestines. They may also be involved in transport/movement of Golgi-derived vesicles. They have several IQ motifs in the neck region near the head suggesting interactions with calmodulin-like molecules and regulation by them.

Myosin V is involved in organelle transport such as synaptic vesicles, melanosomes, vacuoles, and mRNA. It has an extended neck region and a tail with globular ends that permit dimerization but not filament formation. Light chains of myosin V are of the EF hand family and bind to an altered repeat IQ motif (IQXXXRGXXXR). Its cargo binds to the tail region. It is found in all brain neurons and is required for melanosome transport. Mutations in myosin V are associated with neurological malfunctions and depigmentation, especially of hair. It shows processivity in its movement like some kinesins and takes steps of about 36 nm along an actin fiber. Its rate of movement is limited by ADP dissociation and ATP binding, which causes the trailing head of myosin V to dissociate from actin.

Myosin VI is expressed in most cells and tissues. The neck region is extended and contains one calmodulin (IQ motif) binding region per head. It is a dimeric molecule with a coiled tail that has two globular ends (one for each monomer). Defects in the gene for this protein cause hearing problems attributable to defects in movement of the hairs in the inner ear. Unlike others discussed, this myosin can move in either direction.

Kinesins

Kinesins are microtubule-based molecular motors. They do not form filaments like some myosins, but they generate motion by conformational changes on binding and hydrolysis of ATP in a similar manner to myosin actin-based motors. Their motor domains have a similar core structure to myosin and a very high degree of secondary structural overlap, particularly in regions surrounding the catalytic domains. Several regions within the core have nearly complete overlapping secondary structural elements, but they are not contiguous and are separated by varying numbers of amino acid residues. The motor domains of kinesins are smaller than those of myosins. A major function of this class of motor proteins is to effect movement of intracellular cargo: vesicles, organelles, portions of the mitotic apparatus, chromosomes, mRNA, proteins, and other cellular constituents.

There are 14 classes of kinesins. The structures of some are known. Minimum structural elements of several kinesins are shown in Figure 23.40 and demonstrate some of the structural diversity of this class of molecular motors. They have been found in a variety of species and some of their functions in humans have been inferred from analyses and mutations

induced in them in other species of animals. In most cases, kinesins move their cargo toward the plus end of microtubules.

Kinesin-1 is a motor for fast axonal transport (p. 951). Among the cargo it transports are vesicles containing membrane proteins such as those which make ion channels along the axon during development, synaptic vesicle proteins, and those with which they interact at the axon termini such as syntaxin and synaptotagmin. This kinesin is expressed ubiquitously in human neural tissue. Mutations in kinesin-1 may lead to neuronal defects in humans that are reflected by a variety of symptoms.

Kinesin-2 is involved with membrane-associated movements in axons, axonemes, and melanophores. It has been shown to be involved in dispersion of melanosomes in fish melanophores. It has not been detected in humans, but there are human diseases associated with the lack of dispersion and/or movement of melanin containing granules, a defect that may be related more to defects in myosin-V in humans.

Kinesin-4 is associated with maintenance of spindle bipolarity and movement of chromosomes to the metaphore plate.

Kinesin-5 is associated with the mitotic apparatus of dividing cells and is involved in centrosomes and spindle pole body separation.

Kinesin-6 is present in the spindle midbody during telophase and is presumed to mediate the sliding of spindle fibers in the late stages of anaphase that are needed for spindle elongation and separation of chromosomes.

Kinesin-7 is also chromosome associated and provides a direct link between the chromosomes and microtubules of the spindle.

Kinesin-13 is also a chromosomal kinesin that is probably involved in mitotic chromosome movement.

Kinesin-14 is among the minus-end motors like the Ncd mitotic kinesin in *Drosophila* that functions in early stages of mitosis. It is localized to spindles in oocytes.

Kinesins-1 and -2 are related more to material discussed in this chapter, whereas the others are associated with more general aspects of cell division and movement of various components associated with that process.

Dynein

There are two classes of dynein motors: axonemal that effect flagella and cilia movement and cytoplasmic that effect distribution and organization of cytoplasmic structures. These functions include protein sorting and movement; chromosome organization during various stages of its function; distribution and/or redistribution of organelles such as endosomes, lysosomes, and others; and retrograde axonal transport—transportation of cargo in the opposite direction of most kinesins.

The structure of dynein is much more complex than that of the other two classes of motors. Dynein has a seven-member planar ring structure that is overall approximately 10 times the molecular mass of kinesins. A diagrammatic representation of its structure is shown in Figure 23.41.

ATP binds to an AAA motif in domain 1. Its binding and hydrolysis induce conformational changes that are transmitted through domains 2–4 to the stalk that interacts with microtubules and causes step movements of 24–32 nm for an unloaded dynein. Dynein movement responds to load in a downshift, gear-like manner and, under heavy load, takes steps of approximately 8 nm. Down shifting appears to be associated with conformation changes in several of its other domains and the availability of ATP. Under heavy-load conditions, ATP also appears to bind AAA motifs in domain 3. AAA motifs are conserved regions of 220–230 amino acid residues that exist in a family of proteins that participate in a number of diverse cellular activities that depend on energy from ATP hydrolysis to effect their functions, which may include proteolysis, protein folding and unfolding, metal ion metabolism, and other activities in addition to those associated with dynein. The motif name AAA refers to **A**TPase **A**ssociated with diverse cellular **A**ctivities.

In summary, note that dyneins as motors are (1) structurally more complex than myosins or kinesins, (2) generally involved in retrograde movement of cellular material, and (3) involved in various other aspects of structural organization, and (4) dyneins step movement along the microtubule is load dependent.

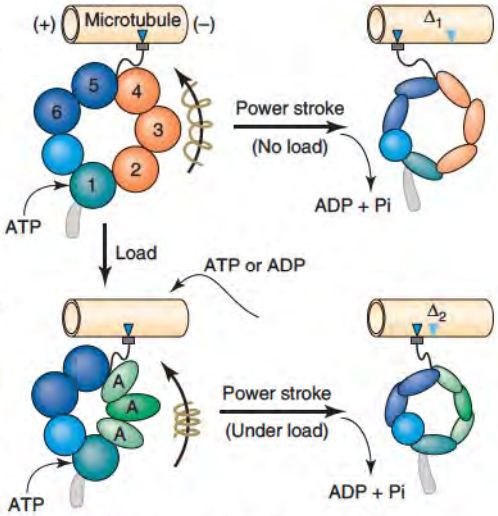

Figure 23.41 Dynein functions as a molecular motor.
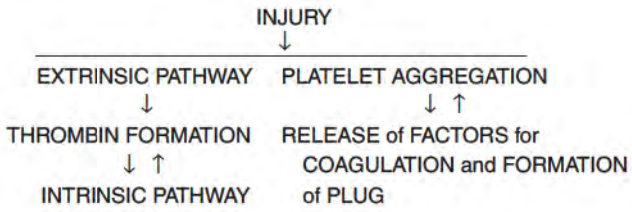
Redrawn from Mallik, R., Carter, B. C., Lex, S. A., King, S. J., and Gross, S. P. Cytoplasmic dynein functions as a gear in response to load. *Nature* 427: 649, 2004.

23.4 • MECHANISM OF BLOOD COAGULATION

Biochemical Processes of Hemostasis

Blood circulation occurs in a very specialized type of closed system in which the volume of circulating fluid is maintained within a constant range. Multiple functions of the system make the transfer of solutes across its boundaries necessary. In order to maintain a state of hemostasis, no loss of blood, leaks that occur from various types of insults must be repaired.

Hemostasis requires that the process of clot formation (**procoagulation,** designated as **Phase 1**) is in balance with processes for stopping clot formation (**anticoagulation**, **Phase 2**) and for clot dissolution (**fibrinolysis, Phase 3**). Procoagulation leads to production of fibrin from fibrinogen and aggregation of fibrin into an insoluble network, or clot that covers the ruptured area and prevents further loss of blood. Concomitantly, aggregation of blood platelets occurs at the site of injury. Platelet aggregation forms a physical plug to help stop the leak. Platelets also undergo morphological changes and release some chemicals that aid in other aspects of the overall process, such as vasoconstriction to reduce blood flow to the area, and enzymes that aid directly in clot formation. Shown schematically in the following diagram are steps involved in the initial phase of this process.



The dual arrows are intended not to imply that those steps are reversible but to indicate that the processes they join are mutually facilitative.

The next phase of hemostasis, the anticoagulation phase, begins early in the process, as soon as it is kinetically feasible, and prevents excessive clot formation. Finally, the process of clot dissolution, or fibrinolysis, occurs when the injured vessel is repaired sufficiently well to prevent further bleeding. Many proteins involved in blood coagulation contain **epidermal growth factor(EGF)** –like domains that may act directly or indirectly to facilitate re-growth of damaged areas in blood vessels. These processes are dynamic, kinetic, and mass-action driven. One phase does not end before another phase begins. Blood clotting is a dynamic process of signal amplification and modulation.

Some major proteins involved in this process are listed in Table 23.9, not necessarily in order of appearance. All are important and others are likely to be added. It is important to emphasize that structural anomalies, primarily mutations in critical regions of any of these proteins may affect adversely the clotting and clot dissolution processes and lead to disease states.

Clot formation involves two pathways: **intrinsic** or **contact factor pathway** and **extrinsic** or **tissue factor pathway**, both of which lead to the activation of Factor X. From this point on, there is a single pathway for clot formation. Historically, the term *intrinsic pathway* came from the observation that blood clotting could occur spontaneously when blood was placed in clean glass test tubes, leading to the idea that all components of the clotting process were intrinsic to circulating blood. Glass contains **anionic surfaces** that form nucleation points that initiate the process. In mammals, anionic surfaces are exposed on rupture of the **endothelial lining** of blood vessels, as are binding and activation sites for specific protein factors that initiate clotting in the intrinsic pathway. Similarly, *extrinsic* came from the observation that there was a factor extrinsic to circulating blood that facilitates blood clotting. This factor was identified as **Factor III**, or tissue factor, an integral membrane protein that becomes exposed on rupture of blood vessels. Whether intrinsic or extrinsic, blood coagulation is initiated and continued on the membrane at the site of injury. There is a great degree of necessity and interdependence on both traditionally designated pathways for affecting the coagulation process.

Throughout this section, coagulation factors in their nonactivated form are referred to by the letter "F" followed by the traditional Roman number designation for that factor,

TABLE 23.9 • Some Proteins Involved in Blood Coagulation, Control, and Clot Dissolution

Factor	*Name*	*Pathway*	*Characteristic*	*Concentration*[a]
I	Fibrinogen	Both		9.1
II	Prothrombin	Both	Contains *N*-terminal Gla residues	1.4
III	Tissue factor	Extrinsic	Transmembrane protein	—
IV	Calcium ions	Both		—
V	Proaccelerin	Both	Protein cofactor	0.03[b]
VII	Proconvertin	Extrinsic	Endopeptidase with Gla residues	0.01[c]
VIII	Antihemophilic factor	Intrinsic	Protein cofactor	0.0003[b]
IX	Christmas factor	Intrinsic	Endopeptidase with Gla residues	0.089
X	Stuart factor	Both	Endopeptidase with Gla residues	0.136
XI	Thromboplastin antecedent	Intrinsic	Endopeptidase	0.031
XII	Hageman factor	Intrinsic	Endopeptidase	0.375
XIII	Proglutamidase	Both	Transpeptidase	0.031[b]
	α_2-Antiplasmin		Plasmin inhibitor	0.953
	Antithrombin III	Both	Thrombin inhibitor	3.0
	Heparin Co-II	Both	Thrombin inhibitor	1.364
	HMWK[d]	Intrinsic	Receptor protein	0.636
	α_2-Macroglobulin		Proteinase inhibitor	2.9
	Plasminogen		Zymogen/clot dissolution	2.4
	Prekallikrein	Intrinsic	Zymogen/activator of factor XII	0.581
	Protein C	(Both)	Endopeptidase with Gla residues	0.065
	Protein C inhibitor		Protein C inhibitor	0.070
	Protein S	(Both)	Cofactor with Gla residues	0.030
	Protein Z	Both	Gla-containing cofactor for protein Z inhibitor	0.08
	Protein Z inhibitor	Both	Inhibitor of factor Xa	0.018
	TFPI[e]		Tissue factor pathway inhibitor	0.003

[a]Concentrations are approximate and shown as micromolar.
[b]These values approximate solution concentrations since some are complexed with other proteins in platelets.
[c]This factor probably circulates as both FVII and FVIIa.
[d]HMWK is high-molecular-weight kininogen.
[e]TFPI is tissue factor pathway inhibitor, formerly known as lipoprotein-associated coagulation factor (LAC1).

for example, **FVII** for Factor VII. The letter "a" will indicate activated forms, for example, FVIIa for the activated form of Factor VII.

Procoagulation Phase of Hemostasis (Phase 1)

The extrinsic pathway initiates formation of a blood clot. This has been demonstrated from kinetic analyses of the appearances and concentrations of various proteins and zymogens involved in the blood coagulation cascade. The extrinsic pathway is a one-step process that activates the key enzyme, FX to FXa, responsible for prothrombin activation. Thrombin, which results from prothrombin during the activation process, is a key enzyme for clot formation. Not only is it of prime importance for fibrin formation, but also it activates many other factors involved in other phases of hemostasis. A schematic of the reactions involved in the procoagulation phase, including both extrinsic and intrinsic pathways, is shown in Figure 23.42.

Extrinsic Pathway and Initiation of Coagulation

Tissue Factor (TF), or FIII, is the membrane receptor that initiates the procoagulation phase. TF is a transmembrane protein of 263 amino acids that is exposed on rupture of the endothelium lining of blood vessels and forms the receptor to which FVII binds. Residues 1–219 are on the extracellular side of the membrane and are exposed upon injury. FVII is a **γ-carboxyglutamyl** (Gla)-containing protein that binds to tissue factor only in the presence of Ca^{2+}. The resulting complex (FVII–Ca^{2+}–TF) is the initial enzyme complex of the extrinsic pathway, and its action initiates blood clotting by activating FX to FXa, the catalytic part of the enzyme complex (FXa:FV) responsible for thrombin formation from prothrombin. **TF** and **FVII** are unique to the extrinsic pathway and are essentially all of

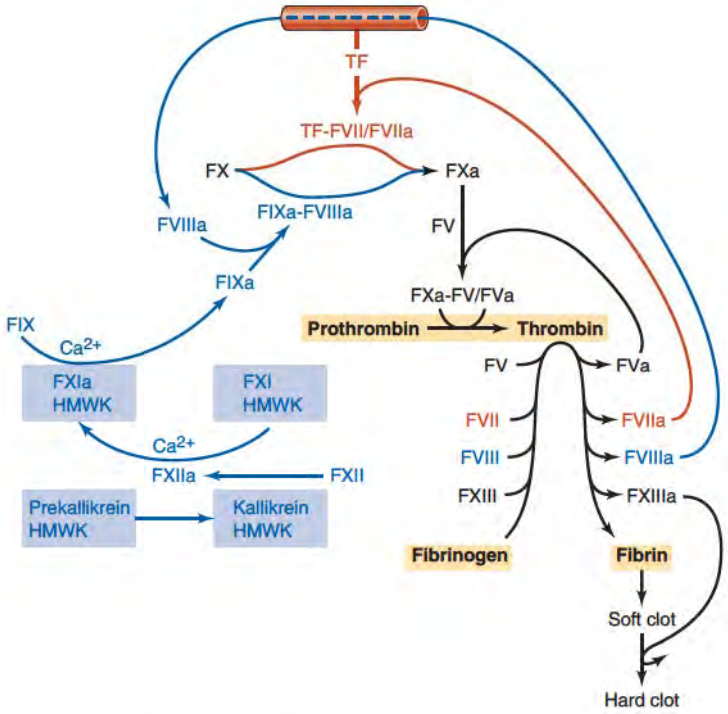


Figure 23.42 Diagrammatic representation of phase one of the blood coagulation scheme. Reactions of the extrinsic pathway are shown in red, those of the intrinsic pathway are shown in blue, and those common to both pathways are shown in black. Major end products of the scheme are highlighted in yellow. The inverted U in the lower right of the figure shows five proteins that are subjected to proteolytic cleavage by thrombin. The inactive forms are on the left, and the activated forms are on the right of the inverted U. Membrane-bound FXII activates prekallikrein to kallikrein, which activates XII to XIIa. These reactions occur in a cyclic manner. Abbreviation: HMWK, high-molecular-weight kininogen. Activated factors are designated with an "a."

its major components. The zymogen form of FVII is activated initially through protein–protein interaction resulting from its binding to TF. Additional FVII is activated by thrombin through specific proteolytic cleavage. FVIIa has a long half-life in circulating blood, and a small amount normally exists. This has no adverse effects since FVIIa is not catalytically active until it forms a complex with TF.

Thrombin Formation

FXa and FV form a complex sometimes referred to as prothrombinase that catalyzes formation of thrombin from prothrombin by a proteolytic cleavage reaction. The relatively small amount of thrombin formed in this initiation phase (Figure 23.42) catalyzes the activation of FV, FVII, FVIII, and FXIII (all of the components on the left side of the inverted loop of Figure 23.42), in addition to its ultimate functional goal of converting fibrinogen to fibrin. Thrombin converts fibrinogen to fibrin by cleavage of four highly negatively charged peptides from the center domain of fibrinogen. Those negatively charged peptides of fibrinogen prevent it from aggregating. Once they are removed by thrombin, the resulting fibrin can aggregate into a network forming a soft clot.

Reactions of the Intrinsic Pathway

Also shown in Figure 23.42 are reactions of the intrinsic pathway. Injury to the endothelial lining of blood vessels exposes anionic membrane surfaces. The zymogen, **FXII**, binds directly to some of these anionic surfaces and undergoes a conformational change that increases its catalytic activity 10^4- to 10^5-fold. **Prekallikrein** and **FXI** are also zymogens and circulate in blood as complexes with **high-molecular-weight kininogen (HMWK)**, either as a FXI–HMWK complex or a prekallikrein–HMWK complex. FXI and prekallikrein bind, through their interactions with HMWK, to anionic sites that become exposed on injury to membrane surfaces. This brings those zymogens to the site of injury and in direct proximity to FXII. The membrane-bound activated form of FXII activates prekallikrein to **kallikrein**, which then permanently activates FXII by specific proteolytic cleavage to give FXIIa. The kallikrein-activated XIIa activates more prekallikrein to kallikrein, which then activates more XII to XIIa in a cyclic autocatalytic manner.

FXI, in the HMWK–membrane-bound complex, is activated by FXIIa by proteolytic cleavage to give FXIa. FXIa activates **FIX** to FIXa (Clin. Corr. 23.14), which in the presence of **FVIIIa**, also activates **FX** to FXa.

CLINICAL CORRELATION 23.14

Intrinsic Pathway Defects: Prekallikrein Deficiency

Components of the intrinsic pathway include Factor XII (Hageman Factor), Factor XI, prekallikrein (Fletcher Factor), and High-Molecular-Weight Kininogen. Inherited disorders in each appear to be autosomal recessive and associated with an increase in activated partial thromboplastin time (APTT). Factor XI deficiency is directly associated with a clinical bleeding disorder.

In prekallikrein (Fletcher Factor) deficiency, autocorrection after prolongation of the preincubation phase of the APTT test occurs. This is explained by activation of Factor XII by an autocatalytic mechanism. The reaction is very slow in prekallikrein deficiency since the rapid reciprocal autoactivation between Factor XII and prekallikrein cannot take place. Prekallikrein deficiency may be due to a decrease in the amount of the protein synthesized, to a genetic alteration in the protein itself that interferes with its ability to be activated or its ability to activate Factor XII. A lack of knowledge of the structure of the gene or the protein will not permit an explanation of the mechanism of this deficiency. Specific deficiencies of the intrinsic pathway, however, can be localized to a specific factor if the appropriate tests are performed. These may include measurement of the amount of each factor in plasma and an APTT test performed with and without prolonged preincubation time. In a 9-year-old girl with prolonged APTT, the functional level of prekallikrein was less than 1/50th of the minimum normal value. An immunological test showed an antigen level of 20%–25% suggesting that she was synthesizing a dysfunctional molecule.

Coleman, R. W., Rao, A. K., and Rubin, R. N. Fletcher factor deficiency in a 9-year-old girl: Mechanisms of the contact pathway of blood coagulation. *Amer. J. Hematol.* 48:273, 1995.

The intrinsic pathway is essentially a four-step cascade started by the contact activation of FXII and the autocatalytic activation of FXII and kallikrein to give FXIIa (step 1). FXIIa activates FXI (step 2). In step 3, FXIa activates FIX; and in step 4, FIXa, in the presence of FVIIIa, activates FX. If each activated enzyme molecule catalyzed the activation of 100 molecules of the next enzyme of the cascade, an amplification factor of 1×10^6 of the intrinsic pathway would be achieved. As shown in the diagram and as stated, several feedback loops accelerate the overall process and produce a fibrin clot in a rapid and efficient manner. During this time, **FXIII**, a transglutamidase (often referred to as transglutaminase) that has been activated also by thrombin (lower right corner of Figure 23.42), is actively catalyzing the formation of cross-links between fibrin monomers of the soft clot to form a hard clot. This is the overall process of clot formation.

Formation of Platelet Plug

Thrombin mediates clumping of platelets at the site of injury. Endothelial cells contain a **thrombin receptor**, a member of the seven-transmembrane-helix family of receptors. This receptor is exposed on injury and is activated by α-thrombin. Aggregation of platelets is facilitated by binding to this activated receptor. In addition to forming a physical plug, platelets undergo a morphological change and release ADP, serotonin, some types of phospholipids, and proteins that aid in coagulation and tissue repair (Figure 23.43). They also release a glycoprotein, von Willebrand factor (vWF) that concentrates in the area of the injury and forms links between the exposed receptor and platelets.

Platelet aggregation becomes autocatalytic on release of ADP and **thromboxane A_2**. Another protein released from platelets is **FIV**, a **heparin-binding protein**, which prevents premature formation of heparin–antithrombin III complexes and it attracts cells with anti-inflammatory activity to the site of injury. About 20% of FV and one form of FXIII, the transglutamidase, are present in platelets. Intact normal vascular endothelium does not bind platelets because (1) receptors and other elements are not exposed, (2) activators such as ADP are rapidly degraded or are not present in blood in sufficient concentration to be effective, and (3) the endothelium secretes prostacyclin (PGI_2), a potent inhibitor of platelet aggregation.

Some Properties of Proteins Involved in Clot Formation

Tissue Factor: (TF, or FIII), (Figure 23.44*a*) is a transmembrane protein of 263 amino acids. Residues 243–263 are located on the cytosolic side of the membrane. Residues 220–242 are hydrophobic residues and represent the transmembrane sequence. Residues 1–219 are on the outside of the membrane, are exposed after injury, and form the receptor for FVII binding and formation of the initial complex of the extrinsic pathway. This domain is glycosylated

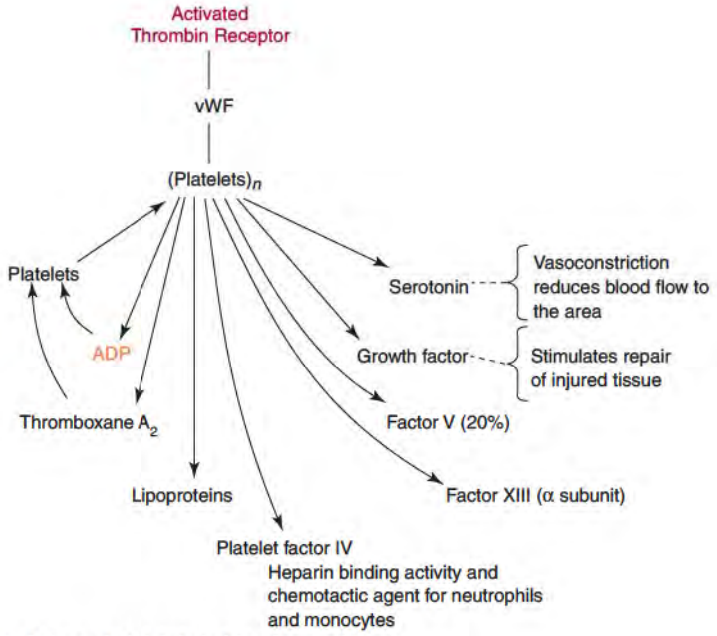

Figure 23.43 Action of platelets in blood coagulation.

and contains four cysteine residues. A stereo representation of a section of it highlighting some of the amino acid residues involved in **FVII** binding is shown in Figure 23.44*b*.

Factor VII: A 3-D ribbon structural representation of FVIIa is shown in Figure 23.45. The regions for TF interaction, Ca^{2+} binding, and the substrate-binding pocket are highlighted (Clin. Corr. 23.17).

Factor X: A stereo view of FXa is shown in Figure 23.46. Both the extrinsic and the intrinsic pathways lead to formation of FXa from FX. FXa is the catalytic component of the FXa:FVa complex.

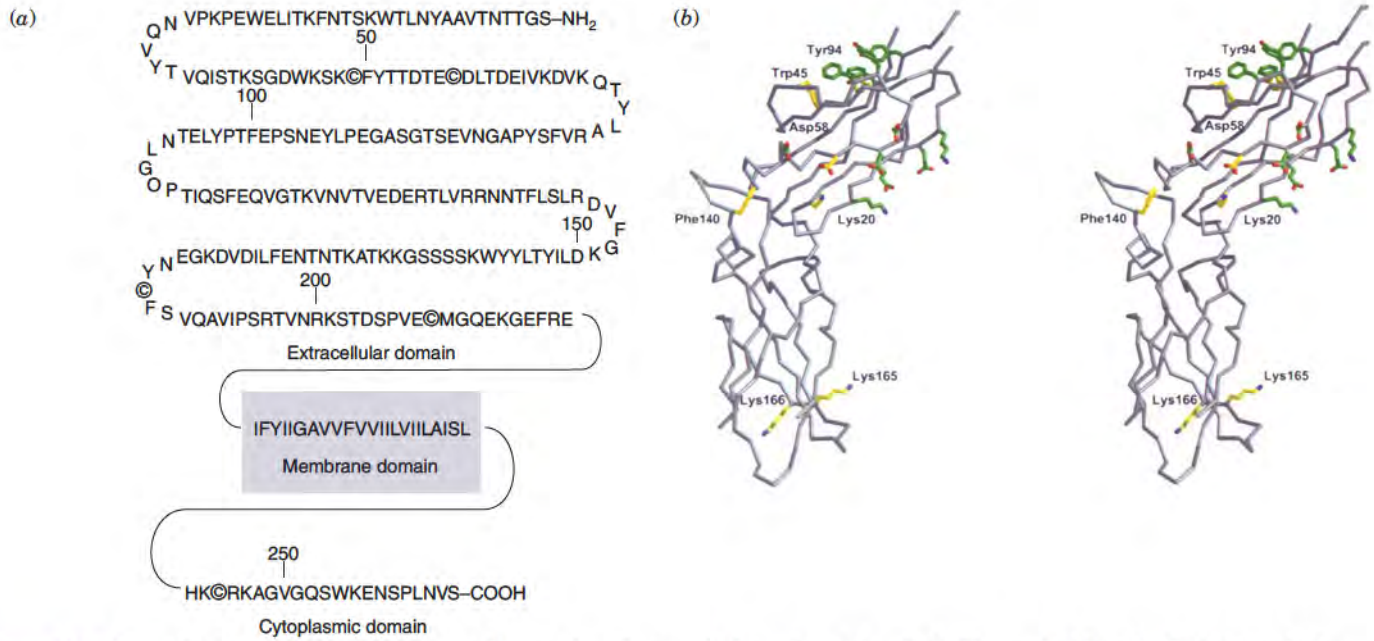

Figure 23.44 Tissue Factor. (*a*) Amino acid sequence of human tissue factor derived from its cDNA sequence. (*b*) A stereo representation of the carbon chain of the extracellular domain of tissue factor. Residues important for binding of Factor VII are shown in yellow. Clusters of aromatic and charged residues are shown in light blue.

Factor V: FV does not have catalytic activity, but it is a protein cofactor for FXa. In its inactivated form it has some activity as a cofactor but is much more active after activation to FVa. FV is a 330-kDa protein that is activated by proteolytic cleavage at Arg^{709} and Arg^{1545}. FVa is a heterodimer consisting of an *N*-terminal domain (105 kDa) and a C-terminal domain (74 kDa) that are held together noncovalently by Ca^{2+} (see Figure 23.51, p. 989). The substrate for the FXa:FVa complex is prothrombin and the complex is sometimes referred to as prothrombinase.

Thrombin: Thrombin circulates in plasma as prothrombin. Prothrombin is a 72 kDa protein (Figure 23.47) that contains ten **γ-carboxyglutamate (Gla) residues** in its *N*-terminal region. Binding of Ca^{2+} to these residues neutralizes negative charges and facilitates binding of prothrombin to membrane surfaces and to the prothrombinase complex (FXa:FVa) at the site of injury. Prothrombin is activated by two proteolytic cleavages on the carboxyl side of arginine residues; first at position 320 and then at position 284. The active thrombin molecule (α-thrombin) consists of two chains, 6 kDa and 31 kDa, that are covalently linked by a disulfide bond. A stereo view of the active α-thrombin molecule is shown in Figure 23.48. Regions involved in some of its functions are highlighted. Thrombin activates many blood coagulation factors as shown in Figure 23.42, p. 984. Its major substrate for clot formation, however, is fibrinogen.

Fibrinogen/Fibrin: Fibrinogen, a large molecule of approximately 340 kDa consists of two sets of tripeptide units with α,β,γ structure (Figure 23.49) that are linked together at their *N*-terminal regions by disulfide bonds. Fibrinogen has three globular domains, one on each end and one in the middle joined by rodlike domains. Short segments of the free *N*-terminal regions project out from the central globular domain. The *N*-terminal regions of α-, α′-, β-, and β′-subunits are highly negatively charged and through charge–charge repulsion prevent

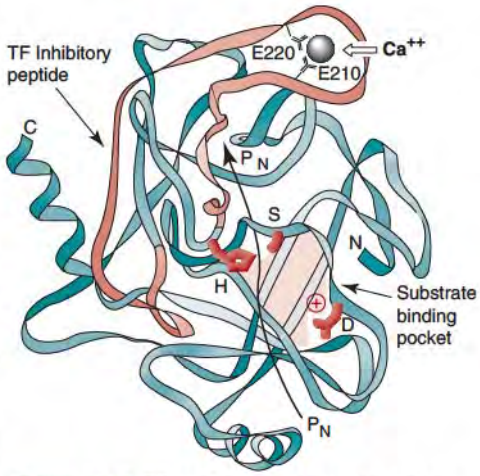

Figure 23.45 Ribbon structural representation of the protease domain of Factor VIIa. The dark ribbon labeled "TF Inhibitory peptide" represents a section involved in binding to Tissue Factor. The catalytic triad is shown in the substrate-binding pocket as H, S, and D for His-193, Ser-344, and Asp-338, respectively. The arrow labeled P_N–P'_N lies in the putative extended substrate binding region. Reproduced with permission from Sabharwal, A. K., Birktoft, J. J., Gorka, J., Wildgoose P., et al. J. *Biol. Chem.* 270: 15523, 1995.

aggregation of fibrinogen. Thrombin cleaves these *N*-terminal peptides and allows the resulting fibrin molecules to aggregate and to form a **"soft" clot**. **FXIIIa** stabilizes the soft clot by catalyzing formation of isopeptide linkages between the δ-carboxylamide of glutamine residues of one fibrin molecule and the ε-amino group of lysine residues of another fibrin molecule (Figure 23.50), that is, exchanges the amide nitrogen of glutamine for the ε-amino group of lysine. Ammonia is released in this reaction and a **hard clot** is formed in which individual fibrin molecules throughout the clot are interconnected by covalent linkages.

Factor VIII: FVIII circulates in plasma noncovalently bound to **von Willebrand Factor (vWF)**. FVIII, a 285-kDa protein, is activated by thrombin cleavage at Arg^{372}, Arg^{740}, Arg^{1648}, and Arg^{1689}. This last cleavage releases FVIIIa from vWF. FVIIIa is a heterotrimer (Figure 23.51) consisting of N-terminal peptides of 40 kDa (A_2) and 50 kDa (A_1), and a C-terminal peptide of 74 kDa (A_3). FVIIIa also contains a Ca^{2+} bridge between the *N*- and C-terminal domains. Classic hemophilia A results from a deficiency in FVIII (Clin. Corrs. 23.15 and 23.16).

Factor XIII: Thrombin also activates FXIII, transglutamidase (Figure 23.52, p. 989). **Protransglutamidase** exists in both plasma and platelets. The platelet enzyme is an α_2 configuration, and the plasma form is an $\alpha_2\beta_2$ configuration. Thrombin activates FXIII by specific cleavage of a peptide bond in the α-subunit of both the platelet and the plasma forms of transglutamidase. Cleavage in the α-subunit of the plasma form leads to dissociation of the β-subunit, which is not catalytically active. The platelet form of the enzyme is released at the site of fibrin aggregation.

High-Molecular-Weight Kininogen (HMWK), Prekallikrein, and **Factor XI:** Two of the proteins involved in the intrinsic pathway, prekallikrein and FXI, circulate in blood as complexes with HMWK. Figure 23.53 shows a schematic diagram of the functional regions of HMWK. The binding site on HMWK for prekallikrein consists of approximately 31 amino acid residues, relative positions of which are shown. FXI binds to approximately 58 amino acid residues (not shown) that overlap the 31 amino acid residues to which prekallikrein binds. A molecule of HMWK can bind to one or the other of these proteins, but not to both simultaneously. Bradykinin, a vasodilator, is released from HMWK by the action of kallikrein. Prekallikrein is a 619-amino-acid protein. Prekallikrein is converted to kallikrein by FXIIa, which cleaves a peptide bond between Arg^{371} and Ile^{372}. Kallikrein contains two chains covalently linked by a single disulfide bond. The C-terminal domain of 248 amino acids contains the catalytic site.

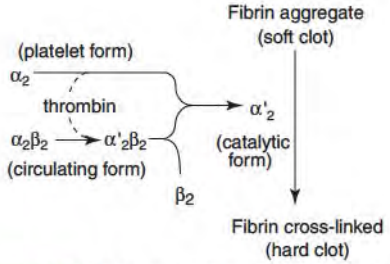

Figure 23.52 Activation of transglutamidase by thrombin.

Anticoagulation Phase of Hemostasis (Phase 2)

Inhibition of the hydrolyases involved in blood coagulation is a kinetic process that begins almost as soon as coagulation itself. Initially, formation of inhibitor complexes is slow because concentrations of the enzymes with which the inhibitors interact are low. As activation of the zymogens proceeds, inhibition increases and becomes more prominent. These reactions, and destruction of protein cofactors, eventually stop the coagulation process completely. In general, **protease–inhibitor complexes** do not dissociate readily and they are removed intact from blood by the liver.

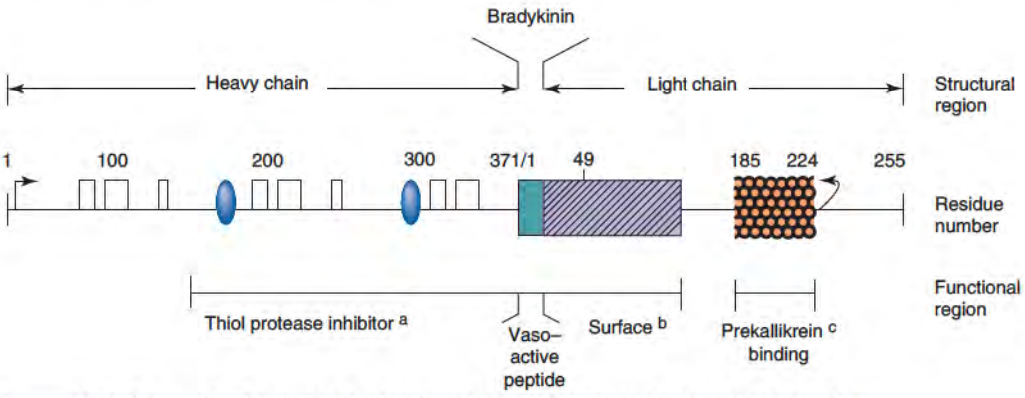

Figure 23.53 Schematic diagram of the functional regions of human high-molecular-weight kininogen (HMWK). Bradykinin is derived from near the middle of HMWK by proteolysis. The resulting two chains are held together by disulfide bonds, horizontal arrows.

CLINICAL CORRELATION 23.15

Classic Hemophilia

Hemophilia is an inherited disorder characterized by a permanent tendency for hemorrhages, spontaneous or traumatic, due to a defective blood-clotting system. Classic hemophilia, hemophilia A (OMIM 306700), is an X-linked recessive disorder characterized by a deficiency of Factor VIII. It affects about 1 in 10,000 males. Of the approximately 25,000 hemophiliacs in the United States, more than 80% are of the A type. Hemophilia B is due to a dysfunction in Factor IX.

Some hemophilia A patients may have a normal prothrombin time if the concentration of tissue factor is high. One possible explanation for this is that Factor V in human plasma is much lower in concentration than Factor X. Activation of an amount of Factor X to Xa in excess of that required to bind all of Factor Va would initiate blood clotting by the extrinsic pathway and give a normal prothrombin time. The intrinsic pathway would not function normally due to the deficiency in Factor VIII. Without the two pathways operating in concert, the overall process of blood clotting would be impaired. Both Factor Xa and thrombin activate Factor V and are involved in a number of other reactions. If the overall process is not accelerated at its onset by intervention of the intrinsic pathway, due to kinetics of the interaction of thrombin and Factor Xa with the normally low concentration of Factor V, the clotting disorder is expressed. The blood level of Factor VIII in severe hemophilia A patients is less than 5% of normal. These patients are generally treated by blood transfusion with its associated dangers: the possibility of hepatitis or HIV/AIDS and a 6% possibility of patients making autoantibodies. Treatment of hemophiliacs has been made much safer as a result of cloning and expression of the gene for Factor VIII. The pure recombinant protein is administered to patients with minimum danger.

CLINICAL CORRELATION 23.16

Use of Recombinant Factor VIIa to Control Bleeding

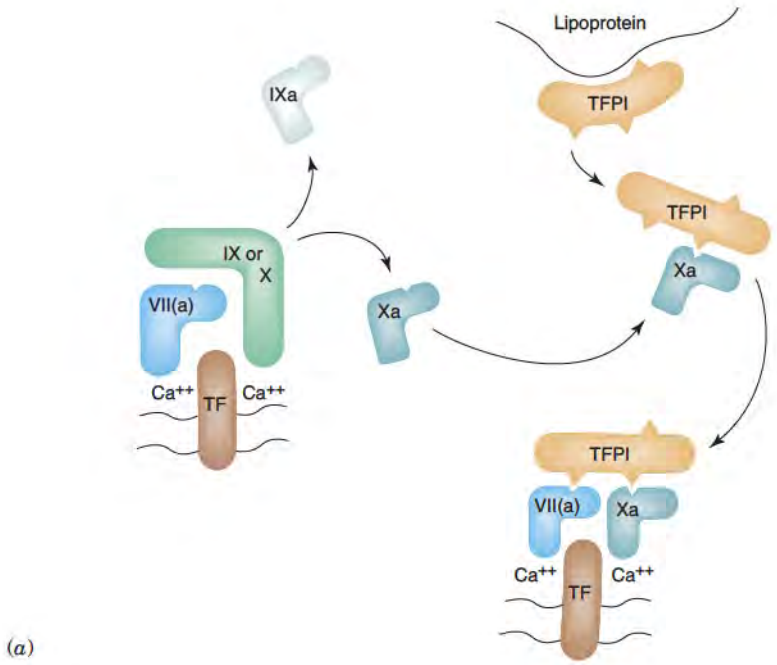
Factor VIIa (FVIIa) is a major component of the extrinsic pathway for blood coagulation. It can be present in circulating blood without causing harmful effects because it is inactive until it forms a complex with Tissue Factor (Factor III). A recombinant form of FVIIa (rFVIIa) was initially developed as a treatment for hemophilia patients who had acquired inhibitors associated with their treatment. It has been commercialized and approved for treatment of various traumatic bleeding problems, particularly some types of surgery and bleeding strokes. It has also been demonstrated that rFVIIa given along with phospholipids enhances thrombin generation and improves its effectiveness.

Aggarwal, A., Malkovska, V., Catlett, J. P., and Alcorn, K. Recombinant activated factor VII (rFVIIa) as salvage treatment for intractable hemorrhage. *Thrombosis J.* 2: 9, 2004; Butenas, S., Brummel, K. E., Paradis, S. G., and Mann, K. G. Influence of Factor VIIa and phospholipids on coagulation in "acquired" hemophilia. *Arterioscler Thromb Vasc. Biol.* 23: 123, 2003.

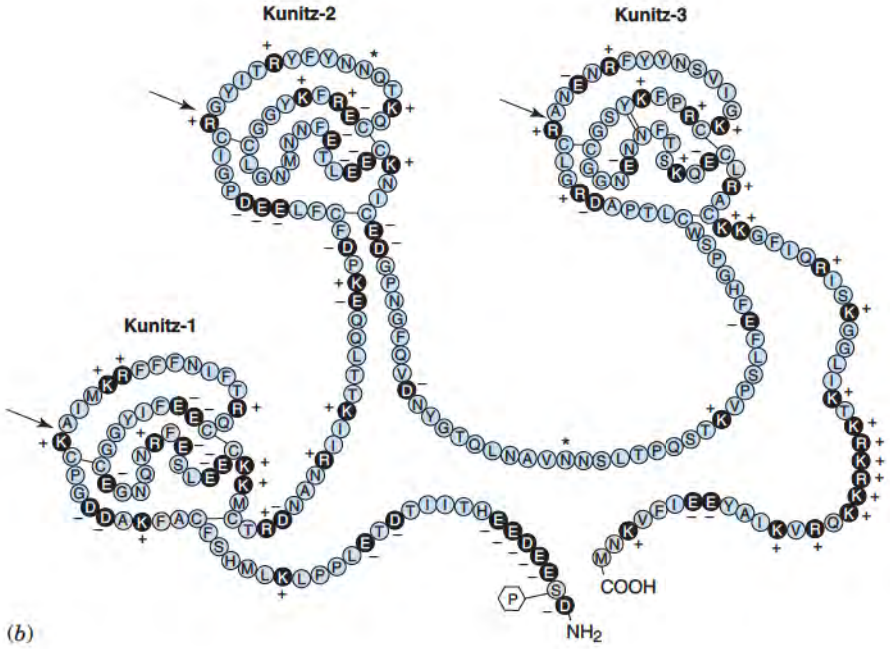
Inhibition of the Extrinsic Pathway

Inhibition of the extrinsic pathway, that is, the TF–FVIIa–Ca^{2+}–FXa complex, is unique and involves specific interaction with **Tissue Factor Pathway Inhibitor (TFPI)**, formerly known as **lipoprotein-associated coagulation inhibitor (LACI)** and as **anticonvertin**. TFPI is a 32-kDa protein that contains three tandem domains (Figure 23.54). Each domain is a functionally homologous protease inhibitor (sometimes referred to as Kunitz domains) that resembles other individual protease inhibitors such as the bovine **pancreatic trypsin inhibitor**. TFPI inhibits the extrinsic pathway by interacting specifically with the TF–FVIIa–Ca^{2+}–FXa complex. First, domain 1 binds to FXa and domain 2 binds to FVIIa of the complex. Binding of TFPI to FVIIa does not occur unless FXa is present. Thus, TFPI is truly a multienzyme inhibitor in which each of its separate domains inhibits the action of one of the enzymes of the multienzyme complex of the extrinsic pathway. Second, the TFPI–FXa complex mediates internalization of FVIIa by an endocytosis mechanism. The C-terminal (third domain) of TFPI appears to be necessary for endocytosis. Most of FVIIa is degraded within the cells but a small amount returns to the surface as intact protein and is apparently one of the sources of circulating FVIIa. As previously stated, FVIIa has no detrimental effects since it is active as a protease only when it is in a complex with TF.

Protease inhibitors of the **serine protease inhibitor (Serpin)** family of proteins in blood interact with and inhibit other enzymes of the blood coagulation system. There is a similarity in tertiary structure among them with a common core domain of about 350 amino acids.



(*a*)



(*b*)

Figure 23.54 Mechanism of inhibition of the extrinsic pathway. (*a*) TFPI is tissue factor pathway inhibitor. A schematic of its secondary structure is shown in (*b*). Kunitz domain 1 inhibits Factor VIIa and Kunitz domain 2 inhibits Factor Xa. Domain 3 is necessary for endocytosis of the complex. Arrows indicate the presumed location of the active-site inhibitor region for each domain. Reproduced with permission from Brooze, G. J., Girard, T. J., and Novotny, W. F. *Biochem.* 29: 7539, 1990. Antithrombin III (AT3) is a serpin that inhibits several hydrolases of the blood coagulation system, but most specifically thrombin and FXa. AT3 inhibits thrombin and FXa more efficiently as complexes with different oligosaccharide groups of heparin. Heparin is a highly sulfated oligosaccharide of the glucosaminoglycan type. It exists as a mixture of oligosaccharides spanning a range of molecular sizes. The interaction of heparin in the different inhibitory complexes is size dependent. At least 18 saccharide units are required for the effective formation of the thrombin inhibitor complex.

$$\text{Thrombin} + \text{Heparin}_{(>18)} + \text{AT3} \rightarrow \text{AT3:Heparin}_{(>18)}\text{:Thrombin}_{(\text{inactive})}$$

AT3 also forms a complex with a specific pentasaccharide form of heparin. The structure of this pentasaccharide is shown in Figure 23.55. Shown in Figure 23.56 is a structural model of AT3 bound to this heparin pentasaccharide. This complex inhibits FXa.

$$\text{FXa} + \text{Heparin}_{(5)} + \text{AT3} \rightarrow \text{AT3:Heparin}_{(5)}\text{:FX}_{\text{inh}}$$

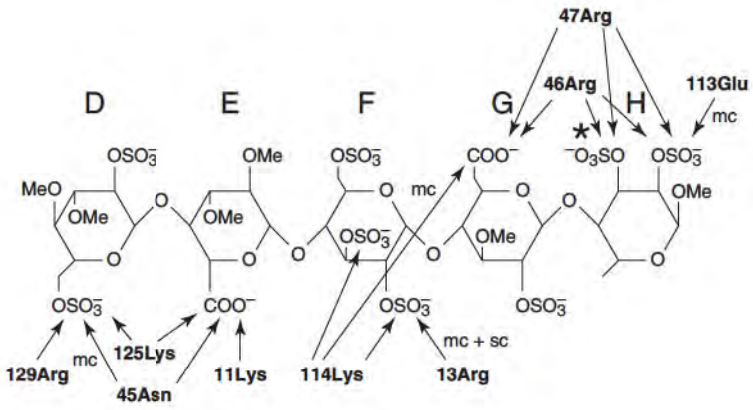

Figure 23.55 Chemical structure of the heparin pentasaccharide and positions of its interactions with specific residues of antithrombin.

Although AT3 inhibits thrombin and FXa in the absence of heparin, heparin enhances inhibition of thrombin by a factor of approximately 9,000 and inhibition of FXa by a factor of approximately 17,000.

There is another pathway for inhibition of FXa. Blood contains a 62-kDa Gla-containing glycoprotein, **Protein Z (PZ)**. Protein Z is a protein cofactor that, in the presence of Ca^{2+}, interacts with membrane and forms a complex with another plasma protein, **Protein Z-dependent protease inhibitor (ZPI)**, a 72-kDa protein. This complex inhibits FXa.

$$FXa + Ca^{2+} + PZ + ZPI \rightarrow (Ca^{2+}{:}PZ){:}ZPI{:}FX_{inh}$$

Protein Z-dependent protease inhibitor (ZPI) in the absence of PZ will inhibit FXIa, and this inhibition is enhanced by heparin. ZPI with or without PZ shows no measurable ability to inhibit other proteases, including thrombin, FVIIa, FIXa, and Protein C.

Inactivation of FVa and FVIIIa

Protein C (PC), a Gla-containing protein, is activated in a membrane-bound complex of thrombin, **thrombomodulin**, and calcium ions. Protein C requires the presence of another

CLINICAL CORRELATION 23.17

Thrombosis: Defects of the Protein C Pathway and Increased Levels of Coagulation Factors

Four major proteins are involved in the action of Protein C in regulating blood coagulation: Protein C itself; Protein S, a cofactor for Protein C; Factor Va; and Factor VIIIa. The latter two are substrates for catalytic action of the Proteins C–S complex. Mutations in any of them can result in venous thrombosis with various degrees of severity.

De novo mutations have been identified in patients with type I Protein C deficiency. One was a missence mutation, a transition of T to C, which changed amino acid residue 270 from serine to proline (Ser270Pro) resulting in decreased activity. The gene for Protein C is on chromosome 2 and has nine exons and eight introns. Another was a *de novo* 5-bp deletion (underlined below) located at the exon VI-intron f junction resulting in a read through of sections of the intron.

Exon VI <> Intron f

Normal sequence:

CAC CCC GCA*G* <> *G*TGAGAAGCCCCCAATAT- - - -

His Pro Ala

Mutated sequence:

CAC CCC GCAGGA GCC CCC AAT AT- - - -

His Pro Ala Gly Ala Pro Asn- - - - - - -

The sequence normally translated is in bold type. The degree of clinical severity of thrombotic events depends on the extent to which the gene inherited from the other parent is normal and expressed.

Resistance to activated Protein C because of single-point mutations in its substrates, Factor Va and Factor VIIIa, can occur and prevent or retard their inactivation (proteolysis) by Protein C. The most commonly identified cause is a single-point mutation in the gene for Factor V results in R506Q, also known as FV-Leiden.

A third cause of Protein C-related thrombosis is a defect in Protein S. Fewer specific details are available that permit a definition of the mechanism of the interaction between Protein C and Protein S, and likewise of the mutations that affect its function. It is quite clear, however, that Protein S deficiency also leads to thrombotic events. Venous thrombosis occurs in almost one-half of patients at some stage of their lives if they have deficiencies in functional amounts of Protein S.

Patients with elevated levels of FVIII, FIX, or FXI appear to be predisposed to venous thrombosis. Risk for thrombosis from these factors is low compared to the Protein-C-associated condition described above, but multiple elevations of these factors increase the risk. The biochemical cause for this is not clear, but hereditary and undetected gene mutations are leading suspects.

Gandrille, S., Jude, B., Alhenc-Gelas, M., Emmerich J., and Aiach, M. First *de novo* mutations in the protein C gene of two patients with type I deficiency: A missence mutation and a splice site deletion. *Blood* 84: 2566, 1994; Reitsma, P. H., Bernardi, F., Doig, R. G., Gandrille, S., et al. Protein C deficiency: A database of mutations, 1995 update. *Thrombosis and Haemostasis* 73: 876, 1995; and Crowther, M. A., and Kelton, J. G. protein cofactor, **Protein S (PS)**, a 75-kDa Gla-containing protein. The PC:PS complex inhibits coagulation by inactivating Factors Va and VIIIa. Inactivation of FVa and FVIIIa occurs by cleavage of peptide bonds at specific arginine residues. Deficiencies and/or mutations in Protein S or Protein C can lead to **thrombotic diseases** (Clin. Corr. 23.17). Disease states are also possible if there are mutations of FV or FVIII that do not affect their ability to function as cofactors but do affect the cleavage sites for the PC:PS complex inactivation reactions.

$$V_a \text{ and } VIII_a \xrightarrow{PC:PS} V_{inh} \text{ and } VIII_{inh}$$

Thrombomodulin is an integral glycoprotein of endothelial cell membranes (A Closer Look 23.10). It is a receptor for thrombin. In the thrombin–thrombomodulin–Ca^{2+} complex, thrombin has a decreased affinity for fibrinogen and an increased affinity for Protein C. Thus, thrombin's role switches from that of procoagulation to anticoagulation.

Thrombin (Figure 23.57) may exist *in vitro* in two conformations: one has high specificity for conversion of fibrinogen to fibrin, and the other conformation has low specificity for fibrinogen conversion but high specificity for thrombomodulin binding and for proteolytic activation of Protein C. These forms are referred to as *fast* and *slow* forms, respectively. This type of dynamic feedback mechanism is important for stopping the clotting process at its point of origin.

There is also a specific inhibitor for Protein C. **Protein C inhibitor (PCI)** has been found in plasma, platelets, and megakaryocytes. ADP, epinephrine, thrombin, and other molecules that stimulate platelet activity cause release of about 30% of PCI from platelets on stimulation. Inactivation of activated Protein C (APC) by PCI occurs on membrane surfaces like most of the other reactions discussed.

A CLOSER LOOK 23.10

Thrombomodulin

Thrombomodulin contains 560 amino acids and shows sequence homology with the low-density lipoprotein receptor, but very little with tissue factor. There is a great deal of similarity in functional domains between tissue factor and thrombomodulin, each of which is a receptor and activator for a protease.

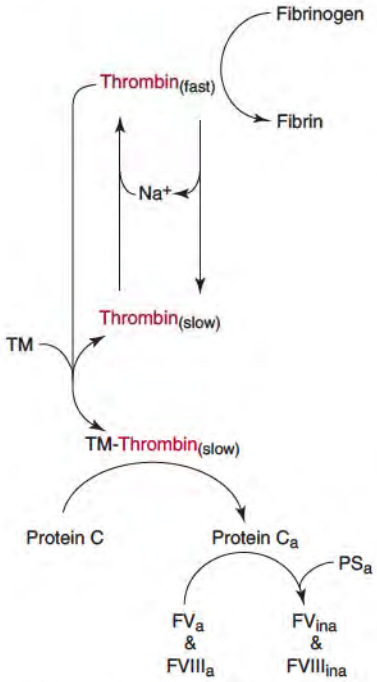

Figure 23.57 Conformational forms of thrombin induced by its interaction with thrombomodulin. Thrombin has high affinity for fibrinogen in the absence of thrombomodulin, but changes to high affinity for Protein C in the presence (complex) with thrombomodulin.

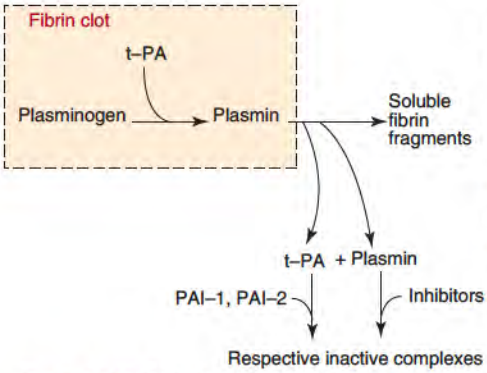

Figure 23.58 Dissolution of fibrin clot by plasmin. Plasminogen is activated to plasmin by t-PA within the matrix of the clot. These reactions are shown within the box in this figure.

Fibrinolysis Phase of Hemostasis (Phase 3)

Fibrinolysis Requires Plasminogen and Tissue Plasminogen Activator (t-PA) to Produce Plasmin

Reactions of fibrinolysis are shown in Figure 23.58. Lysis of a fibrin clot occurs through action of the enzyme plasmin that is formed from plasminogen through the action of **tissue plasminogen activator (t-PA** or **TPA)**. Plasminogen has high affinity for fibrin clots. It diffuses or becomes immersed within the clot and forms complexes with fibrin throughout various regions of the fibrin network. t-PA also binds to fibrin clots (A Closer Look 23.11) and activates plasminogen to plasmin by specific bond cleavage. Plasmin hydrolyzes the fibrin clot producing soluble peptides that are taken out of circulation by the liver and destroyed.

Protein inhibitors regulate activity of t-PA. Four immunologically distinct types of inhibitors of t-PA have been identified, two of which react rapidly with t-PA and are specific for it. They are **plasminogen activator-inhibitor type 1 (PAI-1)** and **plasminogen activator-inhibitor type 2 (PAI-2)**. The human PAI-2 contains 415 amino acid residues.

Starting and stopping blood coagulation follow essentially the same type process, interactions of proteins, formation of multienzyme complexes, and proteolysis. Both are unidirectional and the only mechanism for replenishing the proteins is by resynthesis.

Role of Gla Residues in Blood Coagulation Factors

Posttranslational modification of many proteins involved in blood coagulation results in formation of γ-carboxyglutamyl (Gla) residues that transforms them into excellent chelators of calcium ions. Ca^{2+} forms complexes with Gla residues of those factors and induces conformational and electronic states that facilitate their interaction with membrane receptors. Ca^{2+} also binds at sites other than Gla residues producing protein conformational changes that enhance catalytic activity. Evidence for this second effect of Ca^{2+} comes from the observation that activation of at least one of the enzymes leads to cleavage and elimination of the *N*-terminal region containing the Gla residues, but calcium ions are still required for its effective participation in blood coagulation.

Schematic representations of structures of five of the **Gla-containing proteins** listed in Table 23.9 are shown in Figure 23.59. Gla residues are located in the *N*-terminal region of the molecules followed by a structural area that resembles epidermal growth factor that may play a role in facilitating the healing process. Activation of zymogens involved in blood coagulation generally occurs at peptide bonds located between cysteine residues that have formed disulfide bonds (A Closer Look 23.12). Prothrombin is the only zymogen whose activation occurs by cleavage of a bond in the primary sequence outside of a bridging disulfide bond, and dissociation of this moiety containing the Gla peptide is facilitated (see Figure 23.47, p. 987).

Role of Vitamin K in Protein Carboxylase Reactions

Modification of prothrombin, **Protein C**, **Protein S**, **Protein Z**, and Factors VII, IX, and X, to form Gla residues occurs during their synthesis by a carboxylase located on the luminal side of the rough endoplasmic reticulum. **Vitamin K** (phytonadione, the "koagulation"

A CLOSER LOOK 23.11

Structural Arrangement of Tissue Plasminogen Activator

t-PA is a 72-kDa protein that contains a growth factor domain near its *N*-terminus, two adjacent **Kringle domains** that interact with fibrin, and a protease domain close to its C-terminus. Kringle domains are conserved sequences that fold into large loops stabilized by disulfide bonds. They are important for protein–protein interactions that occur with several blood coagulation factors. t-PA is activated by cleavage between an Arg-Ile bond to give a molecule with a heavy and a light chain. The light chain contains the serine protease activity.

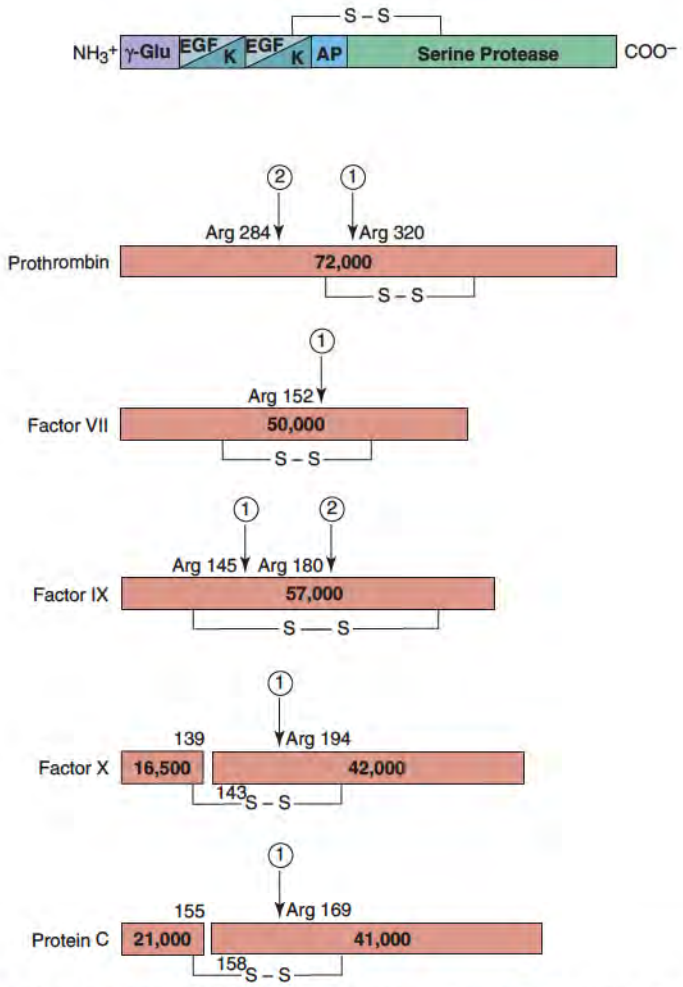

Figure 23.59 ***(a)*** **General structure of the γ-carboxyglutamyl containing proteins. *(b)* Structural organization of the zymogens and their cleavage sites for activation.**

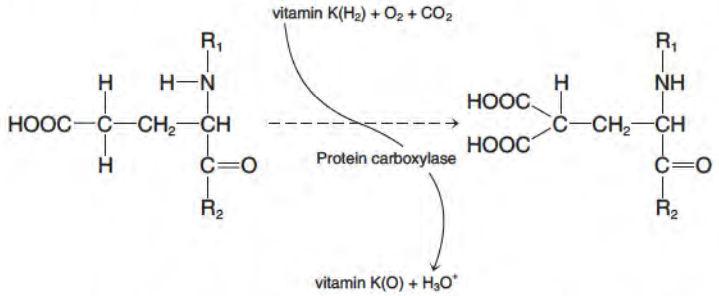
vitamin) is an essential cofactor for this carboxylase. The dihydroquinone, or reduced form of vitamin K (Figure 23.60), is oxidized to the epoxide form by O_2 (A Closer Look 23.13). The **epoxide** is converted back to the **dihydroquinone** by enzymes that require as cofactors dithiols like **thioredoxin**. Analogs of vitamin K inhibit the dihydroquinone reductases and result in conversion of all available vitamin K to the epoxide form that is not functional in the carboxylation reaction. The overall carboxylation reaction is



Structures of two analogs, **dicoumarol** and **warfarin**, that interfere with the action of vitamin K are shown in Figure 23.60. In animals treated with high doses of these compounds, prothrombin, Protein C, Protein S, Factors VII, IX, and X, and other Gla-containing proteins are not posttranslationally modified, are ineffective in binding Ca^{2+}, and cannot participate in blood coagulation. Since dicoumarol and warfarin affect only synthesis of Gla-containing factors, they have no effect on blood coagulation in the test tube.

A CLOSER LOOK 23.12

Activation of Zymogens Involved in Blood Coagulation

Activation may or may not result in loss of small peptides located between disulfide bonds. Factor VII is activated by cleavage of a single Arg^{152}–Ile^{153} bond. Factor IX is activated by cleavages at Arg^{145} and Arg^{180} with the release of an approximate 11-kDa peptide. Factor X consists of two chains connected by a disulfide bridge. It is activated by cleavage of its heavy chain at Arg^{194}-Ile^{195}. The Gla residues are located in the light chain. Protein C also consists of a heavy and a light chain connected by a disulfide bond. It is activated by cleavage of an Arg-Ile bond at position 169.

A CLOSER LOOK 23.13

Possible Mechanism of Vitamin K Action in Protein Carboxylation

A plausible mechanism involves the addition of molecular oxygen to the C1 position of dihydro-vitamin K and its subsequent rearrangement to an alkoxide with a pKa of ~20. This intermediate serves as a strong base and abstracts a proton from the γ-methylene carbon of glutamate yielding a carbanion to which CO_2 can add by a nucleophilic mechanism (Figure 23.60, p. 996).

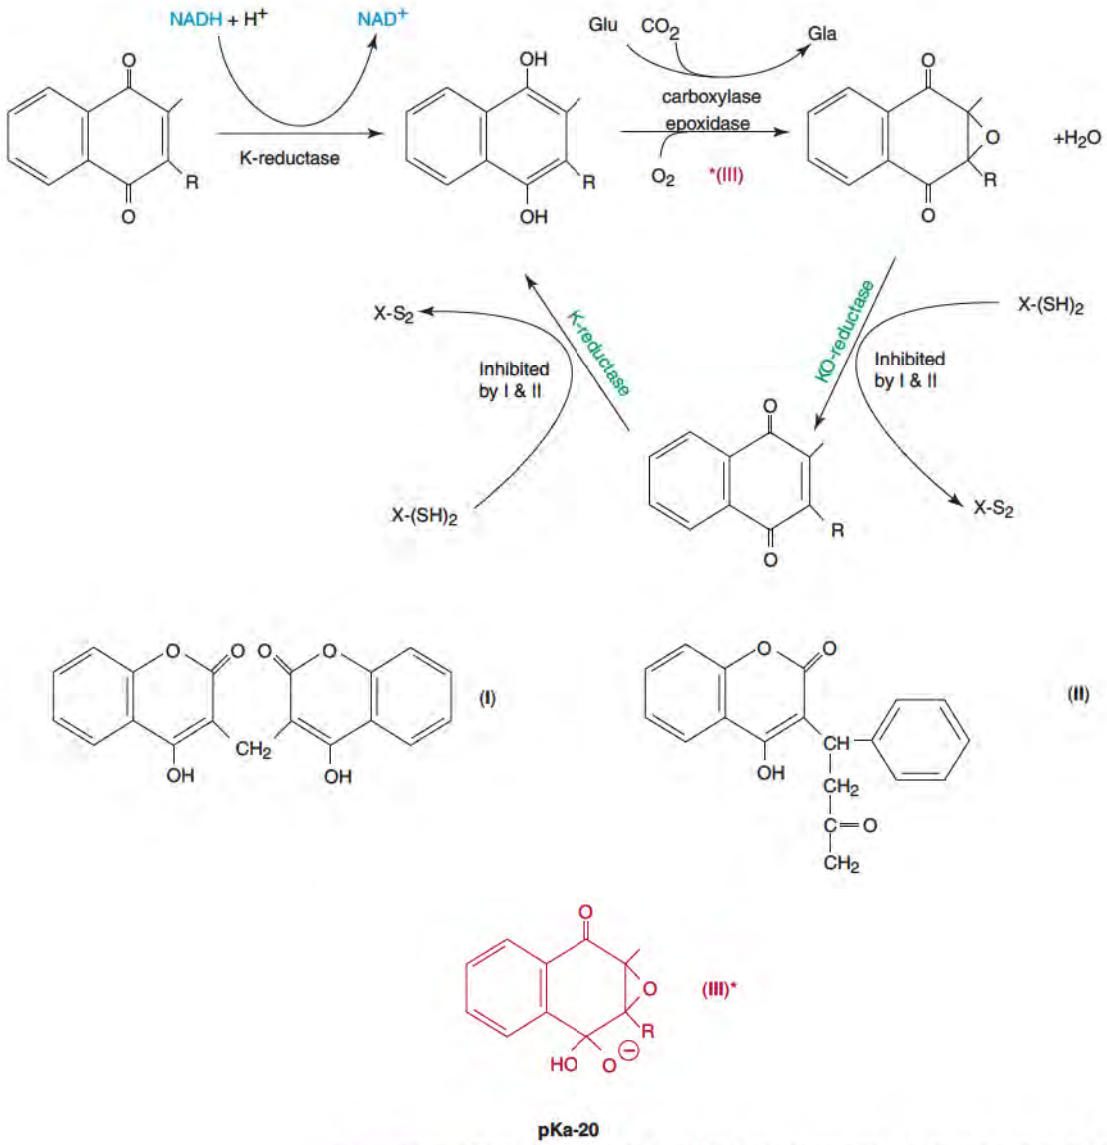


Figure 23.60 The vitamin K cycle as it functions in protein γ-glutamyl carboxylation reactions. X-(SH)2 and X-S2 represent the reduced and oxidized forms, respectively, of a thioredoxin. The NADH-dependent and the dithiol-dependent vitamin K reductases are different enzymes. The dithiol-dependent K and KO reductases are inhibited by dicoumarol (I) and warfarin (II). (*Possible alkoxide intermediate (III), see SIB 13.)
Redrawn and modified from Vermeer, C. *Biochem. J.* 266: 625, 1990.

Control of Synthesis of Gla-Proteins

N-terminal Gla-containing peptides that are released from prothrombin on activation are removed from circulation by the liver. They stimulate *de novo* synthesis of Gla-containing proteins required for blood coagulation (Figure 23.61). The proteins are synthesized even in the absence of vitamin K or in the presence of antagonists of vitamin K, but they do not contain Gla residues and are ineffective in blood coagulation. In addition, they are not secreted into the circulation. Some may remain in the liver and some are degraded. When vitamin K is restored or is added in high enough concentrations to overcome effects of antagonists, the preformed proteins are carboxylated and secreted into the circulation.

Activation of blood coagulation is a one-way process. The use of prothrombin Gla-containing peptides to signal the liver to synthesize more of these proteins maintains their concentrations in blood at effective levels. Monitoring of patients on long-term therapy with vitamin K antagonists is necessary to assure that production of the Gla-containing proteins is not shut down completely. When all of these processes function properly, hemostasis is achieved.

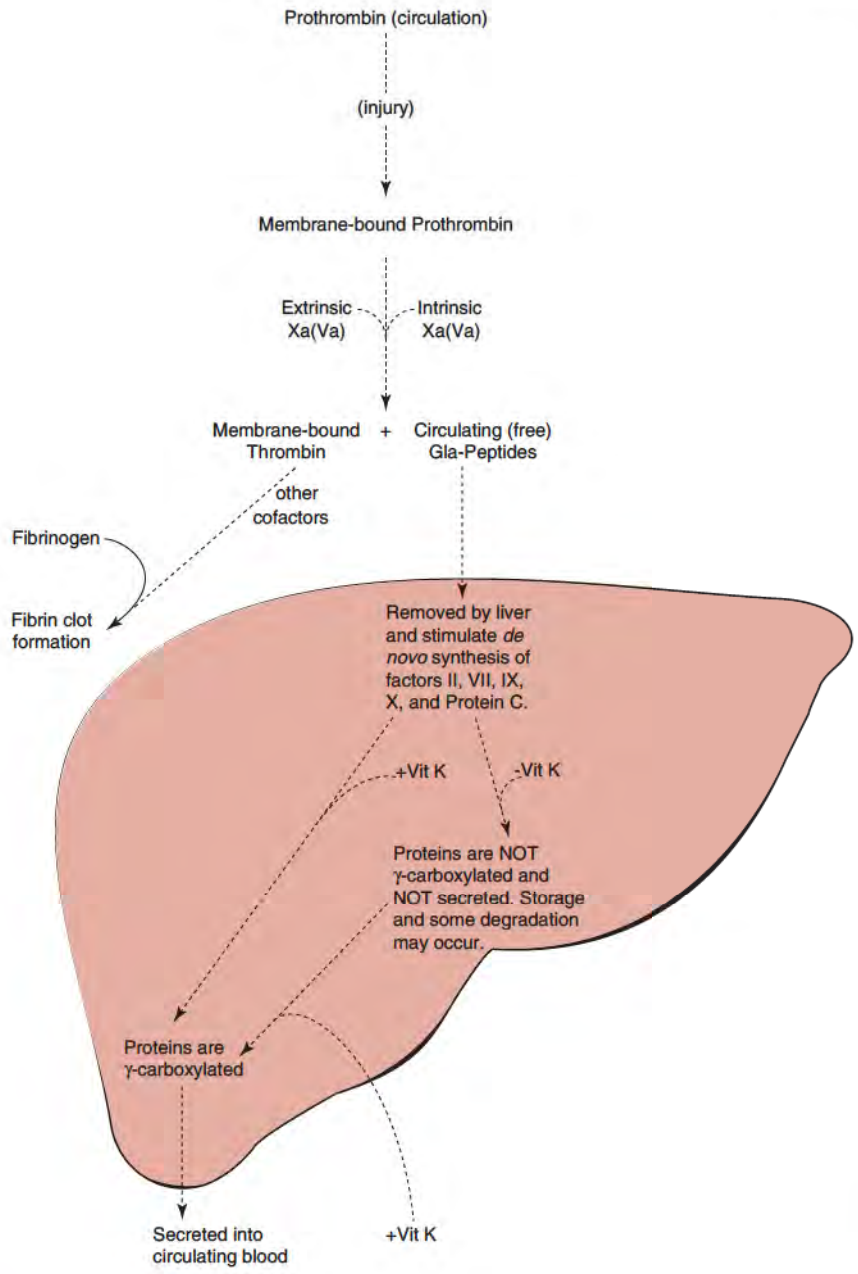

Figure 23.61 Role of Gla-peptides in the regulation of *de novo* synthesis of coagulation factors.

Key Terms

NERVOUS TISSUE

blood–brain barrier
voltage-gated channels
neurotransmitter
calcium–calmodulin kinase
acetylcholinesterase
choline acetyltransferase
catechol-*O*-methyltransferase
monoamine oxidase
GABA shunt
endorphins
enkephalins
neurokinins

THE EYE

glutathione reductase
vascular endothelial growth factor receptor-3
α- and β-crystallins
aldose reductase
polyol (aldose) dehydrogenase
small heat shock proteins
11-*cis*-retinol
all-*trans*-retinol
all-*trans*-retinol dehydrogenase
cyclic GMP (cGMP)
transducin
phosphodiesterase (PDE)
arrestin
guanylate cyclase
rhodopsin kinase

MOLECULAR MOTORS

IQ motifs
kinesin
tropomyosin
troponin subunits
power stroke
cadherin and catenin
caldesmon
adenylate kinase
creatine phosphokinase
myosin light-chain kinase
myosin phosphatase
unconventional myosins
AAA motif
dynein

BLOOD COAGULATION

anticoagulation
fibrinolysis
hemostasis
procoagulation
epidermal growth factor
extrinsic pathway
intrinsic pathway
transglutamidase
thrombomodulin
protein carboxylase
prostacyclin (PGI_2)

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. There are both excitatory and inhibitory neurotransmitters. All of the following are excitatory except
- **A.** acetylcholine.
- **B.** γ-aminobutyric acid (GABA).
- **C.** dopamine.
- **D.** epinephrine.
- **E.** serotonin.

2. Which of the following classes of molecular motors can be involved in both contraction and trafficking?
- **A.** Dyneins
- **B.** Kinesins
- **C.** Myosins
- **D.** All of the above

3. Platelet aggregation
- **A.** is initiated at the site of an injury by conversion of fibrinogen to fibrin.
- **B.** is inhibited in uninjured blood vessels by prostacyclin of intact vascular endothelium.
- **C.** causes morphological changes and a release of the vasodilator serotonin.
- **D.** is inhibited by the release of ADP and thromboxane A_2.
- **E.** is inhibited by von Willebrand factor (vWF).

4. In the formation of a blood clot,
- **A.** proteolysis of γ-carboxyglutamate residues from fibrinogen to form fibrin is required.
- **B.** the clot is stabilized by the cross-linking of fibrin molecules by the action of Factor XIII, transglutaminase.
- **C.** thrombin's only role is in activation of Factor VII.
- **D.** tissue factor, Factor III or TF, must be inactivated for the clotting process to begin.
- **E.** the role of calcium is primarily to bind fibrin molecules together to form the clot.

5. Lysis of a fibrin clot
   - **A.** is in equilibrium with formation of the clot.
   - **B.** begins when plasmin binds to the clot.
   - **C.** requires the hydrolysis of plasminogen into heavy and light chains.
   - **D.** is regulated by the action of protein inhibitors on plasminogen.
   - **E.** requires the conversion of plasminogen to plasmin by t-PA.

6. The eye relies heavily on the metabolism of glucose but different parts of the eye use glucose differently. Which of the following statements is/are correct?
   - **A.** The retina uses glucose primarily by aerobic glycolysis and the TCA cycle.
   - **B.** The cornea uses over half its glucose via the hexose monophosphate pathway.
   - **C.** The lens has the glycolytic pathway but not the hexose monophosphate pathway.
   - **D.** The role of glutathione reductase is to inactivate active oxygen species.
   - **E.** All of the above.

Questions 7 and 8: Two autoimmune diseases that lead to muscle weakness because of interference with neuromuscular signal transmission are Lambert–Eaton myasthenia syndrome (LEMS) and myasthenia gravis. In LEMS, the body raises antibodies against voltage-gated calcium channels. In myasthenia gravis, the antibodies are to the nicotinic–acetylcholine receptor (AchR). In both cases, the amount of acetylcholine released in the synaptic juction is diminished.

7. In the propagation of a nerve impulse by an electrical signal,
   - **A.** the electrical potential across the membrane maintained by the Na^+/K^+-exchanging ATPase becomes more negative.
   - **B.** local depolarization of the membrane causes protein conformational changes in ion channels that allow Na^+ and K^+ to move down their concentration gradients.
   - **C.** charge propagation is bidirectional along the axon.
   - **D.** voltage-gated ion channels have a finite recovery time so the amplitude of the impulse changes as it moves along the axon.
   - **E.** astrocytes function as antenna-like protrusions and receive signals from other cells.

8. The nerve impulse that initiates muscular contraction
   - **A.** begins with binding of acetylcholine to receptors in the sarcoplasmic reticulum.
   - **B.** causes both plasma membrane and transverse tubules to undergo hyperpolarization.
   - **C.** causes opening of calcium channels, leading to an increase in Ca^{2+} within the sarcomere.
   - **D.** prevents Na^+ from entering the sarcomere.
   - **E.** prevents Ca^{+2} from binding to troponin C.

Questions 9 and 10: Genes coding for proteins of visual pigments are located on different chromosomes. The rhodopsin gene is on the third chromosome; blue pigment gene on the seventh; and genes for the red and green pigments on the X chromosome. Females have two X chromosomes so color vision abnormalities are rare, but males have only one X chromosome. About 8 % of males have abnormal color vision that affects either red or green perception. At least one individual is known with blue color blindness.

9. The cones of the retina
   - **A.** are responsible for color vision.
   - **B.** are much more numerous than the rods.
   - **C.** have red, blue, and green light-sensitive pigments that differ because of small differences in the retinal prosthetic group.
   - **D.** do not use transducin in signal transduction.
   - **E.** are better suited for discerning rapidly changing visual events because a single photon of light generates a stronger current than it does in the rods.

10. Which of the following statements about rhodopsin is true?
    - **A.** Rhodopsin is the primary photoreceptor of both rods and cones.
    - **B.** The prosthetic group of rhodopsin is all-*trans*-retinol derived from β-carotene.
    - **C.** Conversion of rhodopsin to activated rhodopsin, R*, by a light pulse requires depolarization of the cell.
    - **D.** Rhodopsin is located in the cytosol of the cell.
    - **E.** Absorption of a photon of light by rhodopsin causes an isomerization of 11-*cis*-retinal to all-*trans*-retinal.

Questions 11 and 12: Ion channels in cardiac muscle, as in other tissues, require a finite recovery time after excitation. This is measured on an electrocardiogram as the QT interval. Initiating the excitation phase is the opening of Na^+ channels, causing depolarization. Then K^+ channels open to permit K^+ to move out of the cell, which is a key element in shutting off the action potential. Inherited defects in these channels lead to a condition called long QT syndrome (LQTS). LQTS can cause sudden death, especially in physically active young people, who have not previously had any symptoms of cardiac irregularities.

11. All of the following statements about actin and myosin are true except
    - **A.** the globular head section of myosin has domains for binding ATP and actin.
    - **B.** actin is the major protein of the thick filament.
    - **C.** binding of ATP to the actin–myosin complex promotes dissociation of actin and myosin.
    - **D.** F-actin is stabilized when tropomyosin is bound to it.
    - **E.** binding of Ca^{2+} to the calmodulin-like subunit of troponin induces conformational changes that permit myosin to bind to actin.

12. When a muscle contracts, the
    - **A.** transverse tubules shorten, drawing the myofibrils and sarcoplasmic reticulum closer.
    - **B.** thin filaments and thick filaments of the sarcomere shorten.
    - **C.** light chains dissociate from the heavy chains of myosin.
    - **D.** H bands and I bands of the sarcomere shorten because thin filaments and thick filaments slide past each other.
    - **E.** cross-linking of proteins in the heavy filaments increases.

Problems

13. In the presence of warfarin, an analog of vitamin K, several proteins of the blood coagulation pathway are ineffective because they cannot bind Ca^{2+} efficiently. Why?

14. Organophosphate compounds are irreversible inhibitors of acetylcholinesterase. What effect does an organophosphate inhibitor have on the transmission of nerve impulses?

Answers

1. **B** GABA stimulates its receptor to form channels through which Cl^- flows, making the inside of the cell more negative.
2. **C** Myosins are involved in contraction and "unconventional myosins" in trafficking. A and B: These are both microtubule-based motors involved in moving cargo.
3. **B** The yin-yang nature of PGI_2 and TXA_2 help to control platelet aggregation until there is a need for it. A: Initiation is by contact with an activated receptor at the site of injury. Clot formation requires activation of various enzymes. C: Serotonin is a vasoconstrictor. D: TXA_2 facilitates aggregation. E: vWF forms a link between the receptor and platelets, promoting aggregation.
4. **B** Cross-linking occurs between a glutamine and a lysine. A and E: γ-Carboxyglutamate residues are on various enzymes; they bind calcium and facilitate the interaction of these proteins with membranes that form the sites for initiation of reaction. C: Thrombin activates Factors V, VII, VIII, XIII and fibrinogen. D: TF, Factor III, is the primary receptor for initiation of the clotting process.
5. **E** The clot is solubilized by plasmin. A: Both formation and lysis of clots are unidirectional. B: Both plasminogen and t-PA bind to the clot. C and D: Both of these refer to t-PA.
6. **B** The NADPH generated, especially in the cornea, is necessary to convert glutathione back to its reduced form. A: The retina depends mostly on anaerobic glycolysis. C: Around 10% of glucose is used by the hexose monophosphate pathway in lens. D: Reduced glutathione (GSH) inactivates these species; glutathione reductase is necessary to reduce glutathione back to GSH.
7. **B** This is the mechanism for impulse propagation. A: The potential becomes less negative. C: It is unidirectional. D: Voltage-gated channels do have a finite recovery time so the amplitude remains constant. E: This describes dendrites. Astrocytes are glial cells involved in processes that insulate neurons from their external environment.
8. **C** Ca^{2+} enters with Na^+. A: Acetylcholine receptors are on the plasma membrane. B: The impulse results in depolarization of both of these structures. D. Both Ca^{+2} and Na^{+2} enter the sarcomere when the channels open. E: Binding of Ca^{+2} to TnC initiates contraction.
9. **A** Rods are responsible for low light vision. C: All three pigments have 11-*cis*-retinal; differences in the proteins are responsible for the different spectra. D: Biochemical events are believed to be the same in rods and cones. E: Cones are better suited for rapid events because their response rate is about four times faster than rods, even though their sensitivity to light is much less.
10. **E** This causes the conformational change of the protein that affects the resting membrane potential and initiates the rest of the events. A: Cones have the same prosthetic group but different proteins, so rhodopsin is in rods only. B: This is the precursor of the prosthetic group 11-*cis*-retinal. C: Isomerization of the prosthetic group leads to hyperpolarization. D: Rhodopsin is a transmembrane protein.
11. **B** Myosin forms the thick filament. Actin is in the thin filament. A: These are both important in myosin's role. C: The role of ATP in contraction is to favor dissociation, not formation, of the actin–myosin complex. D and E: Tropomyosin, troponin, and actin are the three major proteins of the filament.
12. **D** This occurs because of association–dissociation of actin and myosin. A: Depolarization in transverse tubules may be involved in transmission of the signal but not directly in the contractile process. B: Filaments do not change length, but slide past each other. C: This is not physiological. E: Cross-linking occurs in the H band of the sarcomere but does not change during the contractile process.
13. Proteins affected are those with γ-carboxyglutamyl (Gla) residues, which are excellent calcium chelators. Formation of Gla is a post-translational modification catalyzed by a carboxylase whose essential cofactor is vitamin K. Warfarin prevents reduction of vitamin K epoxide formed during carboxylation back to the dihydroquinone form.
14. Acetylcholine is an excitatory neurotransmitter, causing channels to open, Na^+ to enter, and a depolarization of the membrane. Hydrolysis of acetylcholine allows repolarization. The inhibitor keeps the channel open and prevents repolarization, and thus continued transmission of nerve impulses.

Key Concepts

CELL DIVISION CYCLE

- The cell division cycle is divided into highly regulated biochemically distinct phases that are controlled by cyclin-dependent kinases (Cdks). Cdks are regulated by synthesis and degradation of cyclins, phosphorylation of the Cdks, and inhibition.
- Many transcription factors (tfs) are involved in control of cell division. Phosphorylation of retinoblastoma sensitivity protein (Rb) leads to release of E2F (a tf) and entry into S phase. p53 (a tf) halts the cell cycle by increasing the expression of a Cdk inhibitor.
- Mitogen signal pathways activate Ras, which triggers a MAPK kinase cascade that results in expression of Myc to increase the transcription of G_1/S-cyclins.

PROGRAMMED CELL DEATH (APOPTOSIS)

- Cell division is balanced by apoptotic cell death to maintain homeostasis. The death receptor pathway (extrinsic pathway) and the mitochondrial pathway (intrinsic pathway) promote cell death with the activation of a cascade of cytoplasmic proteases (caspases) enzymes.
- The death receptor pathway signal is transmitted by activation of pro-caspase 8.
- The intrinsic pathway involves release of cytochrome c when the mitochondrial proteins Bax and Bak permeabilize the membrane. Other proteins prevent Bax and Bak from acting. Released cytochrome c activates pro-caspase 9.

CANCER

- Malignant tumor cells are characterized by unregulated cell division, resistance to apoptosis, immortality, and ability to metastasize and induce angiogenesis.
- Multiple mutations are required in protooncogenes and tumor suppressor genes that in combination generate a cancer. Cells within a tumor are heterogenic, but are all progeny of a single precursor cell.
- Carcinogenesis is initiated by a mutagenic event and propagated by tumor promoters. Diet, environment, and cultural factors are major determinants in the formation of cancers.
- Genomic, transcriptomic, and proteomic analyses characterize the abnormal biochemical pathways present in cancer, leading to individualized diagnosis and treatment specific to that cancer.

24.1 • INTRODUCTION

At the interface of cell biology and biochemistry are the biochemical pathways that regulate cell division and cell death. These pathways involve proteins that transmit signals, often through their action as enzymes but also through their ability as signaling proteins to bind to other proteins and transmit a signal through induced-conformation changes in the associated proteins. Enzymatic activities commonly present in signal pathways are those of kinases, phosphatases, proteases, and ubiquitin ligases. While the signals are composed of recognizable enzymatic reactions or protein-induced conformational changes, the pathways regulating cell division and cell death are complex. Rather than a simple linear progression of signals from one molecule to the next constituting a pathway, these pathways can be depicted as a network of parallel signaling pathways joined at nodes or hubs that can cross-talk. The inputs are interpreted by these networks in a manner dependent on cell type and on the strength and time course of the extrinsic and intrinsic signals received by the cell, to give an output that causes a cell either to divide, to die, to senesce, or to differentiate. We have only a preliminary understanding of how the networks operate to generate a specific outcome. For many inputs, the complexity of the network makes the outcomes impossible to predict in the absence of computer algorithms to model the multiple node interactions that differ in different cell types and environmental conditions. In this chapter, these pathways will be described in a traditional linear manner to promote a basic understanding of the primary pathways that are the basis of these complex signaling networks. An insight into the complexity of these pathways may be discerned in the discussion of the Ras downstream kinases and their regulation of both cell division and cell death (p. 1010).

In order to maintain cellular homeostasis in a mature organism, an equal number of cells are born and die within a set unit of time. Thus cell division must be balanced by cell death and both cell division and cell death pathways are equally active. Aberrations in these pathways often lead to cancer, and the biochemical basis of cancer will be considered in the last section of this chapter.

24.2 • CELL DIVISION CYCLE

A model of the cell cycle divides the steps of cell division into four phases (Figure 24.1). In the **S phase** the chromosomal DNA is duplicated, and in the **M phase** mitosis occurs leading to the separation of chromosomes, cellular organelles, and cytoplasm of the parent cell into two progeny cells. The gap phases, $\mathbf{G_1}$ and $\mathbf{G_2}$, separate the S phase and M phase. In a simpler cell cycle model, cell division is divided into mitosis (M) and an **interphase** (I) that combines G_1, S, and G_2 phases. Although the time span of the M phase is shorter than the other phases, it is particularly complex. In a fibroblast cell that divides once every 24 h, the M phase spans about 1 h while the S phase takes 10–12 h, and the other two phases (G_1, G_2) occupy the remaining 11–13 h. The observable steps in M phase are presented in Table 24.1. While the processes

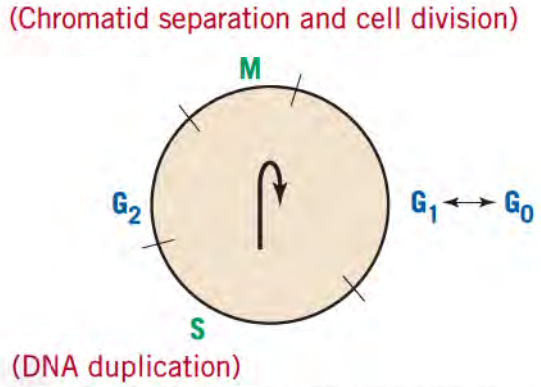

Figure 24.1 **Phases of the cell cycle.** Mitosis occurs in M phase, and DNA synthesis in S phase. Interphase consists of G_1, S, and G_2. G_0 phase is in equilibrium with G_1 phase. Cells in G_0 are either quiescent or senescent.

TABLE 24.1 • Microscopically Observable Steps in the M Phase

1. DNA condenses into chromosomes (46 chromosomes in human cells).
2. Centrosomes separate and mitotic spindle forms from the centrosomes.
3. Nuclear membrane disintegrates.
4. Spindle microtubule connects chromosomes.
5. Chromosomes align along equator of cell.
6. Sister chromatids separate and group around the two centrosomes, creating two sets of chromosomes.
7. Nuclear membrane forms around each set of chromosomes.
8. Chromosomes decondense.
9. Plasma membrane pinches parental cell into two progeny cell (cytokinesis).

that occur in M phase are the most dramatic, essential biochemical processes occur in each of the phases and each phase must be completed before the cell progresses to the next phase. Each phase is under close regulation by biochemical checkpoints that comprise stop or go directives that regulate proceeding to the next biochemical step in the cell division pathway.

An additional phase, in equilibrium with the G_1 phase, is the G_0 phase in which the cell is either in a quiescent or a senescent state. A **quiescent cell**, while not participating in the cell cycle, can be induced to reenter the cell cycle by a mitotic stimulus, such as an increase in concentration of a growth factor in its external environment. In contrast, a **senescent cell** cannot reenter the cell cycle even in the presence of mitotic growth factors. Different cell types vary in their frequency of cell division and thus in the amount of quiescent time spent in G_0. Although fibroblasts and epithelial cells spend very little or no time in G_0, adult liver cells divide about once a year and adult brain cells almost never divide. Thus, adult liver and brain cells spend most of their time in G_0. In G_0 the critical proteins of the cell cycle pathway including cyclin-dependent kinases are absent.

Regulation of Cell Cycle

The cell cycle is regulated by the activity of **cyclin-dependent kinases (Cdks)**, which catalyze phosphorylation of serine and threonine side chains in substrate proteins. The phosphorylated proteins then perform critical functions in the cell cycle pathways. The activities of the Cdks are closely regulated by other protein kinases and phosphatases, by their association with a **cyclin** protein, and by the presence or absence of Cdk inhibitor proteins.

In human cells different cyclin-Cdk heterodimers regulate different steps or phases of the cell cycle. In some cases a particular Cdk activity is required in more than one phase or at an interphase (Figure 24.2). In each case, a Cdk-specific cyclin protein is first synthesized to bind to its Cdk, forming a Cdk-cyclin heterodimer. Then the proper activating phosphates are

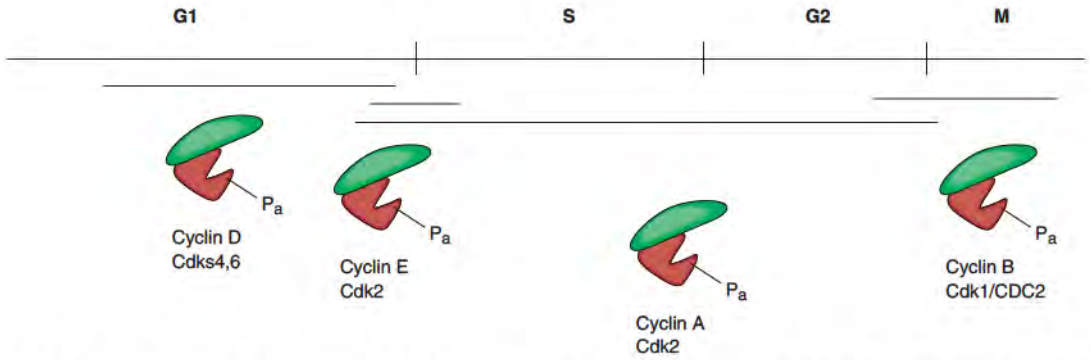

Figure 24.2 Cyclin and cyclin-dependent kinase complexes of the human cell cycle. Top line shows the cell cycle phases; intermediate lines are time frame for activity of the indicated cyclin/Cdk isoform. Both Cdk4 and Cdk6 bind to cyclin D in late G_1. Cyclin E and cyclin A associate with Cdk2 at different time points in S and G_2. Cdk1 is also known as CDC2. Multiple isoforms of some of the cyclins, such as D2 and D3, exist. P_a is an activating phosphate added by a CAK (see text).
Redrawn based on diagram in Morgan, D. O. *Annu. Rev. Cell. Dev. Biol.* 13: 261, 1997.

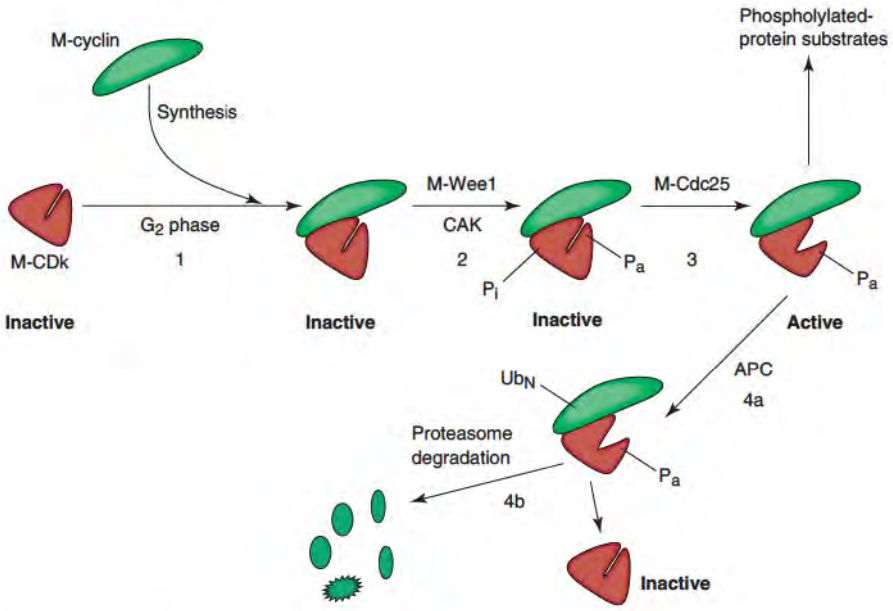

Figure 24.3 Regulation of M phase cyclin-dependent kinase (Cdk) activity. M-cyclin (green) is synthesized in the G_2 phase and combines with M Cdk (red) to form an inactive heterodimer. Phosphorylation by Wee1 kinase at an inhibitory site (Pi) maintains M–Cdk/M–cyclin heterodimer in an inactivated state. Entry into M phase occurs on phosphorylation by CAK at an activation site (P_a) and removal of the inhibitory phosphate by Cdc25 phosphatase. Activated M-Cdk phosphorylates protein substrates that promote M phase. Loss of M-Cdk activity occurs when M-cyclin is polyubiquitinated (Ub_N) by the APC ubiquitin ligase complex and degraded in a proteasome.

added by a **cyclin-dependent activating kinase** (**CAK**) and inhibitory phosphates removed by a **CDC25 phosphatase** to generate the Cdk activity that regulates the cell cycle step. At the end of the cell cycle step, the cyclin protein of the cyclin–Cdk complex is polyubiquitinated by an ubiquitin ligase and the polyubiquitinated cyclin degraded, turning off its associated Cdk activity and allowing the cell cycle pathway to proceed to the next stage of the pathway. Thus for the M phase in human cells, the **M-phase Cdk** (**Cdk1**) binds **M cyclin** (**cyclin B**). Cdk activity is then regulated by both its inhibitory and activating kinases and activating phosphatase (Figure 24.3).

Wee1 is a G_2/M-phase kinase that phosphorylates Cdk1 at an inhibitory site (P_i), preventing Cdk1 activity and entry into M phase. Wee1 obtained its name in yeast experiments in which knockout of the *wee1* gene results in "tiny" or "wee" cells. Thus Wee1 appears in yeast to be a terminal signal of a kinase cascade that prevents a cell from proceeding into M phase when the cell is too small to divide, and the absence of this checkpoint leads to tiny progeny cells. In mammalian cells, signals that prevent a cell from proceeding into M phase are generated by incomplete DNA replication and DNA damage. When the cell is ready to proceed into the M phase, the Wee1 stop signal is released by removal of the inhibitory phosphate group by the phosphatase, Cdc25. In addition to removal of inhibitory phosphates, the Cdk1/cyclin is activated by an M-Cdk activating kinase, M-CAK (**C**dk **a**ctivating **k**inase), that places a phosphate on an activation site residue (P_a) in the Cdk1 molecule. At the end of M phase, ubiquitylation of cyclin B terminates the M-Cdk/cyclin activity (p. 248). The polyubiquitinated cyclin B is degraded by the cellular proteasomes. The ubiquitin system that regulates cyclin B is named the **anaphase-promoting complex** (**APC**), so called because loss of cyclin B and its associated Cdk1 kinase activity is required for initiation of sister chromatid separation in the anaphase stage of mitosis.

While a single Cdk/cyclin regulates the M phase in mammalian cells, at least four different Cdk/cyclin heterodimers regulate progression through the G_1 and S phases (see Figure 24.2). Each of the G_1/S-Cdks is regulated by specific CAK and Wee1-like kinase isoforms that act by mechanisms similar to those that regulate Cdk1. Each Cdk also has a Cdc25 phosphatase isoform to remove inhibitory phosphate groups. A G1/S-Cdk/cyclin is required in G1 for the cell to proceed from G1 into S phase. Several Cdks are active at the G_1/S interface. One of the G1/Cdk/cyclin isoforms is active through the S and G_2 phases. Each Cdk loses its activity on ubiquitylation and degradation of its cyclin (Figure 24.4). The ubiquitin ligase complex that regulates the G1/S- and S-phase cyclins is known as the **SCF complex**.

Rb Regulation of E2F Activity and G_1/S Transition

A cell cycle critical substrate of the G_1/S Cdks is **Rb protein** (**r**etino**b**lastoma sensitivity **protein**), named after its deficiency in the cancer retinoblastoma. Rb protein is unphosphorylated

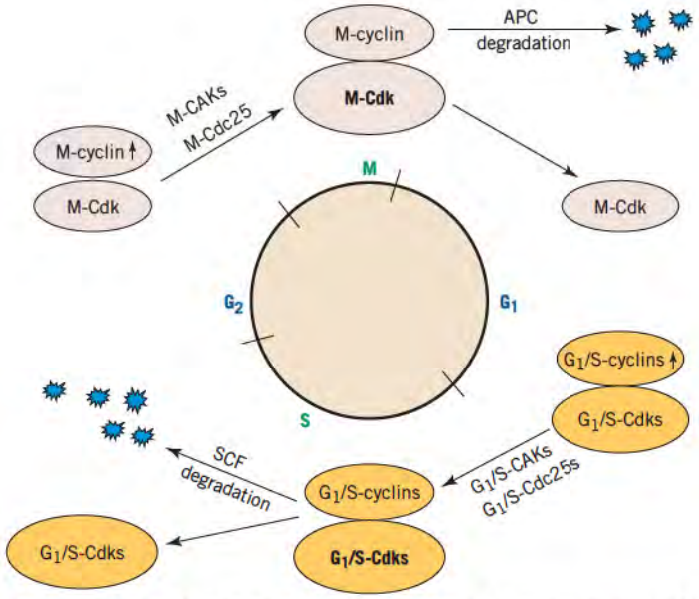

Figure 24.4 Reactions leading to activation and inactivation of the cyclin dependent kinases (Cdks). Binding to their cyclin and the action of their appropriate Cdk-activating kinase (CAK) and CDC25 phosphatase activates the Cdks. Cdk activities are lost on degradation of their cyclin following its ubiquitination by APC in the M phase and SCF in the G_1-S phase. The Cdks are not degraded while the cell remains in the cell cycle, but are degraded when the cell enters G_0.

in the G_1 and G_0 phases, and unphosphorylated Rb binds and sequesters the transcription factor **E2F** (Figure 24.5). On phosphorylation by the G_1 and G_1/S-Cdks, Rb changes conformation and releases E2F. The E2F binds to regulatory elements in target genes to increase transcription of the gene products required for S phase such as DNA polymerase, dihydrofolate reductase, thymidine kinase, and the G_1/S phase cyclin proteins. The G_1/S cyclin proteins increase the activity of G_1/S Cdks. Generation of phosphorylated Rb by the G_1/S-Cdks and release of the E2F transcription factor is a key requirement for entry into S phase from G_1. Unphosphorylated Rb is the active form of Rb, as it acts to sequester and inhibit E2F. The phosphorylated form of Rb that no longer acts to sequester E2F is the inactive form of Rb.

p53 Regulation of the Cdk Inhibitor p21

p53 is a transcription factor that has been described as "the guardian of the genome." On damage to the cellular DNA, p53 stops the cell cycle to give the cell time to repair its DNA. If the DNA damage is irreparable, p53 induces apoptotic cell death. The loss of p53 function results in cell division with damaged DNA, a property of cancer cells.

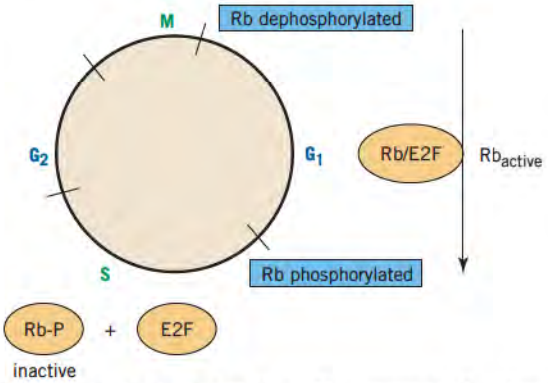

Figure 24.5 Role of Rb in cell cycle regulation. Active Rb is present in G_1, where it binds and inhibits the transcription factor E2F. On phosphorylation by the G_1-S Cdks, Rb releases E2F, which increases expression of genes required for S phase. Phospho-Rb is dephosphorylated by a phosphatase on entering G_1 phase from M phase.

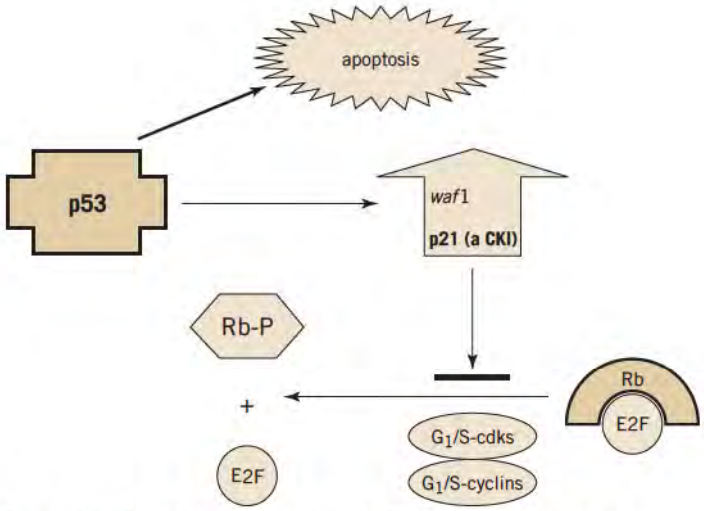

Figure 24.6 Regulation of the G_1-to-S transition by p53. The concentration of the transcription factor p53 is increased on DNA damage, by stress, and by other cell cycle regulatory signals. p53 stops the cell cycle by increasing the transcription of the *waf1* (also called *cip1*) gene to express p21, which is a Cdk inhibitor (CKI) and binds to G_1-S Cdks to inhibit phosphorylation of Rb. Higher concentrations of p53 than required for p21 synthesis initiate apoptosis.

Kinases monitor DNA integrity and are activated on DNA damage (p. 164). The activated kinases phosphorylate p53 directly or activate other kinases that phosphorylate p53. Phosphorylated p53 is resistant to degradation, and its concentration in the cell increases. p53 is a transcription factor protein and higher levels increase the transcription of the p53 target gene *waf1* (also referred to as *cip1*). The product of the *waf1* gene is the protein **p21**, a Cdk inhibitor. **Cdk inhibitor** proteins are called **CKI**s, and p21 protein is the key CKI increased by p53. The increase in p21 inhibits the G_1- and G_1/S-Cdks and their phosphorylation of Rb. Unphosphorylated Rb retains bound E2F, preventing cell entry into S phase of the cell cycle (Figure 24.6). With DNA damage, this mechanism (DNA-kinase → p53 → p21 ⊣ G_1-Cdk) gives the cell time to repair its DNA before proceeding into S phase with replication of the cellular DNA. In over 50% of cancers, the p53 genes are mutated or lost. In the 50% of cancers that contain normal p53 genes, the pathways that regulate p53 are often defective. These defects in p53 genes and in p53 regulation permit the propagation of cancer cells with damaged and unstable chromatin.

Growth Factor Signal Transduction Pathway

The most closely regulated step of the mammalian cell cycle is entry into the S phase, which commits the cell to either completing a cell division cycle or, in the absence of the completion of cell division, to die. Entry into S phase normally requires an extracellular signal such as that given by mitogen factors, commonly called **growth factors**. Growth factors are proteins secreted by cells to either induce their own division (**autocrine mechanism**) or secreted by neighboring or distant cells to induce cell division (**paracrine mechanism**). A low concentration of growth factor proteins is always present in the extracellular environment of mammalian cells and required to maintain cell survival. Higher concentrations of growth factor proteins then cause target cells containing specific receptors for the growth factor proteins to divide.

Growth factor proteins bind to **growth factor receptors** on cellular plasma membranes. This binding causes the receptor proteins to dimerize or polymerize in the plasma membrane, an essential step for transmission of the growth factor signal. The growth factor proteins utilize various mechanisms for oligomerization of receptor proteins. Platelet-derived growth factor (PDGF) forms a homodimer with two equivalent receptor binding sites that bind and join two receptor proteins together to form a receptor dimer in the plasma membrane (Figure 24.7). Other growth factors associate with cofactor proteins that facilitate their binding and simultaneously induce oligomerization of the receptor proteins in the plasma membrane.

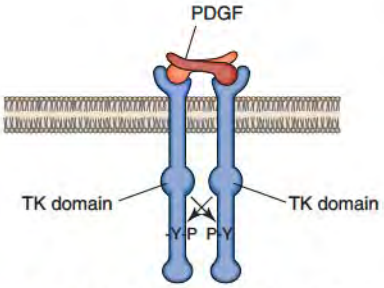

Figure 24.7 Phosphorylation of tyrosine residues within cytoplasmic domains of PDGF receptor. Binding of PDGF as a dimer causes its membrane receptor to also dimerize. The tyrosine kinase activity in the cytoplasmic region of one receptor protein then phosphorylates tyrosine residues (Y) in the cytoplasmic region of the neighboring receptor protein.

Receptor proteins pass through the plasma membrane to connect a growth factor receptor domain on the extracellular surface and a tyrosine kinase catalytic domain on the cytoplasmic side of the plasma membrane. Unlike the serine/threonine kinases (e.g., PKC, PKA, and the Cdks) that place a phosphate group on side chains of serine and threonine residues, tyrosine kinases place a phosphate group on the phenolic side chain of a tyrosine residue. The initial tyrosines phosphorylated on receptor activation are within the cytoplasmic sequence of the receptor protein. The kinase activity of one receptor protein in the oligomer acts on a neighboring receptor protein of the receptor dimer or oligomer complex, and vice versa, to autophosphorylate tyrosines of the partner receptor protein (Figure 24.7). The phosphotyrosines are binding sites for cytoplasmic signaling proteins.

Some growth factor receptors lack tyrosine kinase activity, and on binding growth factor and oligomerization in the membrane, the receptor proteins bind an independent cytoplasmic protein with a tyrosine kinase activity such as **Src**. The addition of the Src protein gives these tyrosine-kinase-deficient receptors a tyrosine kinase activity.

Cellular proteins of the growth factor signaling pathway typically contain **SH2** (**S**rc **h**omology domain **2**) and **SH3** domains, which contain binding sites that lead to the protein–protein interactions that transmit the signal. The SH2 domain in signaling proteins binds to a phosphorylated tyrosine site, and the SH3 domain binds to a region in target proteins having a polyproline helix secondary structure (Figure 24.8). Different P-Ys in the receptor protein sequence are specific to the binding of a particular signal molecule. Thus, each of the signaling molecule SH2 domains has a secondary site specificity that differentiates between the amino acid sequences surrounding the P-Ys to find its P-Y binding site in the receptor protein. Accordingly, the SH2 domain of the signal molecule PI3K has specificity not only for phosphotyrosine but for the phosphotyrosine at tyrosine-740 in the PDGF receptor protein sequence, and PLCγ for the phosphotyrosine residue at position 1021 in the

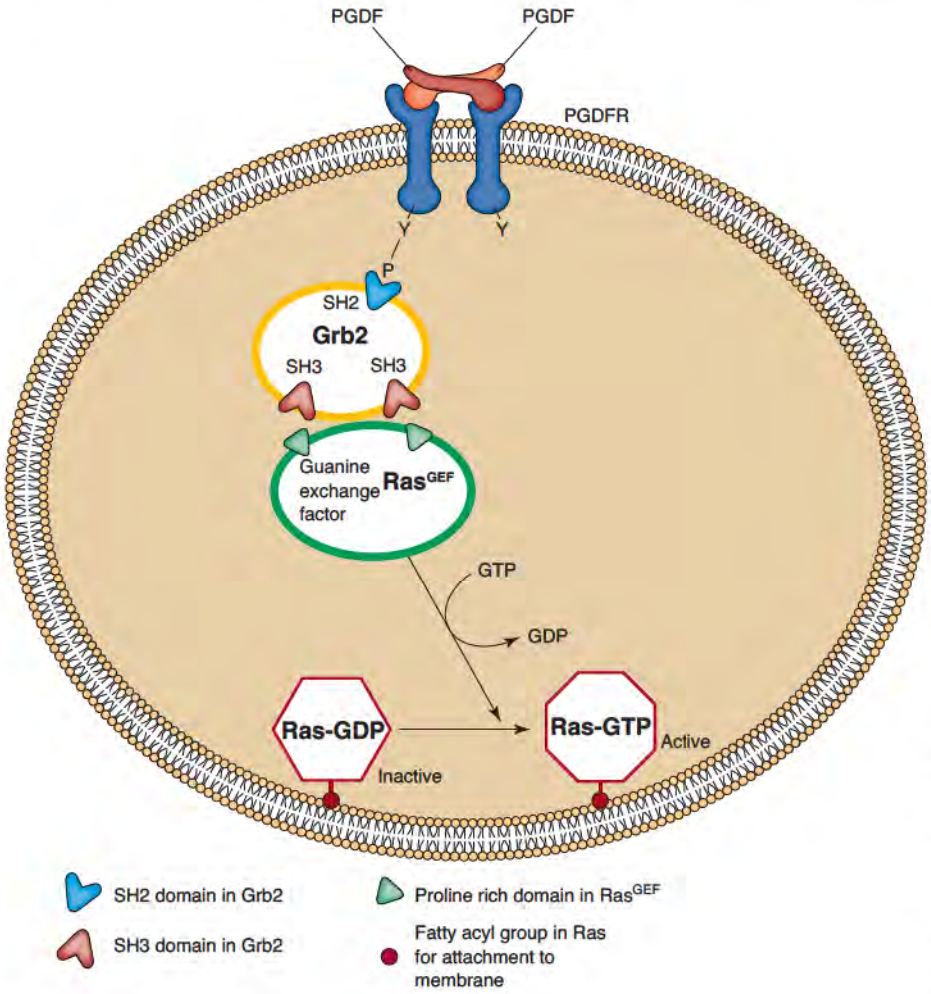

Figure 24.8 Transmission of signal from PDGF receptor to Ras. Plasma membrane containing PDGF receptor becomes autophosphorylated on tyrosine residues. The SH2 domain of Grb-2 binds to phospho-tyrosine residue 416 in the PDGF receptor, and its SH3 domains bind to polyproline helix region in GEF^{Ras} (Ras guanine exchange factor), which promotes exchange of GDP for GTP in Ras. Ras-GTP then transmits its downstream signals.

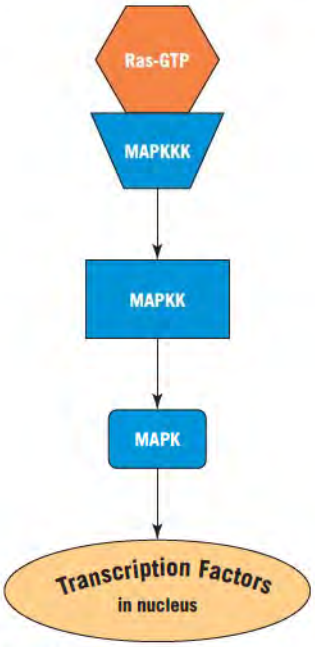

Figure 24.9 GTP-Ras activates a kinase cascade. Ras-GTP activates a kinase cascade resulting in the phosphorylation and activation of the terminal kinase, MAPK. Activated MAPK enters the nucleus and phosphorylates transcription factors that regulate the expression of proteins involved in S phase. MAPK is mitogen-activated protein kinase. MAPKK is MAP kinase kinase, and MAPKKK is MAP kinase kinase kinase.

receptor sequence. On binding to the receptor protein, PI3K and PLC become substrates for the receptor tyrosine kinase. Phosphorylation of tyrosines in the signal molecules activates the signaling protein, and it may dissociate from the receptor to transmit its signal at another site in the cell.

The signal for cell division is transmitted to **Grb2**, which binds to the phosphorylated tyrosine residue 716 in the PDGF receptor. Grb2 has no catalytic activity but is an adaptor protein that transmits its signal through conformational change and protein–protein associations. Grb2 contains both **SH2** and **SH3** domains (Figure 24.8). Binding of Grb2 to the PDGF receptor through its SH2 domain induces a conformation change that opens its SH3 domains to bind a polyproline helix region in the **GEF**^{Ras} protein (**g**uanine-nucleotide **e**xchange **f**actor). Conformationally activated GEF^{Ras} then makes active the signaling protein **Ras** by promoting the exchange of its bound GDP for GTP in the Ras nucleotide binding site (Figure 24.8). GTP-Ras is the active form of Ras that gives a downstream signal by binding to a kinase that becomes activated on GTP-Ras association. The kinase then activates a downstream kinase cascade. Ras is also a GTPase enzyme that inactivates itself by catalyzing the hydrolysis of its bound GTP to GDP, converting the signaling active GTP-Ras to an inactive GDP-Ras.

Activating *ras* mutations resulting in permanently active GTP-Ras occur in approximately 30% of human cancers. The activating mutations are in amino acid residues 12, 13, and 61 of Ras, amino acid residues essential for the Ras GTPase catalytic activity. The oncogenic GTP-Ras conformation cannot deactivate and continuously transmits a downstream signal to enter cell division.

In the normal Ras, the Ras GTPase deactivating activity is increased 100- to 1000-fold by the binding of **GAP**^{Ras} (**G**TPase **a**ctivating **p**rotein). However, the binding of GAP^{Ras} to the GTPase inert oncogenic Ras has no effect, as no GTPase activity is possible due to the catalytic residue mutations in Ras.

Ras also needs to associate with the plasma membrane to be activated. Posttranslational modifications of Ras are required for membrane association. Modifications include removal of the four amino acids from the C-terminal end, methylation of the new C-terminal carboxylic acid group, and addition of a farnesyl fatty acid group to a cysteine side chain near the new COOH-terminal end that acts to anchor the Ras protein to the cytoplasmic surface of the plasma membrane. In some Ras isoforms a second fatty acyl group is added, also near the COOH-terminal end.

Three different Ras genes exist in humans, Ha-*ras*, N-*ras*, and K-*ras*, which produce homologous proteins of 21 kDa. The amino acid sequences of the first 85 residues in each of the isoforms are identical and the next 80 residues show 85% homology, but the C-terminal ends differ more dramatically. While there are differences in some of the downstream signals between the Ras isoforms, in general their signals overlap. These isoforms are characteristically expressed in different cell types, and mutations of residues 12, 13, and 61 constitutively activate all isoforms. Wild-type *ras* genes are **protooncogenes**. Protooncogenes are changed to **oncogenes** by an activating mutation that acts to maintain a cancer cell.

The kinase activated by association with GTP-Ras is a MAP kinase kinase kinase (MAPKKK) (Figure 24.9). The MAPKKK phosphorylates a MAP kinase kinase (MAPKK), which phosphorylates a MAP kinase (MAPK). Activated (phosphorylated) **MAPK** translocates to the nucleus where it phosphorylates and activates transcription factors such as **Jun** and **Fos**. An important target gene of Jun or Fos is the gene for the transcription factor **Myc**. Myc increases the expression of many genes involved in the S phase including those of the G_1- and G_1/S-cyclins and the transcription factor E2F (p. 189). Increasing the levels of the transcription factors Myc and E2F initiate S phase and cell division. However, if conditions are not proper for completion of the S phase and cell division, Myc and E2F may instead initiate a process leading to cell death in the cell that has passed through the critical G_1 to S transition checkpoint.

24.3 • APOPTOSIS: PROGRAMMED CELL DEATH

Apoptosis is the Greek word for "falling leaves," a natural autumn event, and cellular apoptosis is the natural biochemical process of cell death. In an adult human, it is estimated that 3 billion cells are born each minute and therefore 3 billion cells per minute must undergo apoptotic death to maintain homeostasis. Apoptosis is required to restructure tissues and

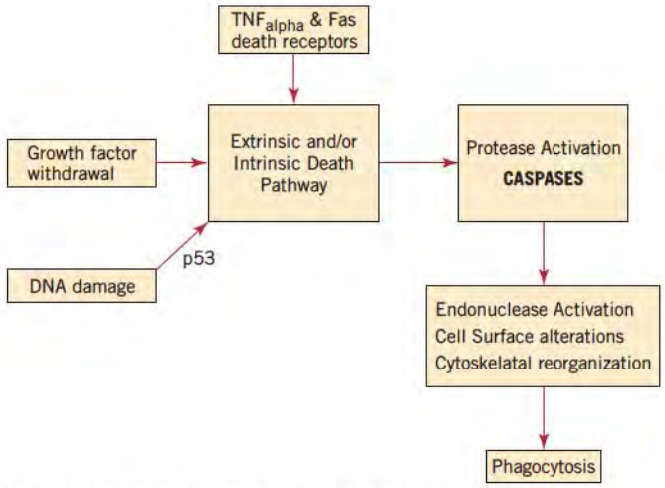

Figure 24.10 Outline of pathway for programmed cell death.

organs in embryogenesis and development. Apoptosis also eliminates immunoresponsive T-cells and B-cells at the end of their response to infection, and regulates wound healing. Apoptotic death differs from **necrotic** cell death. In necrotic cell death, lysis of the cell membrane occurs and releases the cell's contents into the extracellular space generating an inflammatory response, as often occurs in bacterial or viral infections and in trauma. In contrast, apoptosis is often unobservable and does not induce an inflammatory or immunological response. It can be initiated by a variety of signals, including those from damaged DNA, entrance of a cell into the S phase under improper conditions, lack of proper contacts of a cell with extracellular matrix, lack of necessary growth factors in the cellular extracellular environment, or the presence of death signal proteins in the environment of a cell. These signals activate cytoplasmic protease enzymes called **caspases**. The caspases hydrolyze specific peptide bonds in target proteins that on activation by a caspase promote cell death by either a gain or loss of function. Apoptotic death is characterized by caspase-generated changes in the plasma membrane, cytoskeleton, and nuclear DNA. The plasma membrane becomes blebbed and sheds membranous particles that encapsulate the intracellular content. Endonucleases are activated that degrade the chromosomal DNA into nucleosome-size fragments (~170 base pairs in length). The remnants of the cell are engulfed and digested by phagocytic cells such as macrophages (Figure 24.10).

The caspase proteases are activated by precursor caspases in a protease cascade mechanism similar to the protease cascades of blood coagulation and the protease complement reactions of the immunological response. Each caspase is activated by cleavage of a peptide bond by an upstream caspase in the cascade pathway. In turn, the activated caspases act on protein substrates that generate the changes characteristic of apoptotic death.

Major Pathways of Apoptosis

Death Receptor Pathway

The two major pathways that activate the caspase cascade and promote cell death are the **death receptor pathway (extrinsic pathway)** and the **mitochondrial pathway (intrinsic pathway)** (Figure 24.11). The receptor pathway is initiated by binding of a death ligand in the extracellular environment to its receptor in the plasma membrane of a target cell. **Death ligand** binding promotes binding of intracellular adaptor proteins to the cytoplasmic region of the receptor protein in the plasma membrane. Such an adaptor protein is FADD (the DD in the acronym refers to a protein-binding domain present in many proteins of this pathway called the **d**eath **d**omain). The aggregates formed by the adaptor proteins through DD interactions at the cytoplasmic side of the receptor include the caspase 8 precursor protein, pro-caspase 8. The pro-caspase 8 within the aggregate acquires an auto-proteolytic activity, and cleaves peptide bonds in its sequence that change pro-caspase 8 to an active caspase 8. Caspase 8 leaves the aggregate to initiate the protease caspase cascade (Figure 24.11). The cytoplasmic receptor aggregate containing multiple adaptor proteins such as FADD and pro-caspase 8 molecules is referred to as a **DISC** (**d**eath **i**nducing **s**ignaling **c**omplex).

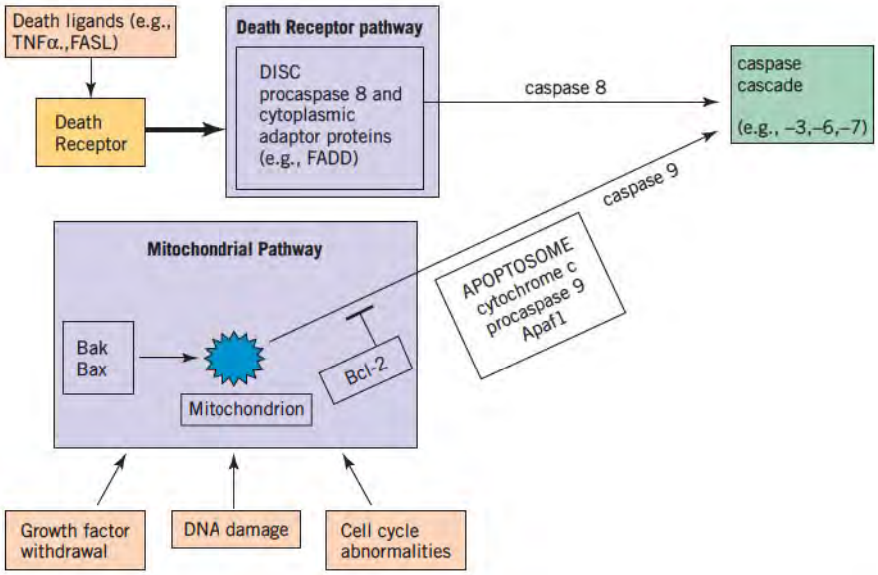

Figure 24.11 Death receptor and mitochondrial pathways activate caspase cascade. The death receptor (extrinsic) and mitochondrial (intrinsic) pathways converge on the activation of caspases. Death ligands activate death receptor to bind adaptor proteins and pro-caspase 8, which is activated to caspase 8. Caspase 8 then activates the caspase cascade. In mitochondrial pathway, Bak and Bax oligomerize to permeabilize the outer mitochondrial membrane to allow cytochrome c to pass into the cytoplasm where it forms an apoptosome with multiple molecules of Apaf1 and pro-caspase 9. Activated caspase 9 then activates caspase cascade. Bcl-2 inhibits cytochrome c passage from mitochondria. Activators of the mitochondrial and receptor pathways (i.e., TNFα and DNA damage) are shown.

Mitochondrial Pathways

The intrinsic, or mitochondrial, pathway is regulated by the relative concentrations of **BH domain** proteins in the outer mitochondrial membrane (A Closer Look 2.1, p. 1013). Cytochrome c is the major mitochondrial signaling protein, and apoptosis is activated by the passing of **cytochrome c** through the outer mitochondrial membrane after permeabilization of the membrane by the pro-apoptotic BH domain proteins Bak and Bax (Figure 24.12). The membrane permeabilization to cytochrome c is generated by hetero- or homo-oligomers of **Bax** and/or of **Bak** BH proteins formed in the outer membrane. In opposition, the anti-apoptotic BH domain proteins **Bcl-2** and **Bcl-X_L** prevent Bax and Bak self-association by binding to Bak and Bax and sequestering them from associating with each other. Whether cell death occurs then depends on the relative concentrations of pro-apoptotic Bak and Bax and anti-apoptotic proteins such as Bcl-2 and Bcl-X_L in the outer mitochondrial membrane. If the concentration of Bcl-2 and Bcl-X_L proteins with empty binding sites is greater than the concentration of Bak and Bax, aggregates of Bak/Bax will not form and the cell survives. However, if the relative concentrations of Bak and Bax proteins are greater than Bcl-2 and Bcl-X_L binding capacity, these proteins will self-aggregate to induce mitochondrial

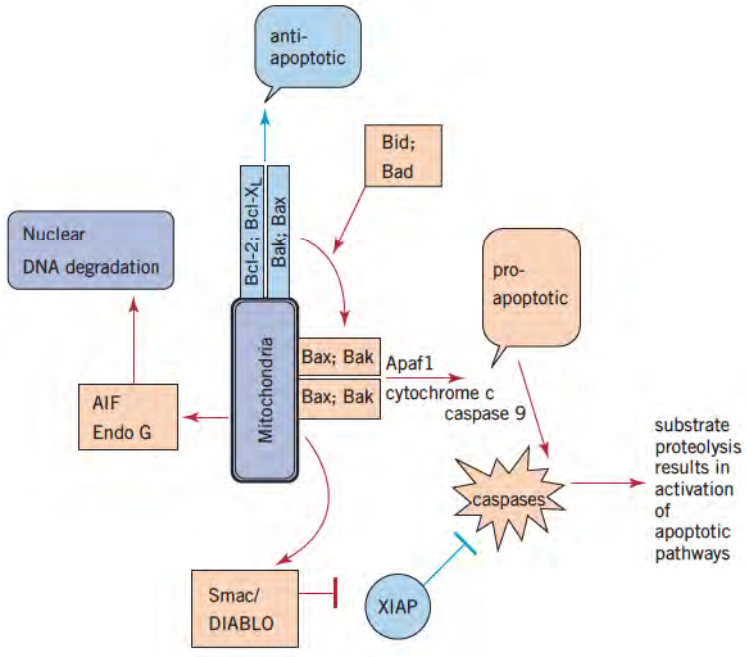

Figure 24.12 Regulation of apoptosis by cytochrome c and other mitochondrial proteins. Oligomerization of Bak and/or Bax in the outer mitochondrial membrane permeabilizes the membrane for transfer of cytochrome c from mitochondria to cytoplasm. Bcl-2 and Bcl-X_L inhibit membrane permeabilization by binding with Bax and Bak to prevent Bax and Bak self-association. Facilitator proteins, such as Bad and Bid, promote apoptosis by either promoting the dissociation of Bak and Bax from Bcl-2 and Bcl-X_L or promoting an active conformation of the Bax/Bak oligomers. In the cytoplasm, cytochrome c binds in apoptosome complex, which leads to the activation of pro-caspase 9 to active caspase 9. Smac/DIABLO can also enter cytoplasm and activate the caspases by inhibiting XIAP. XIAP is an inhibitor of caspase activity. AIF and EndoG can pass from mitochondria into nucleus to promote degradation of the DNA. Blue lines show anti-apoptotic and red lines pro-apoptotic effects.

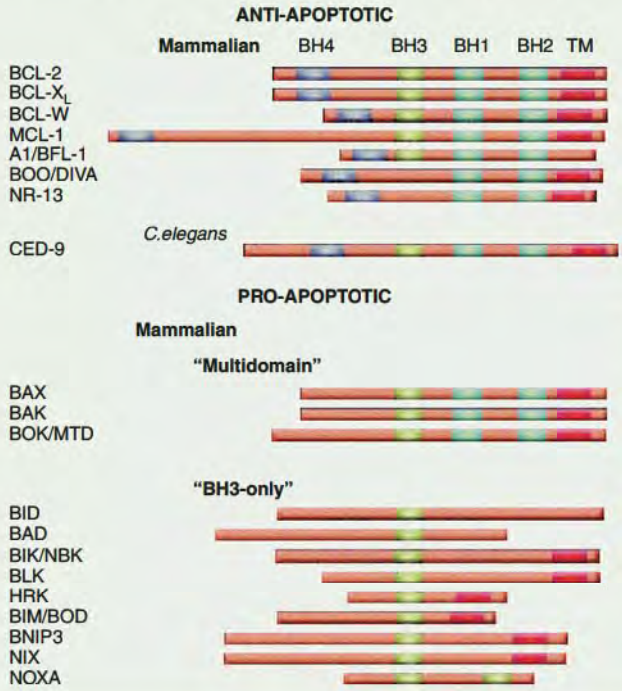
A CLOSER LOOK 24.1

The Bcl-2 Protein Family

The Bcl-2 protein family has pro- or anti-apoptotic roles in the mitochondrial membrane. Members of the family are characterized by their containing one or more **B**cl-2-**h**omology (**BH**) domains. These domains function to bind other proteins of the family through BH-domain interactions. The anti-apoptotic Bcl-2 and Bcl-X_L proteins contain four BH-type domains numbered BH1, BH2, BH3, and BH4. The Bax and Bak proteins that self-polymerize to permeabilize the mitochondrial membrane contain three BH-type domains, BH1, BH2, and BH3. The facilitator BH proteins contain only the BH3 domain and are referred to as BH3-only proteins (see figure).



Schematic diagram showing the BH domains in anti- and pro-apoptotic mitochondrial membrane proteins. Anti-apoptotic proteins that bind and sequester pro-apoptotic proteins contain four different domains (top group): BH1, BH2, BH3, and BH4 (homologues include Bcl-X_L, Bcl-w, A1/Bfl-1, Mcl-1, Boo/Diva, and NR-13). Pro-apoptotic proteins that permeabilize the outer mitochondrial membrane contain three domains (middle group): BH1, BH2, and BH3 domains, but no BH4 domain (homologues are Bak, Bax, and Box/Mtd). Pro-apoptotic facilitator proteins (bottom group) only contain a BH3 domain (homologues include Bid, Bik, Puma, Noxa, Blk, Hrk, Bnip3, and Bim). TM is a transmembrane domain present in many of the BH domain proteins. Different groups of homologues are expressed in different cell types.
Redrawn from Scorrano, L., and Korsmeyer, S. J. *Biochem. Biophys. Res. Commun.* 304:437, 2003

outer membrane permeability and cytochrome c will pass from the mitochondria to the cytoplasm to initiate caspase activation and cell death. In addition to Bax and Bak, other BH domain proteins in the mitochondrial membrane act as facilitator proteins to promote dissociation of Bak or Bax from Bcl-2 or Bcl-X_L by competing for the binding sites in Bcl-2 or Bcl-X_L. Other BH domain facilitator proteins in the plasma membrane bind directly to the Bax/Bak oligomers to promote membrane permeabilization by the Bax/Bak oligomer.

There are at least 24 BH domain mitochondrial membrane proteins in humans, divided into the following three functional classes: (1) anti-apoptotic proteins such as Bcl-2 and Bcl-X_L, (2) pro-apoptotic membrane permeabilization proteins Bax and Bak, and (3) pro-apoptotic facilitator proteins such as Bid, Bad, Bim, PUMA, and Noxa. The proteins in all the functional classes contain **BH domains** (**B**cl-2 **H**omology **domains**), which are the binding sites for self-association and for heteroassociation with the other BH domain proteins (A Closer Look 2.1, p. 1013). Which of the Bcl-2 isoforms are expressed by a cell depend on the cell type.

In the cytoplasm the cytochrome c binds into a protein aggregate containing multiple molecules of the adaptor protein **Apaf1** (**a**poptotic **p**rotease-**a**ctivating **f**actor **1**) and **pro-caspase 9**. This cytoplasmic complex is called an **apoptosome** and is functionally similar to a DISC (p. 1011) of the death receptor pathway. The addition of the cytochrome c to the apoptosome causes an autocatalytic hydrolysis of specific peptide bonds in the sequence of pro-caspase 9, resulting in the active caspase 9. **Caspase 9** leaves the apoptosome and activates the caspase cascade to execute apoptotic death (Figure 24.12).

Proteins from mitochondria other than cytochrome c pass through the permeable mitochondria membrane to initiate cytochrome-c-independent apoptosis under certain conditions (Figure 24.12). The protein **Smac/DIABLO** passes into the cytoplasm and

inhibits **XIAP** (**X**-linked **i**nhibitor of **ap**optosis), a caspase protease inhibitor protein that is normally present to limit basal caspase activity generated in the absence of a pro-apoptotic-activating signal. By inhibiting the inhibitor of caspases (XIAP), Smac/DIABLO activates the caspase cascade. The mitochondrial proteins **AIF** and **endoG** are released from the mitochondria and enter the nucleus to activate DNA degradation in cellular apoptosis.

p53 Induction of Apoptosis

Cells that have damaged DNA are stopped from completing cell division by p53-dependent mechanisms. p53 can act to increase levels of the CKI p21 (p. 1008) to inhibit Cdk-promoted progression through the cell cycle at the G_1-S-phase transition or the G_2-M-phase transition. Increasing p21 stops cell division, giving the cell time to repair DNA. If the DNA damage is irreparable in a reasonable time span, then p53 initiates cellular apoptosis. The elimination of cells with DNA damage prevents the development of tumor cells, and the loss of p53 regulation of cellular apoptosis is common in cancers (p. 1016).

p53 concentration is not determined by the rate of its gene transcription but by the rate of p53 protein degradation. The degradation of p53 is due to Mdm2, an E3 ubiquitin ligase. Mdm2-catalyzed polyubiquitylation promotes p53 degradation by proteasomes. Mdm2 regulation keeps the steady-state concentration of p53 low in the absence of DNA damage or p53-inducing stress such as occurs in telomere shortening and in hypoxia (Figure 24.13). DNA-damage-generated chain breaks activate the chromatin-bound protein kinases ATM, ATR, and DNA-dependent protein kinase (DNA-PK). DNA damage pathways also activate the lysine acetyl-transferase p300/CBP, which acetylates p53 on particular lysine residues. Acetylation acts in conjunction with phosphorylation to prevent ubiquitylation by Mdm2 of p53 and thus increases the p53 concentration. Increases in p53 lead to the transcription of the p21 gene to produce the Cdk inhibitor p21, which stops the cell from proceeding through the G_1 to S and G_2 to M transitions (p. 1004). If the DNA damage is too great to repair, higher concentrations of p53, due to the covalent modifications (phosphorylation and acetylation), result in p53-induced apoptosis by (1) increasing the transcription rates of Bax and several of the facilitator pro-apoptotic proteins such as PUMA and (2) by activation of cytoplasmic Bax causing the cytoplasmic form to associate in the mitochondrial membrane. Both mechanisms increase the concentrations of pro-apoptotic BH proteins in the mitochondrial membrane, resulting in cellular apoptosis.

p53 levels are also regulated by the transcription factors Myc and E2F in the S phase of the cell cycle (p. 1004). While these transcription factors promote the expression of proteins critical for the S phase in cell division, they also initiate cell death when conditions are unfavorable for cell division. This emphasizes that the commitment to enter the S phase is

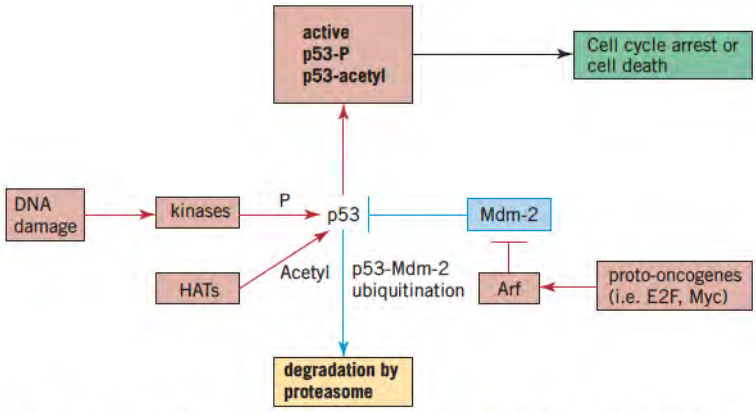


Figure 24.13 Regulation of p53 activity. Under normal conditions p53 concentrations are kept low by Mdm2, which promotes ubiquitination of p53 and its degradation by proteasomes. Phosphorylation and acetylation of appropriate residues by kinase and HAT enzymes prevents degradation of p53 and also increases its transcriptional activity. Certain protooncogene transcription factor proteins, such as E2F and Myc, here act as tumor suppressor proteins. Under favorable conditions E2F and Myc promote the expression of genes required in cell division, but under abnormal conditions increase Arf expression. Arf binds to Mdm2 to prevent its interaction with p53 and thereby increases p53 concentration. The Arf-induced mechanism may be a cellular safety valve to stop a cell from dividing when certain negative signals or conditions arise after the cell has initiated the cell division process. Increased p53 activity leads to cell cycle arrest, or apoptosis. Red lines show steps leading to activation of p53 and blue lines to inactivation of p53.

a critical irreversible decision for the cell that results in either cell division or death, depending on the circumstances. Under conditions unfavorable for cell division in the S phase, the elevated levels of E2F and Myc increase the transcription of the gene for the protein Arf. Arf binds to Mdm2 and prevents its association with p53 (Figure 24.13). Thus Myc and E2F through Arf increase p53 concentration and cellular apoptosis. The E2F- or Myc-initiated cell death pathway is not functional in the p53-deficient cancer cells.

MAPK Pathways Regulate Both Cell Death and Cell Survival

Like Myc and E2F, MAPKs have dual roles in regulating both cell division and cell death. The MAPK pathways are activated by a mitogen growth factor signal and transmit the signal to transcription factors in the nucleus (see Figure 24.9, p. 1010). In the primary signal pathway transmitting the cell division signal, the MAPKKK is Raf, followed by the MAPKK MEK, and the MAPK ERK. In actuality, there are multiple MAPK pathways downstream from Ras, so that Ras is a focal point for a network of pathways (Figure 24.14). Which of these Ras downstream pathways are activated, the level of activation and the duration of the MAPK pathway signal depend on cell type and on cellular context. Although the Ras upstream signal can activate multiple MAPK cascades, other signaling molecules can separately activate individual Ras downstream MAPK pathways. Thus, particular MAPK pathways are activated by UV light, radiation, cytokines, or the stress molecules of inflammation, in the absence of Ras activation. How these MAPK pathways then regulate cell division, differentiation, or cellular apoptosis depends on the integration and interpretation by the cell of the intensity, timing, and duration of all the MAPK pathway signals, some of which may be negative and others positive for a particular process or cellular outcome. Thus, activation of the MAPK **c-Jun N-terminal kinase (JNK)** commonly promotes apoptosis, but more rarely and only in particular cell types, JNK promotes cell survival. JNK promotes cell

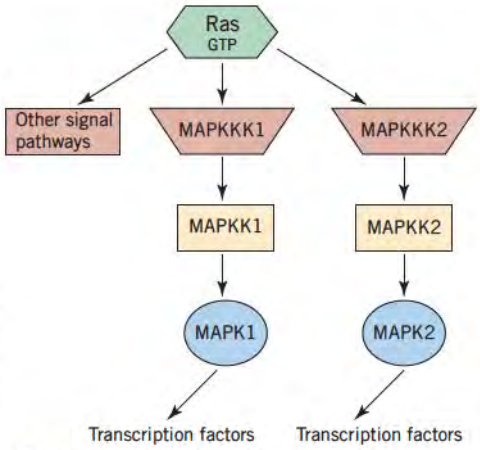

Figure 24.14 Multiple pathways may be regulated by Ras. Ras is the hub of multiple pathways that regulate not only cell division but also cell apoptosis, differentiation, and other important cellular functions.
MAPKKK is a MAPK kinase kinase and MAPKK is a MAPK kinase. MAPKs on activation by a MAPKK can localize to the nucleus to phosphorylate and thereby regulate transcription factors. The kinases may also phosphorylate proteins other than transcription factors. Alternative targets of the kinases include BH domain pro- and anti-apoptotic proteins and p53.

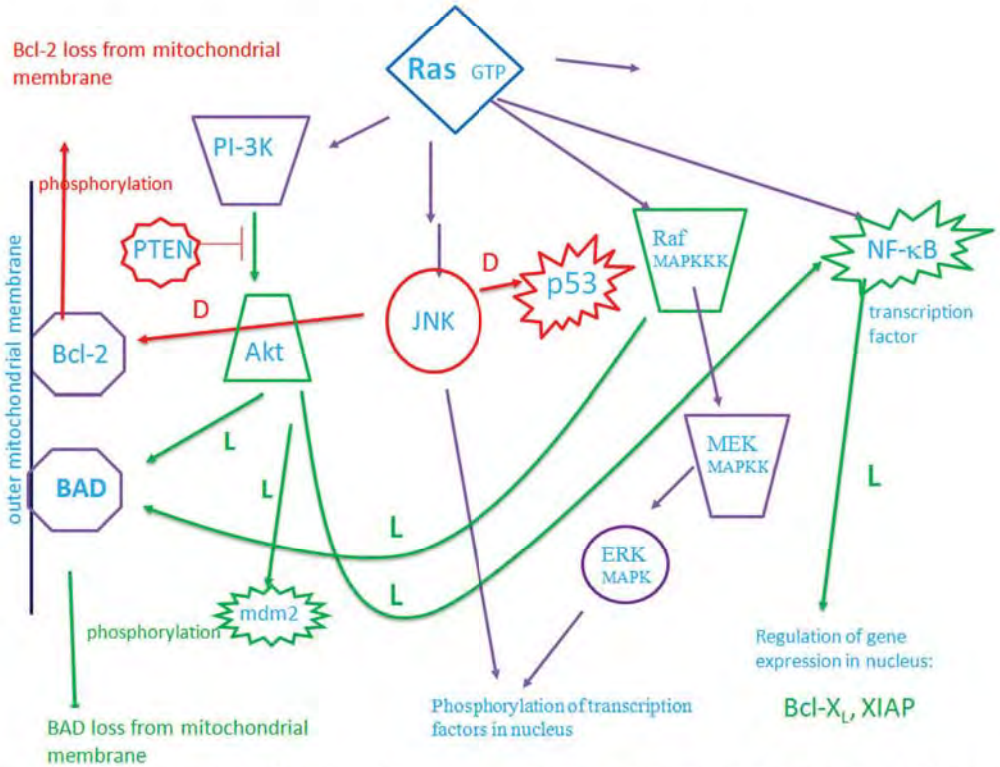

Figure 24.15 Ras downstream effectors regulation of apoptosis. Abbreviations: **L**, Live (pathway promotes cellular survival); **D**, Die (pathway promotes apoptotic cellular death). Raf, MEK, ERK, JNK, and Akt are protein kinases. PI3K is the signaling molecule 1-phosphatidylinositol-3-kinase upstream from Akt. Activation of Akt by PI3K is inhibited by the PTEN phosphatase. By inhibiting the Akt survival pathway, PTEN is an important tumor suppressor activity that is lost in many cancer cells. NF-κB is a transcription fact that promotes cell survival by increasing expression of Bcl-X and XIAP. Under certain conditions and in particular cell types, NF-κB can promote apoptosis rather than survival. Bcl-2 and BAD are phosphorylated by kinases that cause them to leave the mitochondrial membrane. Symbols: *circles*, MAPKs; *trapezoids*, other protein kinases; *stars*, transcription factors and other molecular types such as ubiquitin ligases and phosphatase; and *octagons*, mitochondrial membrane proteins. Red arrows show death pathways and green arrows survival pathways.

death by phosphorylating anti-apoptotic Bcl-2 to promote its dissociation from the mitochondrial membrane (Figure 24.15). JNK can also phosphorylate p53, making it resistant to Mdm-2 ubiquitylation. In contrast, the MAPK ERK, the MAPKKK Raf, and the kinase Akt, promote cell survival by phosphorylating BH domain pro-apoptotic proteins, which decreases their mitochondrial membrane concentrations and activities (Figure 24.15). The kinase Akt also activates the transcription factor NFκB, which increases the transcription of genes that promote cell survival. Thus, different kinases downstream from Ras transmit opposing survival and death signals; the actual outcome of the MAPK signaling depends on the presence or absence of other extracellular signals, the physiological status of the cell, and the cell type.

24.4 • CANCER

Oncogenes and Tumor Suppressor Genes

The promotion of the cell division cycle and resistance to apoptosis are critical properties of a cancer cell. Genes that encode proteins that promote cell division or promote resistance to apoptosis and cell survival are **protooncogenes** (Table 24.2). Activating mutations in a protooncogene convert it to an **oncogene**. Activating mutations can also occur in the protooncogene noncoding regions when the mutation leads to overexpression of the protooncogene product. A single activated allele of a protooncogene is sufficient to promote an oncogenic effect in a cell. Thus activating mutations in protooncogenes are autosomal dominant for promotion of a cancer.

Protooncogene products promote cell division or cell survival and include genes for growth factors, growth factor receptors, Grb-like adaptor molecules, Src-like tyrosine kinases, kinases of MAPK cascades, Cdks, cyclins, CAKs, Cdc25s, and transcription factors such as Jun, Fos, Myc, and E2F that increase expression of cell division cycle proteins. Anti-apoptotic or survival-promoting protooncogenes are Bcl-2 and Mdm-2, whose expressions are elevated in many cancers. The most prominent oncogene in human cancers is activated *ras,* which is found in approximately 30% of human cancers.

In contrast to the effect of oncogenes, products of **tumor suppressor genes** suppress cell division or promote apoptosis. For tumor suppressor activities, the loss of its

TABLE 24.2 • Examples of Protooncogene Products That Regulate Cell Division and Apoptosis

A. Activators of Cell Division	
Growth factors	PDGF (*sisI*), FGF, and other mitogen factors
Growth factor receptors	PDGFR and other growth factor receptors
Tyrosine kinase cytoplasmic proteins	Src family of proteins
Adaptor proteins	Grb-2
Ras GTP-binding proteins	K-Ras, H-Ras, N-Ras
Kinases and kinase cofactors	Cyclins, Cdk, CAK, and MAPKs
Phosphatases	Cdc25
Transcription factors	Myc, Jun, Fos, and E2F
B. Activators of Apoptotic Resistance (Survival)	
BH domain anti-apoptotic proteins	Bcl-2, Bcl-X_L
Promotes degradation of p52	Mdm2
Caspase inhibitors	XIAP
Anti-apoptotic kinases	Akt, Raf (MAPKKK)
Transcription factor	NFκB

activity promotes a cancer. p53, which induces apoptosis with DNA damage, is the most prominent of the tumor suppressor proteins. The p53 gene is inactive or lost in approximately 50% of human cancers and p53 pathways are dysregulated in the great majority of the other 50%. Rb protein is a prominent tumor suppressor, and its loss releases E2F to continuously induce entrance into S phase from G_1. CKIs, such as p21, are tumor suppressors as they act to inhibit cell cycle progression on DNA damage. Pro-apoptotic BH domain proteins such as Bak, Bax, and Bad are tumor suppressors (Clin. Corr. 24.1). Both alleles of a tumor suppressor gene must be inactivated to eliminate their tumor suppressor activity in a cell. In contrast to protooncogenes, inactivating mutations in tumor repressor genes must therefore occur in both alleles for the loss of the suppressor activity. Hence, inactivating mutations in both suppressor gene alleles are most often required for the inactivations to effectively contribute to a cancer phenotype.

Properties of Cancer Cells

Two major properties acquired by a cancer cell have been emphasized, namely, unregulated cell division and resistance to apoptosis. Malignant cancer cells also exhibit cellular **immortality**, the ability to induce angiogenesis, and the ability to metastasize. Genes that

CLINICAL CORRELATION 24.1

Oncogenic DNA Viruses

Oncogenic DNA viruses produce viral proteins that act to promote survival of their host cell during viral replication and to induce the expression of S-phase enzymes from host cell genes to replicate its viral DNA. After viral replication is complete, the virus kills the host cell by lysing the host cell plasma membrane (lytic cycle). In rare instances during a viral infection, the viral genes that promote entry into S phase or promote resistance to apoptosis become incorporated into their host cell DNA by a recombinational event. This recombination must occur in a host cell that also survives the viral infection, in order to be carcinogenic to the host organism. If the viral gene within the host DNA is then overexpressed in an unregulated manner, it is a viral oncogene and can initiate a carcinogenic process leading to a cancer. DNA viruses known to cause cancers are human papillomavirus (HPV), Epstein–Barr virus (EBV), Kaposi's sarcoma-associated herpevirus (KSHV), and Hepatitis B virus (HBV) (see following table).

Papillomavirus is a causative factor in over 95% of uterine cervical cancers. The viral EBV E7 protein binds to the cellular-Rb-binding pocket and displaces E2F from Rb, resulting in the E2F-dependent up-regulation of S-phase proteins. The viral oncoprotein E6 binds to cellular p53 and promotes its degradation, eliminating p53-dependent cell cycle regulatory and apoptotic mechanisms. Two vaccines are currently approved for prevention of infection by strains of papillomavirus commonly associated with female cervical cancers. Other viral oncoproteins similarly interfere with molecules within cellular pathways to promote unregulated cell division, cell survival, and cellular immortality; all properties of cancer cells (see following table).

Human DNA Viruses[1]

DNA Virus Types	*Cancer Types*	*Viral Oncogene Proteins and their Actions*[2]
Human papillomavirus (HPV), certain subtypes	cervical, anogenital cancers	E7 inhibits Rb, E6 inhibits p53
Epstein-Barr virus (EBV)	lymphoproliferative disease, Burkitt lymphoma, nasopharyngeal cancers, Hodgkin lymphoma, non-Hodgkin lymphoma in immunosuppressed patients	LMP-1 increases telomerase, increases c-Myc, decreases Bax, decreases caspases, increases c-IAP, and increases Bcl-2
Kaposi sarcoma-associated herpevirus (KSHV)	Kaposi sarcoma, AIDS related primary effusion lymphoma, multicentric Castleman's disease	LANA-I increases telomerase and decreases p53. EBNA2 increases NFκB activity to promote survival
Hepatitis B virus (HBV)	Hepatocellular carcinoma	HBV X disrupts mitotic spindle, decreases DNA repair, dysregulates centrosome synthesis and function, and decreases p53

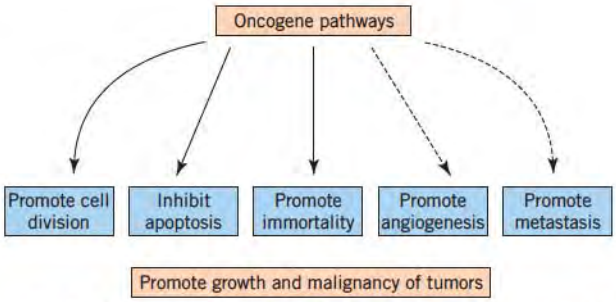

Figure 24.16 Oncogene pathways. Oncogene pathways promote cell division, inhibit apoptosis, promote cellular immortality, promote tumor cell metastasis, and promote angiogenesis. Dotted line indicates involvement of non-transformed neighboring cells to that of the tumor cell.

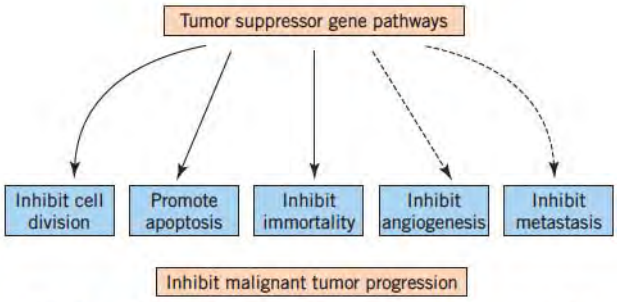

Figure 24.17 Tumor suppressor pathways. Tumor suppressor pathways inhibit cell division, promote apoptosis, inhibit cellular immortality, inhibit cancer cell metastasis, and inhibit angiogenesis. Dotted line indicates involvement of non-transformed neighboring cells to that of the tumor cell.

contribute to these properties may also be considered protooncogenes, and those which inhibit these properties tumor suppressor genes (Figures 24.16 and 24.17).

Cellular **immortality** is the ability of a cell to produce infinite generations of progeny. Mortal cells, such as normal human epithelial cells in cell culture, divide to produce 20–40 generations and then enter senescence. Cells in culture derived from an immortal cell continue to divide indefinitely.

Angiogenesis refers to the growth of new blood vessels. This is required to provide a growing tumor mass with nutrients and oxygen for survival and continued growth. The malignant tumor cell also has the ability to metastasize. The **metastasis** of cancer cells to grow tumors at multiple sites is what usually kills patients with cancer. In blood-borne metastasis, tumor cells dissociate from their contacts with other cells within the tumor mass, pass through the basement membrane and the surrounding extracellular matrix into capillaries, travel through the blood to a target tissue, extravasate out of the blood vessels, and proliferate in the new site to form a secondary tumor.

Immortality of Cancer Cells

Cellular immortality primarily depends on the ability of most cancer cells to maintain expression of their telomerase activity (p. 156). Telomerase maintains the length of the telomer regions at the ends of chromatids. A terminal nucleotide segment is lost each time chromatids are duplicated, and if telomer extension by telomerase is lacking, progeny cells enter senescence to protect against DNA damage. Whereas most normal cells lose telomerase activity with increasing age of the organism and repeated generations of cell division, 90% of cancer cells retain the ability to express telomerase and acquire the ability to indefinitely proliferate.

Metastasis of Cancer Cells

The major barrier to metastasis is the basement membrane surrounding the primary tumor. Tumor cell invasion through the basement membrane can be divided into steps. (1) The tumor cell laminin receptors bind to laminin protein in the basement membrane. (2) Transmission by the activated laminin receptors of intracellular signals leads to the secretion of proteases into the extracellular matrix (ECM). (3) The tumor cell moves through the holes in the basement membrane created by the protease activity. These three steps are reiterated multiple times as the cell invades through the basement membrane. Many tumor cells also express urokinase plasminogen activator receptor (uPAR) in their plasma membranes to bind secreted urokinase plasminogen activator (uPA) and give their outer membrane a plasminogen activator activity.

Step 3 requires the tumor cell to have a **cellular motility**. Development of motility in a normally stationary cell involves biochemical and structural changes in the cellular cytoskeleton and membrane.

In step 2 the tumor or neighboring cells must secrete enzymes that degrade the basement membrane and extracellular matrix to produce a path for tumor cell migration. Basement membrane (or *basal lamina*) consists of an ordered collagen type IV matrix, proteoglycans, the large protein laminin, and other proteins (p. 367). Metastatic tumor

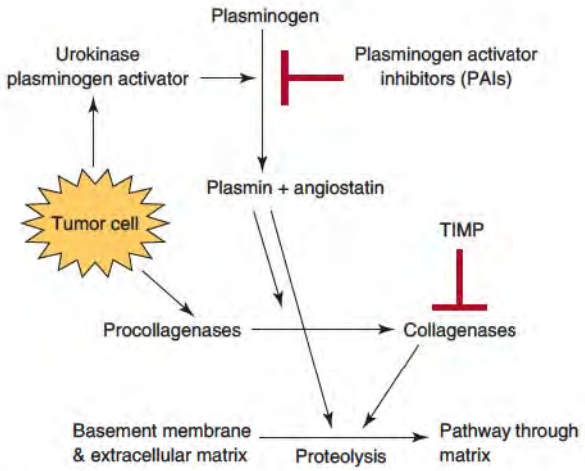

Figure 24.18 Secreted proteases generate pathway through basement membrane in metastasis. Tumor or normal neighboring cells secrete proteases **u**rokinase **p**lasminogen **a**ctivator (uPA) and type IV procollagenases (members of the group of **m**atrix **m**etallo**p**roteinases [MMPs]) and decrease secretions of protease inhibitor proteins TIMP (**t**issue **i**nhibitor of **m**etallo**p**roteinases) and PAIs (**p**lasminogen **a**ctivator **i**nhibitors). uPA cleaves plasminogen into plasmin and angiostatin (an angiogenesis inhibitor, discussed in next section). Plasmin activates procollagenase to collagenase and also acts on other basement membrane proteins to promote their degradation.

cells express an elevated concentration of laminin receptors in their plasma membrane, which on binding to basement membrane laminin (step 1) induces signals that initiate cellular processes related to metastasis. Malignant cells either produce the proteases **urokinase plasminogen activator (uPA)** and **type IV procollagenase** or induce neighboring stroma cells to produce and secrete these proteases. The type IV collagenases are members of the matrix metalloprotease (MMP) class of enzymes containing a catalytically essential Zn metal atom. Two gene products, MMP2 and MMP9, are type IV procollagenases. Activation of **type IV collagenase** from its procollagenase form is catalyzed by uPA-generated **plasmin** results in the type IV collagenase proteolytic cleavage of the type IV collagen in the *basal lamina.* The uPA generates the plasmin protease from plasminogen (Figure 24.18). The **plasminogen** is synthesized in the liver and ubiquitously distributed in extracellular matrix, where it is remains inert till activated by a plasminogen activator (uPA) protein. In addition to plasmin-catalyzed activation of type IV collagenase, the plasmin protease degrades other proteins of the *basal lamina* to allow the tumor cells to invade through the membrane barrier (Figure 24.18).

Under normal conditions, the turnover of extracellular matrix is regulated by the balance of protease and protease inhibitor activities. Two plasminogen activator inhibitors are known, **PAI-1** and **PAI-2** (**p**lasminogen **a**ctivator **i**nhibitor 1 and 2), and several collagenase inhibitors or **TIMPs** (**t**issue **i**nhibitor of **m**etallo**p**roteinases) (Figure 24.18). Cancer cells or neighboring cells increase the protease activity in their extracellular environment by both increasing cellular secretions of proteases and decreasing their synthesis and secretions of the protease inhibitors (the PAIs and TIMPs).

Angiogenesis Induced by Cancer Cells

Angiogenesis is a normal process during embryonic and fetal development and in wound healing and is induced by cancer cells. Tumor cells secrete vascular endothelial cell chemoattractant proteins to promote angiogenesis. Angiogenic proteins are **VEGF** (**v**ascular **e**ndothelial cell **g**rowth **f**actor) and **FGF** (**f**ibroblast **g**rowth **f**actor). Their secretions by tumor cells induce blood vessel endothelial cells to migrate and proliferate to form new blood vessels into the tumor (Figure 24.19). The mechanism of migration and invasion by the endothelial cells mimics the mechanism utilized by tumor cells in metastasis. On receiving the chemoattractant signal, the endothelial cells increase their secretion of plasminogen activator and MMPs, including type IV procollagenase, and decrease their secretion of PAIs and TIMPs. This gives them the ability to pass through basement membrane and ECM.

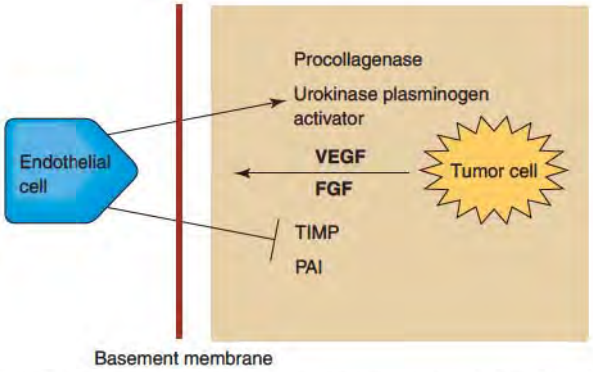

Figure 24.19 Induction of invasion and growth of blood vessel endothelial cells by tumor cell in angiogenesis. Tumor cells secrete endothelial mitogenic and chemotactic factors VEGF and/or FGF, which promote endothelial cells proliferation and migration toward the tumor and formation of blood vessels. In their migration through the extracellular matrix toward the tumor, the endothelial cells use a similar mechanism to that of the tumor cell in metastasis. Endothelial cells increase their secretion of uPA and procollagenases and decrease their secretion of proteases inhibitors PAI and TIMP.

The plasminogen activator uPA cleaves a peptide bond that divides the plasminogen molecule into two halves. The C-terminal segment has the plasmin protease activity, which facilitates the migration of vascular endothelial cells toward the tumor. The N-terminal sequence of plasminogen, produced by plasminogen activator proteolysis, surprisingly has an anti-angiogenic activity and is called **angiostatin**. The angiostatin generated by plasminogen cleavage at the primary tumor site has insufficient activity to inhibit angiogenesis at the primary site where the pro-angiogenic processes predominate. However, the angiostatin has a long lifetime and travels through blood to distant sites to inhibit angiogenesis at secondary metastatic sites. This anti-angiogenic activity is overcome when and if the metastatic tumors develop, but initially this anti-angiogenic activity slows the development of the metastatic tumors at the secondary sites. Other anti-angiogenic proteins are also generated by proteolysis of ECM proteins near the primary tumor. One of these is **endostatin**, which is produced from the C-terminal end of type XVIII collagen. Endostatin, angiostatin, and other anti-angiogenic proteins from extracellular matrix introduced at high concentrations into mice have been shown to cure cancers in mice. These observations have stimulated the investigation of anti-angiogenic drugs for treatment of human cancers.

Multiple Mutations Are Required to Form a Cancer

A single mutation is not sufficient to transform a normal cell into a cancer cell unless it occurs on a background of previous oncogenic mutations. The evidence for a requirement of multiple mutations comes from many observations. A cancer typically forms many years after an initial mutagenic event, indicating that time is required for the accumulation of additional multiple mutations. The increasing incidence of cancer with age also shows the need to accumulate mutations over time in carcinogenesis. More direct is the documentation of mutations in the progressive stages in the development of a cancer. Thus in cervical cancer, a region of the cervix initially shows epithelial cells with a higher-than-normal proliferative rate. These abnormal cells may proceed to form a benign adenoma. A minority of the adenomas progress through additional stages that form a malignant tumor. Analysis of cells from each of the progressive stages shows the acquisition of new activating mutations in protooncogenes and inactivations of tumor suppressor genes that in combination generate the malignant cancer cell.

Experiments with primary human epithelial cells show that a minimum of four changes will generate a transformed epithelial cell. In these experiments, different oncogenes and inhibitors of tumor suppressor gene products were introduced by transfecting normal epithelial cells with gene expression plasmids. A minimum of three particular genes that affect four biochemical activities could transform the cells. Required for

CLINICAL CORRELATION 24.2

Molecularly Targeted Anticancer Drug

Imatinib (formerly known as STI-571 and marketed as Gleevec in the United States) is the first successful drug targeted to a specific oncogene product. It inhibits the tyrosine kinase activity of the chimeric Bcr-Abl tyrosine kinase protein expressed in chronic myelogenous leukemia (CML) and the c-Kit growth factor receptor overexpressed in many gastrointestinal stromal tumors. It has been approved by the U.S. Food and Drug Administration for treatment of these cancers. Tyrosine kinases transfer phosphate from ATP to protein substrates in growth factor signaling pathways. Imatinib binds to the ATP binding site of the Abl and Kit tyrosine kinases, inhibiting the normal binding of the ATP substrate (see figure).

CML arises by a translocation between chromosome 9 and 22 in a pluripotent hematopoietic stem cell to produce aberrant chromosomes in which a part of chromosome 22 is translocated to chromosome 9 and a part of 9 to 22. The smaller of the two abnormal chromosomes, $22q^-$, is easily recognizable in leukemia cells and is called the Philadelphia chromosome. At the translocation site, the reading frame of the 5′ end of the Bcr gene is fused with the 3′ sequences of the Abl gene to produce the chimeric protein Bcr-Abl. Abl is a Src-like tyrosine kinase (p. 1009). The gene fusion results in a highly expressed and active Abl tyrosine kinase activity, which is critical for initiating and maintaining the leukemia.

The progression of CML is divided into stages; the initial chronic stage characterized by the expansion of terminally differentiated neutrophils typically spans a 5-year period. The later blastic stage is characterized by excessive numbers of undifferentiated lymphoid progenitor cells and carries a poor prognosis. The Bcr-Abl oncogene is expressed at all stages, but cells in the blast stage contain additional molecular and cytogenetic changes. The initial chronic stage has the highest response in treatment with imatinib (complete or nearly complete cytogenetic remissions of Philadelphia chromosome containing cells in 80%–90% of patients). Blast stage CML often shows partial remission (cytogenetic response rate of 16%–24% reported). It is hoped that better responses in blastic-phase disease will be achieved in combinations with other drugs. There are reports of the development of resistance to imatinib in the blastic stage by the appearance of point mutations in Bcr-Abl that decrease its affinity for imatinib. Other mutations can lead to imatinib resistance by causing an amplified expression of the Bcr-Abl fusion protein.

transformation were a gene that overexpressed telomerase, a *ras* oncogene, and the gene for the SV40 virus T antigen protein. The T antigen protein binds and inhibits both Rb and p53 in the infected epithelial cells. Rb suppression, p53 suppression, Ras activation, and telomerase overexpression were all essential for cellular transformation (Clin. Corr. 24.2.).

CLINICAL CORRELATION 24.3

Environmental Cause of Human Cancers

Environmental and cultural factors are the predominant causes of human cancer. If these factors can be regulated, the incidence of cancers may be reduced by greater than 75%. Cigarette smoking is responsible for approximately 30% of U.S. cancer deaths. It is estimated that there are 1,100,000 worldwide lung cancer deaths per year of which 85% are caused by tobacco. While cigarette consumption rates have recently begun to decrease, the time lag in cancer development will result in dramatic increases in smoking-induced cancers over the next two or three decades to 2 million per annum.

It is estimated that diet can prevent the development of approximately 30% of U.S. cancers (estimates vary from 10% to 70%). These numbers are primarily based on epidemiological data of the incidence of cancer types in different geographical locations, cultures, and environments (see table). On migration from one culture or location to another, the incidence of a cancer type often approaches that of the population in the new culture as the individuals or their offspring assimilate. Also changes in diet or lifestyle over time within a country show the importance of these factors in the incidence of cancers.

The quarter of the U.S. population with the highest dietary fruit and vegetable content has a 30% to 40% lower incidence for many cancer types. However, the constituents of these foods that inhibit the formation of these cancers are not yet clear. Inadequate folic acid levels in the U.S. diet have been implicated as a risk factor for colon and breast cancers. Folic acid intake may be particularly critical in individuals with a polymorphism in their gene for methylenetetrahydrofolate reductase, an enzyme involved in folic acid metabolism, which results in decreased activity in the enzyme. Folate deficiency causes excessive incorporation of uracil into DNA and chromosome breaks. Folate deficiency is common in alcoholics and may be the reason for an increase in the incidence of certain cancers with alcohol. Preadolescent diet and lifestyle affect the onset of menarche, and the early onset of menarche and length of time between menarche and menopause are associated with increased risk of breast cancer in women. Obesity is inversely correlated with risk of breast cancer in premenopausal women and positively correlated in postmenopausal. High animal fat in the diet has been associated with increased risk of colon cancer, but the data are inconsistent. Rather then total animal fat in the diet, the data may suggest that it is the ratio of polyunsaturated to saturated fat that correlates with colorectal cancer risk. Colon cancer incidence has also been inversely correlated with lack of activity or exercise. Environmental and dietary studies are difficult as large population must be studied over a generation of time, and multiple variables must be controlled. However, advances in our knowledge and control of these dietary and environmental factors have an enormous potential for decreasing the incidence of cancer.

The effect of environment and lifestyle on cancer incidence is interpreted through a genetic background. An individual's susceptibility to environmental factors is influenced by her or his genetic polymorphisms and acquired mutations that control metabolic, regulatory, and hormonal pathways.

Variation in the Incidence of Cancer Type in a Two Location Comparison[a]

	Location Comparison	*Incidence in Location 1*	*Incidence in Location 2*	*Fold Difference in incidence*
Lung	New Orleans (blacks)–Madras (India)	110	5.8	19
Breast	Hawaii (Hawaiians)–Israel (non-Jews)	94	14	7
Prostate	Atlanta (blacks)–China (Tianjin)	91	1.3	70
Uterine cervix	Brazil (Racife)–Israel (non-Jews)	83	3.0	18
Liver	China (Shanghai)–Canada (Nova Scotia)	34	0.7	49
Colon	United States (Connecticut, whites)–India (Madras)	34	1.8	19
Melanoma	Australia (Queensland)–Japan (Osaka)	31	0.2	155

Genetic and Biochemical Heterogeneity of Cancers

Cells in a tumor contain mutations in multiple protooncogenes and tumor suppressor genes. Although specific oncogenes and inactivated tumor suppressor genes are commonly present in all the cells of a tumor, other mutations occur that are different among the cells within a tumor mass. In addition, epigenetic marks may differ in the cells within the tumor, resulting in differences in protooncogene and tumor suppressor gene expressions among the population of tumor cells. This heterogeneity is demonstrated experimentally by showing that cells from different regions of the same tumor have differences in metastatic ability. The heterogeneity was generated in the cells over time with successive cell divisions. However, genetic markers can trace each of the cells in a tumor to a single parental cell, in which the initial mutational events occurred that led to a cancer cell. Thus while the tumor cell population is genetically and epigenetically heterogenic, all the cells within a tumor are derived from a single precursor cell.

Mutagens and Promoters Cause Cancers

Most cancers are caused by environmental factors (Clin. Corr. 24.3), which act as mutagens or as promoters in carcinogenesis. A promoter acts as a growth factor after the mutagenic event to increase the number of cells containing an initial mutagenic defect. It expands clones of mutant cells to give a higher probability of additional mutations in these cells. Natural factors such as estrogen act as tumor promoters on epithelial breast and ovarian cells, and women with high levels of estrogen over time have a higher incidence of breast and ovarian cancers. Diet can inhibit carcinogenesis by providing components that inhibit mutagens and tumor promoters. Alternatively factors within the diet can act as tumor repressors by providing cofactors for antioxidant enzymes and enzymes involved in DNA repair (Clin. Corr. 24.3).

Biochemical Analysis of Individual Cancers

Each cancer has a different pattern of activated oncogenes and inactivated tumor suppressor genes (Figure 24.20). Although certain gene mutations are commonly found in particular cancer types, individual cancers have genetic differences from other cancers even within the same cancer type. Because of the differences in activated oncogenes and inactivated tumor suppressor genes in individual cancers, the biochemical characterization of an individual cancer may be critical for its accurate prognosis and efficacious treatment. Gene microarray and proteomic techniques can precisely determine the abnormal biochemical patterns due to the oncogene activations and tumor suppressor losses within a particular cancer (Figure 24.21). Future pharmacological treatments will be based on the exact molecular characterization of a cancer to which will be designed selective treatments against the particular biochemical activities that sustain the cancer.

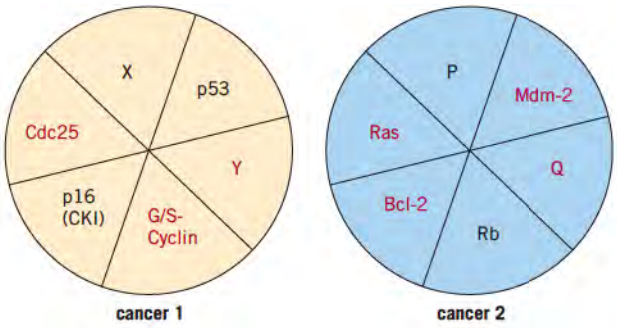

Figure 24.20 Each cancer has a different pattern of activated protooncogenes and deactivated tumor suppressor genes. Oncogenes are colored red and deactivated tumor suppressor genes black. X, Y, P, and Q are unidentified oncogenes or deactivated tumor repressor genes in the particular cancer.

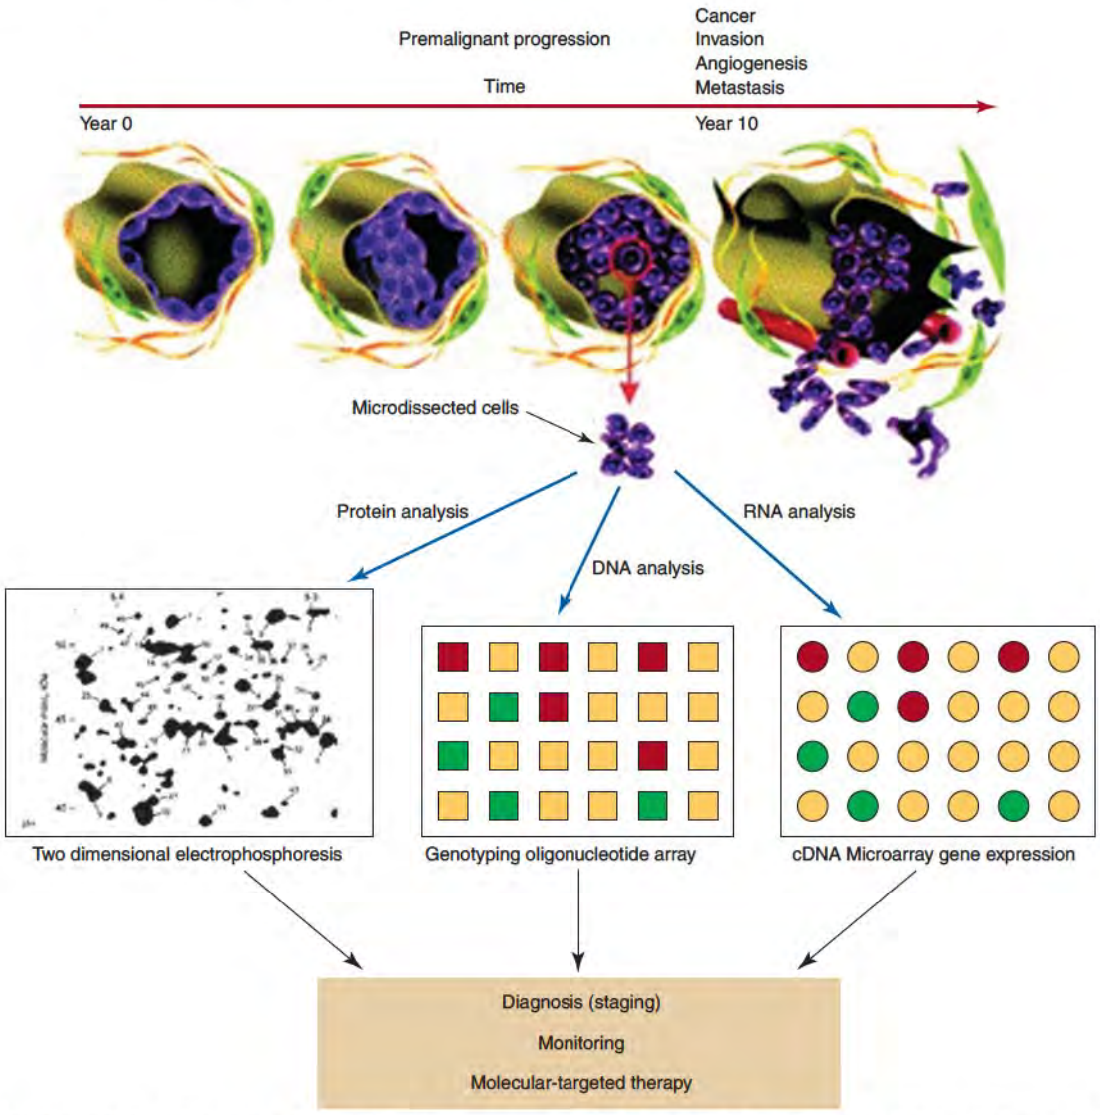

Figure 24.21 Molecular analysis of laser microdissected cells characterizes the specific tumor. Different stages in development of a malignant cancer may be analyzed for their genetic and epigenetic expression patterns with microdissected cells extracted for molecular analysis (top). Molecular analyses are by two-dimensional gel electrophoresis to determine expressed proteins (p. 124), genomic analysis, and cDNA analysis for expressed mRNAs. Staging, monitoring, and treatment of cancer are then based on biochemical and genetic analysis of the particular cancer. Biochemical characterization of an individual cancer will lead to a personalized treatment specific to the cancer.

Key Terms

Cell Cycle
G1, G2, S, and M phases
quiescent
senescent
CDC25 phosphatase
Cdk inhibitor
Cdk-activating kinase
cyclin
cyclin-dependent kinase
Wee1 kinase
Anaphase-promoting complex
E2F
SCF complex
p21
p53
retinoblastoma sensitivity protein

Growth Factors
autocrine and paracrine mechanisms
growth factor receptors
tyrosine kinase
Grb2
GEF^{Ras}
Ras
GAP^{Ras}
MAPK cascade
Jun/Fos

Apoptosis
caspase cascade
cytochrome c
extrinsic (death receptor) pathway
intrinsic (mitochondrial) pathway
Bax, Bak
Bcl-2, Bcl-X_L
apoptosome
DISC
inhibitor of apoptosis
Smac/DIABLO
Mdm-2
Arf

Cancer
oncogene
protooncogene
tumor suppressor gene
angiogenesis
immortality
metastasis
matrix metalloproteinase
type IV collagenase
urokinase plasminogen activator
VEGF
carcinogenesis

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. In the cell cycle,
   - **A.** M phase is both the most complex and the longest phase.
   - **B.** there is a G_0 phase in equilibrium with the G_1 phase.
   - **C.** quiescent cells cannot be induced to reenter the cell cycle.
   - **D.** microtubule spindles form during the S phase.
   - **E.** the order of phases is G_1, G_2, S, and M.

2. Cyclin-dependent kinases (Cdks)
   - **A.** occur only in the M phase.
   - **B.** are always inactivated by phosphorylation.
   - **C.** typically phosphorylate proteins on tyrosine residues.
   - **D.** in addition to binding cyclin, require other modifications for activity.
   - **E.** that phosphorylate Rb (retinoblastoma sensitivity) protein inhibit the synthesis of S-phase proteins.

3. Elements of growth factor pathway regulation of the cell cycle include all of the following except
   - **A.** dimerization or polymerization of receptor proteins in the plasma membrane.
   - **B.** binding of ATP to a tyrosine kinase domain of growth factor receptor proteins.
   - **C.** nonspecific binding of SH2 domains to any phosphorylated tyrosine.
   - **D.** conformational changes of proteins as part of signal transmission.
   - **E.** location of the growth factor receptor proteins in the plasma membrane.

4. Ras protein of the signal pathway
   - **A.** is active in the GDP-Ras conformation.
   - **B.** transmits a signal by initiating a kinase cascade.
   - **C.** from a mutated gene in many cancers that has inactivated GTPase activity so it inhibits the downstream signal to divide.
   - **D.** is formed from an oncogene.
   - **E.** becomes inactive as a signaling protein by phosphorylating transcription factors.

5. Apoptotic death of a cell may include all of the following except
   - **A.** lysis of the cell membrane with inflammation.
   - **B.** activation of enzymes called caspases.
   - **C.** phagocytosis.
   - **D.** binding of a ligand in the extracellular environment to a plasma membrane receptor.
   - **E.** transfer of toxic molecules from the mitochondria to cytoplasm through protein-induced outer membrane permeabilization.

6. Malignant cancer cells have all of the following properties except
   - **A.** unregulated cell division.
   - **B.** inhibition of angiogenesis.
   - **C.** resistance to apoptosis.
   - **D.** cellular immortality.
   - **E.** ability to metastasize.

7. The property of cellular immortality refers to a cell's ability to
   - **A.** grow new blood vessels.
   - **B.** invade through the basement membrane of its tissue.
   - **C.** resist apoptosis.
   - **D.** continue to divide without limit to the number of cell generations.
   - **E.** grow tumors at multiple sites.

8. Telomerase
   - **A.** activity generally increases as an individual ages.
   - **B.** catalyzes the resynthesis of telomer regions.
   - **C.** activity is high during all stages of the carcinogenesis process.
   - **D.** plays a role in apoptosis but not immortality.
   - **E.** when present at a high level, leads to cell senescence.

Questions 9 and 10. Human papillomavirus (HPV) is a causative factor in over 95% of cervical cancers. Other viruses such as Epstein–Barr, Kaposi's sarcoma-associated herpes virus, and hepatitis B virus also are known to cause cancer. For this to happen, viral genes that promote entry into S phase or that promote resistance to apoptosis must become incorporated into the host cell DNA in a host cell that also survives the viral infection. If the viral gene within the host DNA is then overexpressed in an unregulated manner, it is a viral oncogene.

9. The Epstein–Barr protein binds to the cellular Rb-binding pocket and displaces E2F from Rb. The effect would be to
- **A.** require that Rb be phosphorylated.
- **B.** stall the cell cycle in the G_1 phase.
- **C.** increase the transcription of gene products for S-phase proteins.
- **D.** inhibit the action of cyclin-dependent kinases (Cdks).
- **E.** inhibit apoptosis.

10. A viral protein could bind to cellular P53 and promote its degradation. P53, which is an inducer of apoptosis,
- **A.** is activated by kinases located in chromatin.
- **B.** increases the transcription of several pro-apoptotic genes for Bcl-2 proteins.
- **C.** concentration is normally low because it is subject to ubiquitination.
- **D.** concentration may be increased by acetylation.
- **E.** all of the above.

Questions 11 and 12: Environmental and cultural factors are the predominant causes of human cancer. Cancers from environmental damage may not appear until years after exposure to carcinogens (for example, lung cancer from smoking). It takes mutations of numerous protooncogenes and tumor suppressor genes to convert a protooncogene into an oncogene or to render a tumor suppressor gene less active.

11. Protooncogenes
- **A.** produce protein products that promote cell division.
- **B.** produce protein products that promote apoptosis.
- **C.** are converted to oncogenes by a mutation that inhibits their expression.
- **D.** require both alleles to be mutated to show a pro-proliferative effect.
- **E.** are constitutively activated.

12. Tumor suppressor genes
- **A.** have the same effect as protooncogenes.
- **B.** contribute to cancer if only one allele is inactivated by mutation.
- **C.** produce protein products that promote apoptosis.
- **D.** produce products that promote cancer.
- **E.** all of the above.

Problems

13. What is the role of type IV collagenase in metastasis of a tumor cell?

14. What is the difference between the two pathways that activate the caspase cascade?

Answers

1. B A: M phase is the shortest although it is highly complex. C: Senescent cells cannot be induced to reenter the cell cycle. D: This occurs in the M phase. E: G_1 and G_2 separate the M and S phases.

2. D For example, M-Cdk-cyclin heterodimer must be correctly phosphorylated. A: Other phases also have Cdks. B: There are both activation and inhibitory phosphorylation sites. C: Serine and threonine residues are the phosphorylation sites. E: Phosphorylation of Rb causes release of E2F and thus promotes synthesis.

3. C Each SH2 domain has a secondary specificity that differentiates between phosphorylated tyrosines. A: This seems to be critical to transmission of the signal. B: Many receptors operate this way. Those that don't cause dimerization by binding a protein with a tyrosine kinase domain. D: This is a common occurrence.

4. B GTP-Ras activates MAPKKK, which phosphorylates the next kinase, and so on. A: GTP-Ras is the active form. C: Inhibiting GTPase activity prevents the conversion to GDP-Ras so the signal remains active. D: The Ras gene is a protooncogene and requires an activating mutation to become an oncogene. E: The transcription factors are at the end of the chain so don't react directly with Ras.

5. A This occurs in necrotic cell death. B: These proteases degrade cell protein. C: This happens to the remainder of the cell after multiple digestions. D: This is the extrinsic or death receptor pathway. E: This is the intrinsic pathway with pro-apoptotic BH domain proteins acting to permeabilize the outer mitochondrial membrane.

6. B Tumor cells must have the ability to induce the growth of blood vessels in order to grow. A, C, D, and E are all properties that allow tumors to grow.

7. D This may occur because such cells have high levels of telomerase. A: This allows a cancer cell to grow a tumor mass. B and E: These are part of metastasis. C: Apoptosis is a separate property from immortality.

8. B A terminal nucleotide segment is lost each time chromatids are duplicated in cell division and must be replaced. A, and E: Telomerase decreases on cell aging, leading to senescence. C: There is believed to be a low level at early and intermediate stages, leading to chromosomal instability and mutations. D: This is believed to be a major factor leading to immortality.

9. C By removing the normal control of releasing and sequestering E2F, the virus is promoting the entry into the S phase. A: This is the usual mechanism for releasing E2F which is bypassed. B: This promotes entry into S phase. D: These are the enzymes that usually phosphorylate Rb. E: This is not involved.

10. E A: DNA chain breaks and changes in chromatin structure initiate this. B: There is also a nontranscriptional method; both lead to the intrinsic pathway. C: Binding Mdm-2 catalyzes polyubiquitination. D: Acetylation prevents binding of Mdm-2.

11. A This is part of the definition. B: The products promote resistance to apoptosis. C: Oncogenes result in higher gene activity. D: One is sufficient. E. This occurs on mutation.

12. C Also products that suppress the cell cycle. A: These effects are opposite to those of protooncogenes. B: Both alleles need to be inactivated. D: Their normal products promote apoptosis which is opposite to what cancer cells require.

13. Type IV collagen is part of the basement membrane. Tumor cells typically promote the secretion of a plasminogen activator and a type IV procollagenase. This leads to formation of plasmin, which cleaves proteins of the extracellular matrix and activates procollagenases to collagenases. Type IV collagen is degraded. These two activities acting together provide a path through which the tumor cell passes to the blood.

14. The death receptor (extrinsic) pathway is initiated by binding of a death ligand in the extracellular environment to its plasma membrane receptor in the target cell. The mitochondrial (intrinsic) pathway occurs by BH domain proteins in the outer mitochondrial membrane altering the membrane to allow cytochrome c to pass. In both cases, after the initial stages, protein aggregates form; this ultimately leads to activation of a procaspase, which initiates the caspase cascade.

Key Concepts

- Dietary proteins are polymers that are broken down to amino acids or di- and tripeptides for absorption. Dietary carbohydrates consist mostly of dimers and polymers that need to be digested to monosaccharides for absorption. Dietary fats consist mainly of fatty acids esterified to glycerol (triacylglycerols) that require biological detergents (bile acids) for their dispersion and digestion to monoglycerides and free fatty acids.
- Digestion of nutrients requires a range of conditions, some very harsh (e.g., pH < 1), and large amounts of an array of digestive enzymes that sequentially degrade nutrient molecules to smaller pieces. Soluble digestive enzymes are secreted mostly as inactive precursors by salivary glands, the stomach, and the pancreas.
- Terminal digestion of peptides and carbohydrates to absorbable molecules is accomplished by ectoenzymes on the brush border surface of enterocytes.
- Monosaccharides, free amino acids, and di- and tripeptides are absorbed predominantly by co-transport with sodium, a positive charge, or a proton. Free fatty acids are also absorbed actively.
- Active electrolyte secretion, electrolyte absorption, and secondary active transport are all powered by Na^+/K^+-exchanging ATPase in the contraluminal plasma region of epithelial cells.
- Absorbed lipids are resynthesized within cells to triacylglycerols and released into lymph as small globules consisting of neutral lipids, phospholipids, and specific lipoproteins.

- Bile acids are biological detergents necessary to facilitate lipid digestion and absorption by dispersion of lipids into micelles and increasing transport of free fatty acids and monoglycerides through an unstirred layer over the lining enterocytes. Bile acids synthesized by the liver are secreted as conjugates with taurine and glycine.
- Bile acids are mostly retained by the body through an enterohepatic cycle of active reabsorption in the ileum, transport through blood to the liver, and resecretion by the liver.

25.1 • INTRODUCTION

Nutrient Types

Three types of biochemicals serve as nutrients for humans: proteins, carbohydrates, and fats. Many different foods can satisfy the nutritional needs of humans, even though they differ in the ratio of different types of nutrients and of digestible-to-nondigestible material. Unprocessed plant products are especially rich in fibrous material that cannot be digested by human enzymes or easily degraded by intestinal bacteria. These fibers are mostly polymers of carbohydrates, such as cellulose (β-1,4-glucan) or pectins (mixtures of methyl esters of polygalacturonic acid, polygalactose, and polyarabinose). High-fiber diets enjoy a certain popularity nowadays because they add bulk to stool and may have a preventive effect on development of colonic cancer.

Table 25.1 describes average contributions of different food classes to the diet of North Americans. Intake by individuals may substantially deviate from the average, as food consumption depends mainly on availability and individual tastes. The ability to utilize a wide variety of food reflects great adaptability and digestive reserve capacity of the gastrointestinal tract.

Knowledge of the nature of proteins and carbohydrates in the diet is important from a clinical point of view. Certain proteins and carbohydrates, although good nutrients for most humans, cannot be properly digested by some individuals and produce gastrointestinal disease. In this case, omission of the offending food constituent eliminates the problems. For example, many humans, particularly non-Caucasians, lose the ability to digest the common milk disaccharide lactose after childhood and ingested milk produces diarrhea, gas, and bloating (lactose intolerance). Another common example is provided by gluten, one of the protein fractions of wheat. One of its digestion products produces an immune and inflammatory response in some people, which can lead to reduced intestinal mucosal surface, reduced digestive/absorptive capacity, and diarrhea (gluten enteropathy or celiac disease).

Several Gastrointestinal Organs Contribute to Food Digestion

Secretion of digestive fluids and digestion of food were among the earliest biochemical events to be investigated at the beginning of the era of modern science. The discovery of gastric HCl production goes back to the American physician William Beaumont (1785–1853). In 1822 he treated a patient with a stomach wound. The patient recovered from the wound, but retained a gastric fistula (abnormal opening through the skin) so that Beaumont could obtain and study gastric juice during and after meals. Chemical analysis revealed, to the surprise of chemists and biologists, the presence of the inorganic acid HCl. This discovery established the principle of unique secretions by specialized glands. Soon thereafter, in 1836, Theodor Schwann, a German anatomist and physiologist (1810–1882), noticed that gastric juice would degrade albumen in the presence of dilute acid. He recognized that this

TABLE 25.1 • Contribution of Major Food Groups to Daily Nutrient Supplies in the United States

Type of Nutrient	*Total Daily Consumption (g)*	*Dairy Products, Except Butter (%)*	*Meat, Poultry, Fish (%)*	*Eggs (%)*	*Fruits, Nuts, Vegetables (%)*	*Flour, Cereal (%)*	*Sugar, Sweeteners (%)*	*Fats Oils (%)*
Protein	100	22	42	6	12	18	0	0
Carbohydrate	381	7	0.1	0.1	19	36	37	0
Fat	155	13	35	3	4	1	0	42

process involved a new chemical principle, namely, enzymatic digestion, and coined the word *pepsin* from the Greek *pepsis,* meaning "digestion."

The bulk of ingested nutrients consists of large polymers that have to be broken down to smaller units, mostly monomers, before they can be absorbed and made available to all cells of the body. The complete process from food intake to absorption of nutrients into the blood includes (Figure 25.1) (1) mechanical homogenization of food and mixing of

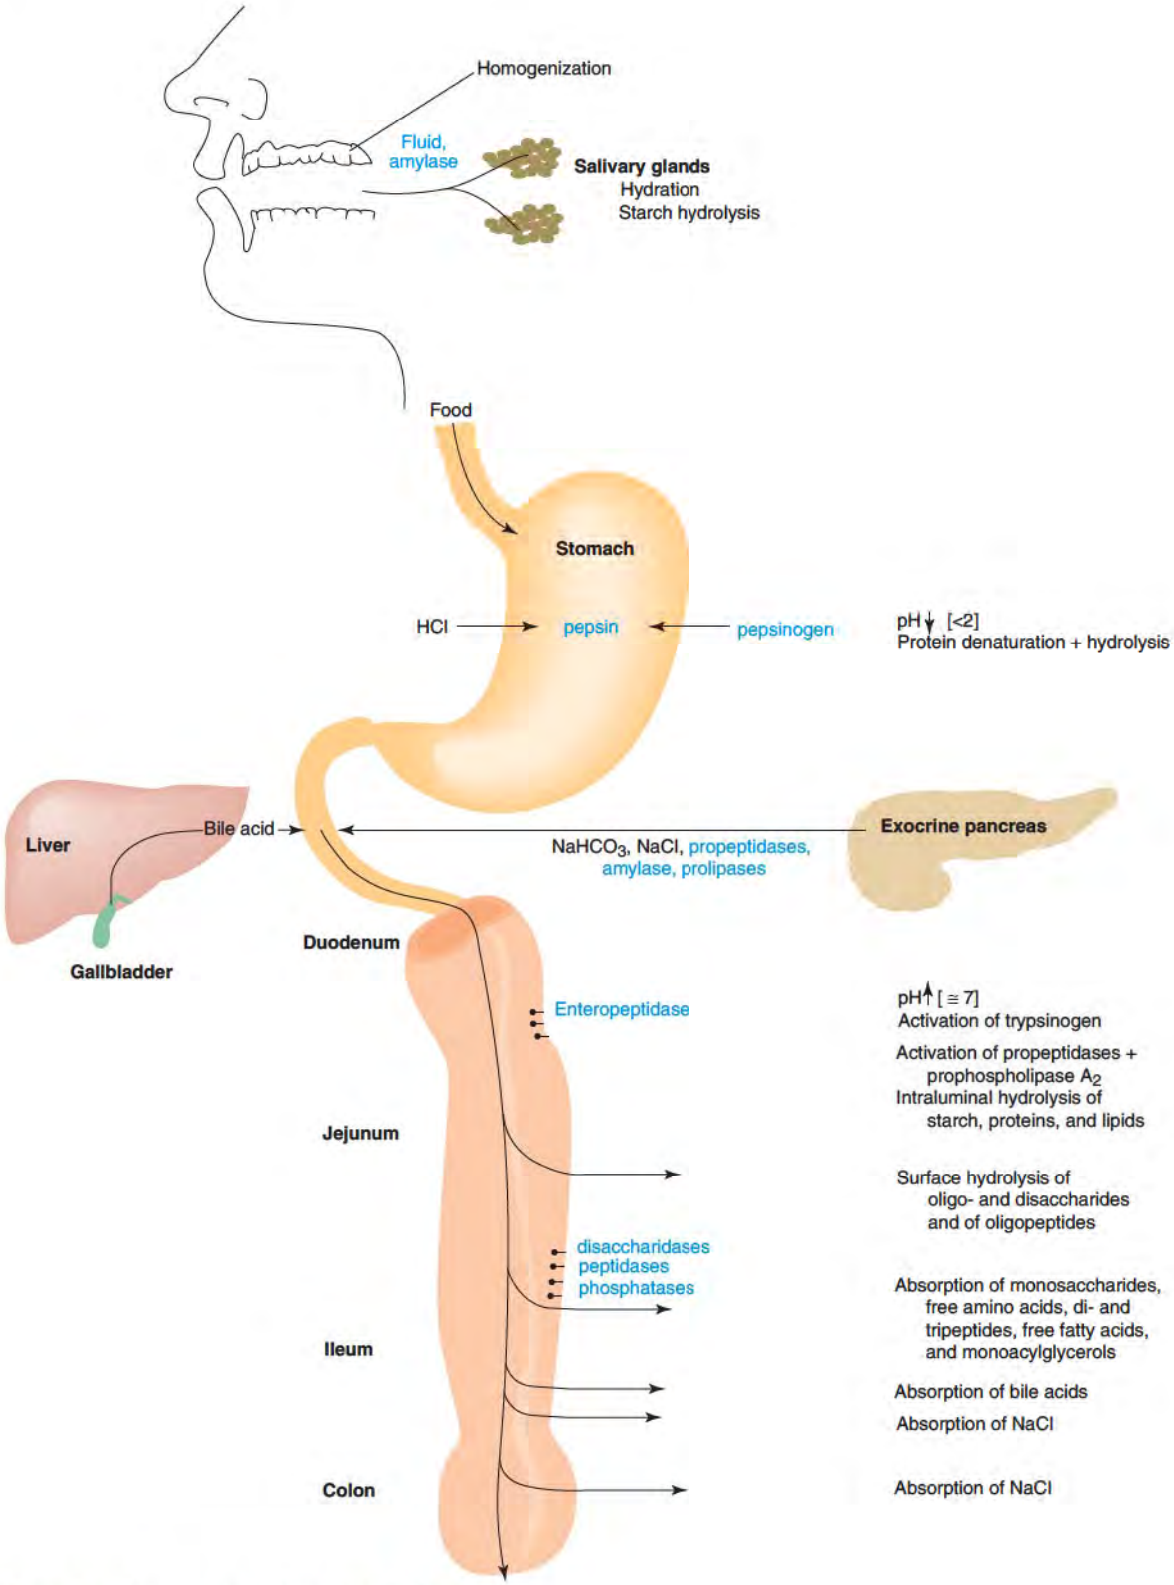

Figure 25.1 Gastrointestinal organs and their functions.

TABLE 25.2 • Functions of Specialized Glands and Tissues in Digestion and Absorption

Organ	*Major Function in Digestion and Absorption*
Salivary glands	Elaboration of fluid and digestive enzymes
Stomach	Elaboration of HCl and digestive enzymes
Pancreas	Elaboration of $NaHCO_3$ and enzymes for intraluminal digestion
Liver	Elaboration of bile acids
Gallbladder	Storage and concentration of bile
Small intestine	Terminal digestion of food, absorption of nutrients and electrolytes
Large intestine	Absorption of electrolytes

ingested solids with fluids secreted by glands of the gastrointestinal tract; (2) secretion of digestive enzymes that hydrolyze macromolecules to oligomers, dimers, or monomers; (3) secretion of electrolytes, acid, or base to provide an appropriate environment for optimal enzymatic digestion; (4) secretion of bile acids as detergents to solubilize lipids and facilitate their absorption; (5) hydrolysis of nutrient oligomers and dimers by enzymes on the intestinal surface; and (6) absorption of nutrient molecules and electrolytes from the intestinal lumen by intestinal epithelial cells. To accomplish these functions, the gastrointestinal tract contains specialized glands and surface epithelia (Table 25.2).

The pancreas and small intestine are essential for digestion and absorption of all basic nutrients. Fortunately, both organs have large reserve capacities. Thus, maldigestion due to pancreatic failure generally becomes a clinical problem only when the pancreatic secretion rate of digestive enzymes drops to below 1/10th of the normal rate. Secretion of bile by liver is important for efficient lipid digestion and absorption, which depend on bile acids. In contrast, gastric digestion of food is nonessential for adequate nutrition, and loss of this function can be compensated for by the pancreas and the small intestine. Yet normal gastric digestion greatly increases the smoothness and efficiency of the total digestive process. The stomach aids in the digestion through its reservoir function, its churning ability, and initiation of protein and lipid hydrolysis, which, although minor, is important for stimulation of pancreatic and gallbladder output. Peptides, amino acids, and fatty acids liberated in the stomach stimulate the coordinated release of pancreatic juice and bile into the lumen of the small intestine, thereby ensuring efficient digestion of food.

25.2 • GENERAL CONSIDERATIONS

Different Sites of Digestion

The first steps in the breakdown of food are catalyzed by soluble enzymes and occur within the lumen of stomach and small intestine. Digestive enzymes are secreted by the salivary glands, stomach, and pancreas; the pancreas makes the largest and essential contributions. Secreted enzymes amount to at least 30 g of protein per day in a healthy adult. Pancreatic enzymes together with bile are poured into the lumen of the second (descending) part of the duodenum, so that the bulk of the intraluminal digestion occurs distal to this site. Whereas lipid digestion completely relies on soluble lipases, a substantial portion of carbohydrates and peptides remains as dimers and oligomers even after exhaustive luminal digestion and depends for further breakdown on the digestive enzymes of intestinal epithelial cells (enterocytes).

The luminal plasma membrane of enterocytes is enlarged by a regular array of microvilli that look like a brush and have led to its name of brush border. This brush border membrane is covered on its outer surface with many di- and oligosaccharidases, amino- and dipeptidases, and esterases (Table 25.3). Many of these enzymes protrude up to 100 Å into the lumen, attached to the plasma membrane by an anchoring polypeptide. This arrangement provides effective surface digestion generating small molecules that can be absorbed by enterocytes. Carbohydrates have to be broken down to monosaccharides for absorption, whereas amino acids as well as di- and tripeptides generated in the process of luminal and surface digestion

TABLE 25.3 • Digestive Enzymes of Small Intestinal Surface

Enzyme (Common Name)	*Substrate*
Maltase	Maltose
Sucrase/isomaltase	Sucrose/α-limit dextrin
Glucoamylase	Amylose
Trehalase	Trehalose
β-Glucosidase	Glucosylceramide
Lactase	Lactose
Endopeptidase	Protein (cleavage at internal hydrophobic amino acids)
Aminopeptidase A	Oligopeptide with acidic NH_2 terminus
Aminopeptidase N	Oligopeptide with neutral NH_2 terminus
Dipeptidyl aminopeptidase IV	Oligopeptide with X-Pro or X-Ala at NH_2 terminus
Leucine aminopeptidase	Peptides with neutral amino acid at NH_2 terminus
γ-Glutamyltransferase	Glutathione + amino acid
Enteropeptidase (enterokinase)	Trypsinogen
Alkaline phosphatase	Organic phosphates

can be absorbed by enterocytes. For the peptides, intracellular breakdown to free amino acids is accomplished by cytoplasmic peptidases, thus completing protein digestion.

An interesting question is how the surface enzymes, which are themselves proteins, escape digestion by soluble proteases. It appears that their heavy glycosylation affords some protection as it prevents access of proteases to relevant peptide bonds.

Digestive Enzymes Are Secreted as Proenzymes

Soluble digestive enzymes are produced and secreted by specialized cells of salivary glands and pancreas (acinar cells) and gastric mucosa (chief cells). The secretion is termed exocrine because of its direction toward the lumen (Figure 25.2). Proteins destined to become soluble digestive enzymes are synthesized on polysomes of the rough endoplasmic reticulum (p. 231) and transported via the Golgi complex to storage vesicles in the apical cytoplasm. The storage vesicles (zymogen granules) have a diameter of about 1 μm and are bounded by a typical cellular membrane. Most digestive enzymes are produced and stored as inactive proenzymes (zymogens) (Figure 25.3; p. 1036). When an appropriate stimulus for secretion is received, zymogen granules move to the luminal plasma membrane and fuse with the plasma membrane to release their contents into the lumen (exocytosis). Activation of digestive proenzymes occurs only after they have been released from the cells.

Secretion Is Regulated by Many Secretagogues

Secretion of enzymes is regulated and coordinated with that of electrolytes and acid or base (sodium bicarbonate). Transport of electrolytes from blood into the ductal system of glands draws water into this compartment, and the resulting fluid solubilizes enzymes and flushes them out of glands into the alimentary canal. Regulation of secretion is through secretagogues that interact with receptors on the surface of exocrine cells (Table 25.4).

TABLE 25.4 • Physiological Secretagogues

Organ	*Secretion*	*Secretagogue*
Salivary gland	NaCl, amylase	Acetylcholine, catecholamines?
Stomach	HCl, pepsinogen	Acetylcholine, histamine, gastrin
Pancreas-acini	NaCl, digestive enzymes	Acetylcholine, cholecystokinin, secretin
Pancreas-duct	$NaHCO_3$, NaCl	Secretin
Small intestine	NaCl	Acetylcholine, serotonin, vasoactive intestinal peptide (VIP), guanylin

Neurotransmitters, hormones, pharmacological agents, and certain bacterial toxins can be secretagogues. Secretagogue–receptor interactions are cell specific, and different glands usually possess different sets of receptors. Binding of secretagogues to receptors activates intracellular signaling events that lead to release of the contents of zymogen granules into the lumen. Major signaling pathways for secretion are (Figure 25.4) (1) activation of phosphatidylinositol-specific phospholipase C with liberation of inositol 1,4,5-trisphosphate and diacylglycerol (p. 534), in turn, triggering Ca^{2+} release from the endoplasmic reticulum into the cytosol and activation of protein kinase C, respectively, and (2) activation of adenylate or guanylate cyclase, resulting in elevated cAMP or cGMP levels, respectively.

Acetylcholine (Figure 25.5) is the major neurotransmitter for stimulating enzyme and electrolyte secretion throughout the gastrointestinal tract. It mediates regulation of salivary and gastric secretions by the autonomic nervous system during the early phase of digestion (cephalic phase of gastric secretion) and of pancreatic and intestinal secretions by the enteric nervous system during subsequent digestion. The acetylcholine receptor of exocrine cells is of the muscarinic type; that is, it can be stimulated by muscarinic acid and blocked by atropine (Figure 25.6). Atropine used to be given by dentists to "dry up" the mouth for dental work.

The biogenic amines **histamine** and 5-hydroxytryptamine (**serotonin**) are secretagogues that function mainly in a paracrine fashion, that is, affecting neighboring cells. Histamine is produced by specialized regulatory cells in the gastric mucosa (enterochromaffin-like or ECL cells). 5-Hydroxytryptamine is produced by many specialized epithelial cells that are diffusely distributed throughout the lining epithelium of the stomach and the intestines. The amines are stored in vesicles and released when cells receive appropriate stimuli. Since 5-hydroxytryptamine-producing cells release most of their product toward the blood side, they are also called epithelial endocrine cells.

Histamine (Figure 25.7) is a potent stimulator of HCl secretion. It interacts with the H_2 receptor on the contraluminal plasma membrane of gastric HCl-producing (parietal) cells. Antagonists at the H_2 receptor (H_2 blockers) are used medically as antacids.

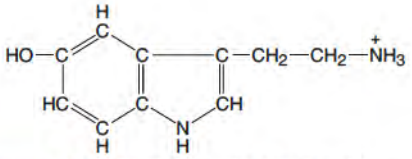

Figure 25.8 **5-OH-Tryptamine (serotonin).**

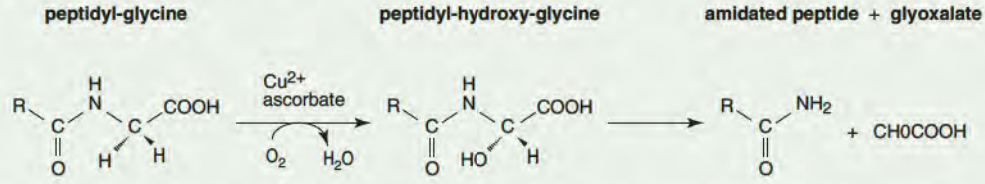
5-Hydroxytryptamine (Figure 25.8) stimulates intestinal NaCl secretion, but also functions as neurotransmitter, for example, initiating the sensation of nausea.

A third class of secretagogues consists of peptides, some of which function predominantly as hormones, others as neurotransmitters, and again others as both (Table 25.5). Many of these peptides are stabilized against digestion and chemical degradation by formation of an amide at the carboxyl-terminus (A Closer Look 25.1). The intestinal peptide hormones are produced by a number of different epithelial endocrine cells, of which many

A CLOSER LOOK 25.1

Amidation of Peptide Hormones and Neuropeptides

Most peptide hormones or neuropeptides, including most gastrointestinal ones (Table 25.5, p. 1035), are stabilized by carboxyl-terminal α-amidation. This amide group is usually required for full biological activity. Amidation is generated by a single enzyme with two different functions, namely, peptidyl-glycine α-amidating mono-oxygenase and peptidyl-α-hydroxyglycine α-amidating lyase activities The enzyme is targeted within cells to secretory granules where it acts on glycine extended prohormones (peptidyl-glycine) that are produced from larger precursors by proteolytic cleavage. The enzyme converts the carboxy terminal glycine to glyoxalate while leaving behind the amino group of glycine as amide of the finished hormone peptide (see figure).



Eipper, B. A., Milgram, S. L., Husten, E. J., Yun, H. Y., and Mains, R. E. Peptidylglycine alpha-amidating monooxygenase: A multifunctional protein with catalytic, processing, and routing domains. *Protein Sci.* 2:489, 1993: and Takahashi, K., Satani, M., Gao, Y., and Nogucki, M. The reaction mechanism of peptidylglycine α-hydroxylating monooxygenase. *Internation Congress Series* 1233:235, 2002.

also produce 5-hydroxytryptamine and store both products in small intracellular vesicles. Among the many peptide hormones, gastrin, cholecystokinin (pancreozymin), secretin, and guanylin have particular importance for digestive enzyme and fluid secretion. **Gastrin** occurs naturally in two forms: "big" gastrin is a peptide of 34 amino acids (G-34), which is cleaved to yield "little" gastrin comprising the 17 residues at the carboxyl terminus (G-17). The functional portion of gastrin resides mainly in the carboxyl-terminal pentapeptide, and synthetic pentagastrin can be administered intravenously to assess the potential for gastric HCl and pepsin secretion in a patient. Gastrin and cholecystokinin have a sulfated tyrosine, which considerably enhances the potency of each hormone.

Cholecystokinin and **pancreozymin** denote the same peptide, but *cholecystokinin* is the preferred term. The peptide stimulates gallbladder contraction (hence cholecystokinin) and secretion of pancreatic enzymes (hence pancreozymin). Cholecystokinin is released into the bloodstream by epithelial endocrine cells of the small-intestine lining, particularly in the duodenum, in response to ingestion of food and contact with cholecystokinin releasing factors secreted into the lumen by pancreas and intestinal cells. The releasing factors are themselves proteins and thus substrates for pancreatic proteases (p. 1044). The state of their degradation serves as feedback for adequate pancreatic enzyme delivery to the intestine as lack of digestion of the releasing factors stimulates further cholecystokinin and hence pancreatic enzyme secretion. Cholecystokinin and gastrin are thought to be evolutionarily related because they share an identical amino acid sequence at the carboxyl terminus.

Secretin, a polypeptide of 27 amino acids, is released by another type of endocrine cell in the small intestine. Its release is stimulated particularly by luminal pH less than 5. Its major biological activity is stimulation of secretion of pancreatic juice rich in $NaHCO_3$. This is essential for neutralization of gastric HCl in the duodenum. Secretin also enhances pancreatic enzyme release, acting synergistically with cholecystokinin.

Guanylin is a peptide that is produced by goblet (mucin-producing) cells and released mainly into the lumen. It stimulates NaCl secretion by binding to a brush border receptor/guanylate cyclase and thereby elevating cytosolic cGMP levels. The peptide was discovered because it activates the same receptor/guanylate cyclase as a heat-stable *E. coli* enterotoxin, one of the factors responsible for traveler's diarrhea.

Among neuropeptides, **vasoactive intestinal peptide** (**VIP**) is a potent and physiologically important secretagogue for NaCl and fluid in the intestines and the pancreas. Enterocytes possess receptors for VIP and release of this neuropeptide by enteric nerves regulates intestinal electrolyte and fluid secretion.

25.3 • EPITHELIAL TRANSPORT

Solute Transport May Be Transcellular or Paracellular

The barrier properties of epithelia are determined by the plasma membranes of the epithelial cells and their intercellular tight junctional complexes (Figure 25.9). Tight junctions extend in a beltlike manner around the perimeter of each epithelial cell and connect neighboring cells. They constitute part of the barrier between the two extracellular spaces on either side of the epithelium, that is, the gastrointestinal lumen and the intercellular (interstitial) space on the blood or serosal side. Tight junctions mark the boundary between luminal and contraluminal regions of the plasma membrane of epithelial cells.

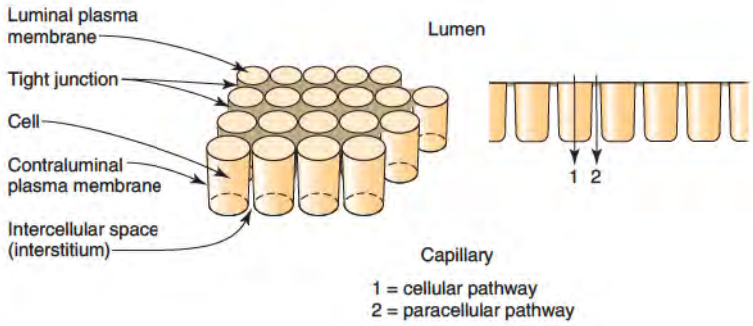


Figure 25.9 **Pathways for transport across epithelia.**

TABLE 25.6 • Characteristic Differences between Luminal and Contraluminal Plasma Membranes of Enterocytes

Parameter	*Luminal*	*Contraluminal*
Morphological appearance	Microvilli arranged as brush border	Few microvilli
Enzymes	Di- and oligosaccharidases Aminopeptidase Dipeptidases γ-Glutamyltransferase Alkaline phosphates Guanylate cyclase C	Na^+/K^+ exchanging ATPase Adenylate cyclase
Transporters/channels	Na^+-glucose cotransporter (SGLT1, SLC5A1)	Facilitative glucose transporter (GLUT2, SLC2A2)
	Facilitative fructose transporter (GLUT5, SLC2A5)	Facilitative neutral amino acid transporter (SLC3A2/SLC7A8)
	Na^+-neutral amino acid cotransporter (SLC6A19)	
	Apical Na^+-bile acid cotransporter (ASBT, SLC10A2)	Sodium-potassium-2-chloride cotransporter (NKCC 1, SLC12A2)
	H^+-peptide cotransporter (PEPT1, SLC15A1))	
	Cystic Fibrosis Transmembrane Regulatory protein (CFTR, ABCC7)	

Names in parentheses are original abbreviations and corresponding new classifications according to SLC (solute carrier) or ABC (ATP Binding Casette) nomenclature; see http://www.bioparadigms.org/s1c/menu.asp and http://nutrigene.4t.com/humanabc.htm.

Two parallel pathways can be distinguished for solute transport across epithelial cell layers, one through the cells (transcellular) and the other through the tight junctions between cells (paracellular) (Figure 25.9). Nutrient or electrolyte flux through either pathway can influence flux through the other one by changing driving forces. The transcellular route in turn consists mainly of two barriers in series, formed by the luminal and contraluminal plasma membranes.

Different regions of the gastrointestinal tract differ with respect to permeability characteristics of the tight junction. In regions with steep solute concentration gradients across the epithelium, such as stomach and distal colon, tight junctions have low permeability (or high resistance) to Na^+ and other ions, whereas they possess high permeability in regions with nutrient absorption or NaCl secretion as both processes require paracellular solute flux (p. 1036).

A major function of intestinal epithelial cells is active absorption of nutrients, electrolytes, and vitamins. The cellular basis for this vectorial solute movement lies in the different complement of transporters in luminal and contraluminal membranes. The small-intestinal epithelial cells provide an example of the differentiation and specialization of the two types of membrane in terms of morphological appearance, chemical composition, and complement of enzymes and transporters (Table 25.6). The luminal membrane is in contact with the nutrients in chyme (semifluid mass of partially digested food) and is specialized for terminal digestion of nutrients through hydrolytic enzymes on its external surface and for nutrient absorption through transporters or channels for monosaccharides, amino acids, peptides, fatty acids, cholesterol, and electrolytes. In contrast, the contraluminal plasma membrane is in contact with the intercellular fluid and therewith indirectly with capillaries and lymph vessels. It has properties similar to the plasma membrane of most cells and possesses receptors for hormonal or neuronal regulation of cellular functions, a Na^+/K^+-exchanging ATPase for removal of Na^+ from the cell, and transporters for entry of nutrients needed for cell maintenance. It also contains the transporters necessary for exit of absorbed nutrients so that the digested food becomes available to all cells of the body. Many of the nutrient transporters in the contraluminal membrane are bidirectional and serve to release nutrients into blood or lymph after a meal and provide nutrients to enterocytes in between meals.

NaCl Absorption Depends on Na^+/K^+-exchanging ATPase, Membrane Transporters, and Channels

Transport of Na^+ plays a crucial role not only for epithelial NaCl absorption or secretion but also for energization of nutrient uptake. The **Na^+/K^+-exchanging ATPase** (p. 491)

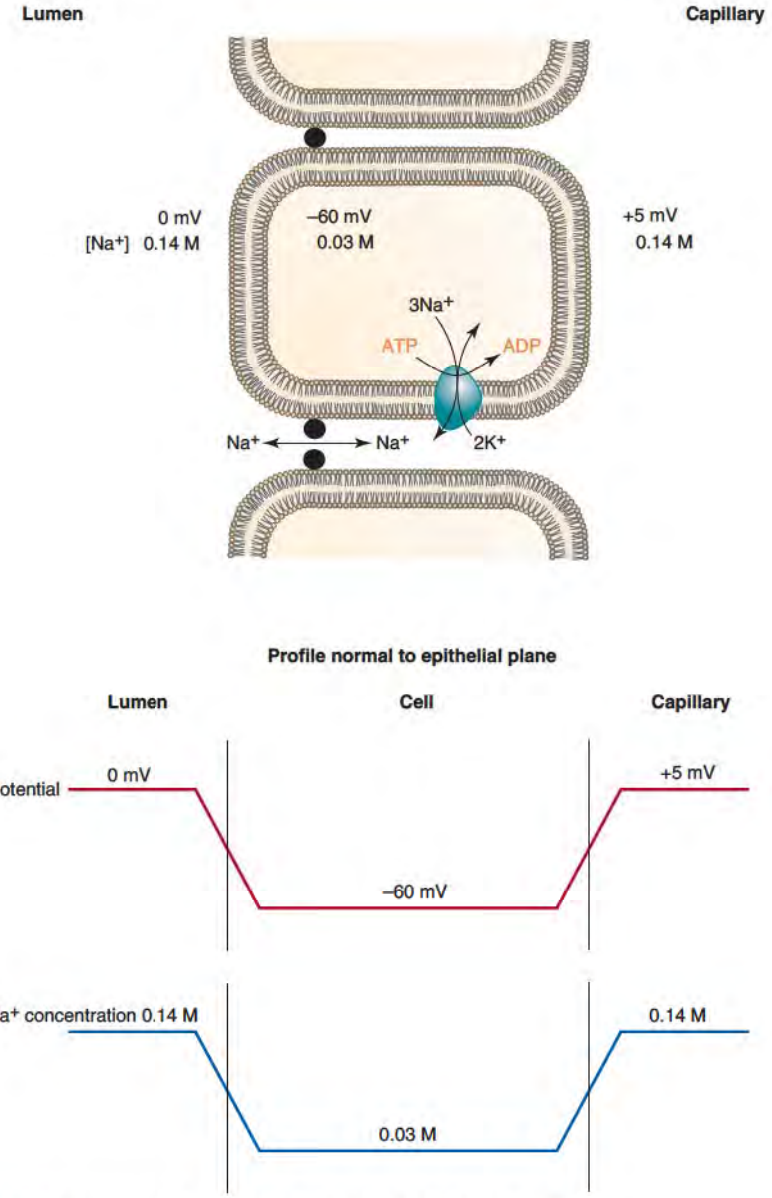

Figure 25.10 **Na^+ concentrations and electrical potentials in enterocytes.**

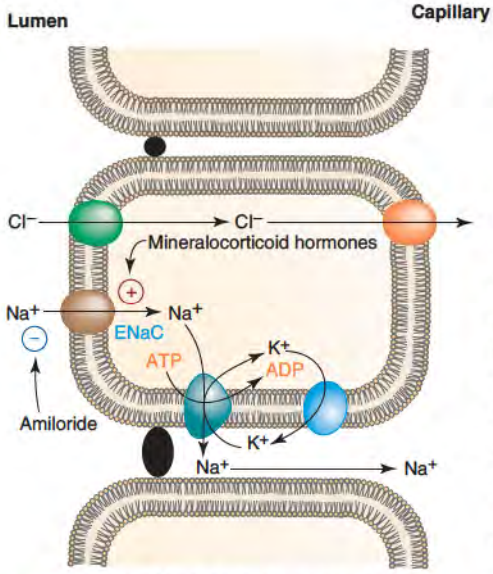

Figure 25.11 **Model for electrogenic NaCl absorption in lower large intestine.** Na^+ absorption proceeds via luminal epithelial sodium channel (ENaC) and Na^+, K^+-exchanging ATPase. The nature of Cl^- channels is not known.

is the dominant mechanism for transduction of chemical energy in the form of ATP into osmotic energy of a concentration (chemical) or a combined concentration and electrical (electrochemical) ion gradient across the plasma membrane. In gastrointestinal epithelial cells this enzyme is located exclusively in the contraluminal membrane (Figure 25.10). The ATPase maintains the high K^+ and low Na^+ concentrations in the cytosol and is responsible, in conjunction with a K^+ channel in the same membrane, for an electrical potential of about -60 mV of the cytosol relative to the extracellular solution. Transepithelial NaCl movements result from the combined actions of the Na^+/K^+-exchanging ATPase and additional passive transporters in the plasma membrane, which allow the entry of Na^+ or Cl^- into the cell. NaCl absorption results from Na^+ entry from the lumen and its extrusion by the Na^+/K^+-exchanging ATPase across the contraluminal membrane. Epithelial cells of the lower portion of the large intestine possess a luminal Na^+ channel (Epithelial Na Channel, ENaC, or SCNN1. *Note:* Acronyms used to identify the channels and transporters are being changed. Thus, where appropriate, both the older and newer acronym will be given). The channel allows the uncoupled entry of Na^+ down its electrochemical gradient (Figure 25.11). This Na^+ flux is electrogenic, that is, it is associated with an electrical current that, in turn, changes any electrical potential. It can be inhibited by the diuretic drug

amiloride at micromolar concentrations (Figure 25.12). This transport system, and hence NaCl absorption, is regulated by mineralocorticoid hormones of the adrenal cortex.

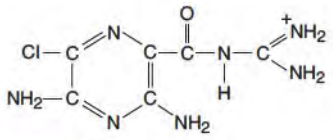

Figure 25.12 **Amiloride.**

Epithelial cells of the small intestine have a transporter in their brush border membrane, which catalyzes an electrically neutral Na^+/H^+ exchange; Na^+/H^+ transporter-3 (NHE3, or SLC9A3) is the predominant isoform in the intestine (Figure 25.13). This transporter is not affected by low concentrations of amiloride and not regulated by mineralocorticoids. The Na^+/H^+ exchange sets up a H^+ gradient that secondarily drives Cl^- absorption through a specific Cl^-/HCO_3^- transporter in the luminal plasma membrane, as illustrated in Figure 25.13. The intestinal Cl^-/HCO_3^- transporter is coded for by the "down-regulated in adenoma" (DRA) gene (SLC26A3) (Clin. Corr. 25.1). The need for two types of NaCl absorption mechanisms arises from the different physiological functions of upper and lower intestine, which require different regulation. The upper intestine absorbs the bulk of NaCl derived from diet and secretions of the exocrine glands, whereas the lower intestine scavenges remaining NaCl depending on overall NaCl balance of the body.

NaCl Secretion Depends on Na^+/K^+-exchanging ATPase, Membrane Transporters, and Channels

Glands and intestinal crypts secrete each day a large amount of electrolytes and fluids into the gastrointestinal lumen (equivalent to at least a third of the extracellular fluid in humans). This is an energy-consuming process with active transport of electrolytes and passive flow of water. The water movement is due to osmotic forces exerted by secreted electrolytes. In other words, any primary secreted fluid has a greater osmolarity than plasma or cytosol and is said to be *hypertonic*. However, most gastrointestinal epithelia have a very high permeability to water due to the presence of water channels, aquaporins (p. 479), in the plasma membranes so that osmotic equilibrium is rapidly approached. As a result, the secretions actually emerging from the acini of glands or intestinal crypts are essentially *isotonic* (same osmolarity as plasma). Ionic compositions of gastrointestinal secretions are presented in Figure 25.14.

Major secreted ions are Na^+ and Cl^-, and net NaCl secretion is an energy-consuming process that depends on Na^+/K^+-exchanging ATPase located in the contraluminal plasma membrane (Figure 25.15). Hence, the secretion mechanism provides insight into energy coupling. Experimental evidence for the involvement of Na^+/K^+-exchanging ATPase in both NaCl secretion and absorption is provided by the finding that specific inhibitors of this enzyme, so-called cardiac glycosides, abolish both salt secretion and absorption. How can the Na^+/K^+-exchanging ATPase power Na^+ movement from the capillary side to the lumen when it actually extrudes Na^+ from the cell toward the capillary side? This paradox is resolved by an electrical coupling of Cl^- secretion across the luminal plasma membrane and Na^+ movements via the paracellular route, illustrated in Figure 25.15. Cl^- secretion depends on coupled uptake of two Cl^- ions with Na^+ and K^+ across the contraluminal membrane, extrusion of Na^+ and K^+ across the contraluminal membrane, and luminal exit

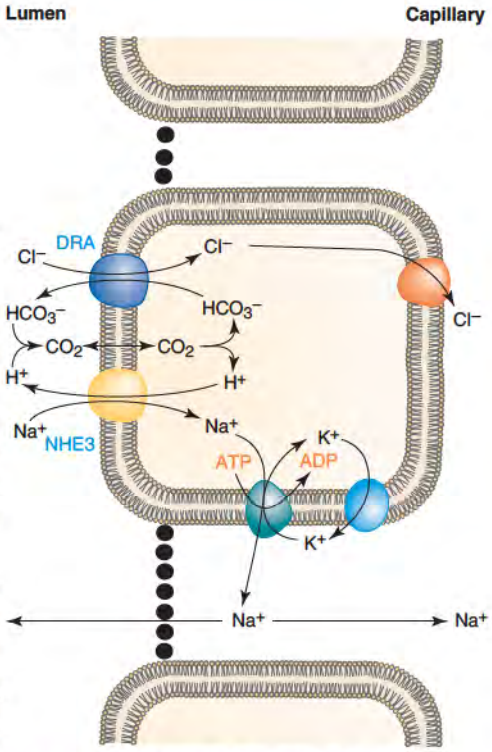

Figure 25.13 **Model for electrically neutral NaCl absorption in the small intestine. Na^+ absorption proceeds via sodium/proton exchanger 3 (NHE3) and Na^+, K^+-exchanging ATPase.** Cl^- absorption proceeds via 'down-regulated in adenoma" protein (DRA). The nature of the contraluminal Cl^- channel is not known.

CLINICAL CORRELATION 25.1

Familial Chloridorrhea Causes Metabolic Alkalosis

Loss-of-function mutations in the human DRA (down-regulated in adenoma) gene (SLC26A3, OMIM 126650) causes familial chloridorrhea. Patients with this disease have moderate diarrhea, generate acidic stool, and suffer from metabolic alkalosis (alkaline plasma at normal carbon dioxide concentration). The normal DRA gene product is a Na^+-independent Cl^-/HCO_3^- exchanger in epithelial cells of the lower ileum and colon. The exchanger absorbs Cl^- from stool in exchange for bicarbonate. Bicarbonate secretion is important for neutralization of protons secreted in exchange for Na^+ via sodium/proton exchanger NHE3 (SLC9A3). Chronic HCl loss with the stool leads to a corresponding metabolic alkalosis of the body fluids. In addition, the extra electrolytes in stool are responsible for its greater fluid contents, i.e., diarrhea, due to osmotic effects.

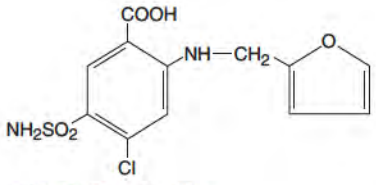

Figure 25.16 Furosemide.

of Cl^- via channels. The uptake is mediated by a $Na^+/K^+/2Cl^-$-cotransporter (NKCC1 or SLC12A2), which is pharmacologically characterized by inhibition by the diuretic furosemide (Figure 25.16), and utilizes energy of the Na^+ gradient to accumulate Cl^- within the cytosol above its electrochemical equilibrium. As the Na^+/K^+-exchanging ATPase generates and maintains the Na^+ gradient across the plasma membrane, it indirectly also powers Cl^- uptake from capillaries into cells and its movement into the lumen. The exit of Cl^- via luminal channels is associated with loss of a negative charge; this, in turn, sets up an electrical potential that draws Na^+ into the lumen via the paracellular route. The predominant luminal Cl^- channel in pancreatic ducts and the intestines is the cystic fibrosis transmembrane regulatory (CFTR) protein, and malfunctions of this channel lead to reduced amounts of secretions in the human disease cystic fibrosis (Clin. Corrs. 25.2 and 25.3).

Pancreatic acinar cells secrete a fluid rich in Na^+ and Cl^-, which provides the vehicle for transport of digestive enzymes from the acini to the lumen of the duodenum. This fluid is modified in the ducts by the additional secretion of $NaHCO_3$ (Figure 25.17). Bicarbonate concentrations can reach up to 120 mM in humans.

CLINICAL CORRELATION 25.2

Cystic Fibrosis of the Pancreas

Cystic fibrosis (OMIM 602421) transmembrane regulatory (CFTR) protein is a member of the ABC transporter family (subfamily ABCC7) and the predominant Cl^- channel in the luminal plasma membrane of epithelial cells in tissues affected in cystic fibrosis (airways, pancreatic duct, intestine, vas deferens, sweat gland ducts) (see Clin. Corr. 12.5, p. 496). The channel is normally closed but opens when phosphorylated by protein kinase A and ATP is present. Cl^- flux through CFTR depends on the existing electrochemical Cl^- gradient, which is set up by other cellular transporters and is different in secretory and absorptive cells. In most tissues, CFTR controls secretion of NaCl and fluid. (See Clin. Corr. 25.3 for activation of the CFTR Cl^- channel.) However, in sweat gland duct cells, which are absorptive, CFTR mediates efficient reabsorption of Cl^-, which is initially secreted in sweat gland acini. A defect in CFTR explains both excessive loss of Cl^- in sweat (sweat test for cystic fibrosis) and insufficient NaCl and fluid secretion in lungs, pancreas, and intestine. The gastrointestinal symptoms in cystic fibrosis patients (maldigestion, meconium ileus, and fecal impaction) stem from the diminished fluid secretion and the resulting partial or total blockage of pancreatic ducts and the intestine. The decrease in pancreatic juice delivered to the intestine explains maldigestion, whereas retention of digestive enzymes within the pancreas produces autodigestion, inflammation, scarring, and cyst formation.

CLINICAL CORRELATION 25.3

Bacterial Toxigenic Diarrheas and Electrolyte Replacement Therapy

Voluminous, life-threatening intestinal electrolyte and fluid secretion (diarrhea) occurs in patients with cholera, an intestinal infection by Vibrio cholerae. Certain strains of *E. coli* also cause (traveler's) diarrhea that can be serious in infants. The secretory state is a result of enterotoxins produced by the bacteria. The mechanisms of action of some of these enterotoxins are well understood at the biochemical level. Cholera toxin activates adenylate cyclase by causing ADP-ribosylation of the $G_{\alpha s}$ protein resulting in constitutive stimulation of the cyclase (p. 527). Elevated cAMP levels in turn activate protein kinase A and protein phosphorylation, which opens the luminal CFTR Cl^- channel in secretory cells and inhibits the Na^+/H^+ exchanger (NHE3) in absorptive cells. The net result is gross NaCl secretion. *E. coli* produces a heat-stable toxin that binds to guanylate cyclase C, which has an extracellular binding domain and intracellular catalytic domain. Binding of *E. coli* heat-stable toxin or of the peptide guanylin produced physiologically by intestinal goblet cells, activates guanylate cyclase resulting in increased cGMP levels. Elevated cGMP, similarly as elevated cAMP, inhibits NaCl reabsorption and stimulates Cl^- secretion.

Modern, oral treatment of cholera takes advantage of the presence of Na^+-glucose cotransport in the intestine, which is not altered by elevated cAMP and remains fully active in this disease. In this case, the presence of glucose allows uptake of Na^+ to replenish body NaCl. Composition of solution for oral treatment of cholera patients is glucose 110 mM, Na^+ 99 mM, Cl^- 74 mM, HCO_3^- 29 mM, and K^+ 4 mM. The major advantages of this form of therapy are its low cost and ease of administration when compared with intravenous fluid therapy.

The composition of sport drinks for electrolyte replacement is based on the same principle, namely more rapid sodium absorption in the presence of glucose.

Carpenter, C. C. J. In Field, M., Fordtran, J. S., and Schultz, S. G (Eds.), *Secretory Diarrhea.* Bethesda, MD: American Physiological Society, 1980, 67.

Ion Concentration Gradients and Electrical Potentials Energize Transport of Nutrients

Many solutes are absorbed across the intestinal epithelium against a concentration gradient. Energy for this active transport is directly derived from a Na^+ or H^+ concentration gradient or the electrical potential across the luminal membrane, and only indirectly from ATP hydrolysis. Intestinal glucose transport is an example of such uphill solute transport, driven in this case by an electrochemical Na^+ gradient (Figure 25.18).

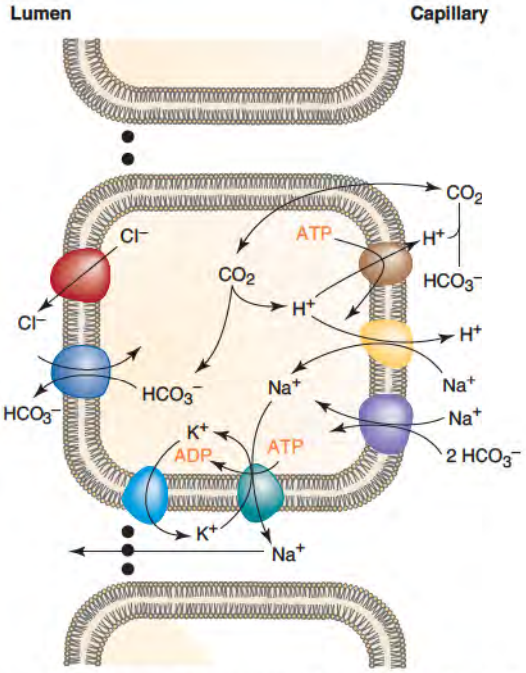

Figure 25.17 Model for $NaHCO_3$ secretion by pancreatic duct cells. Luminal Cl^- efflux and Na^+ flux are similar to those in NaCl secretion (see Figure 25.15). *Note:* Three mechanisms exist for bicarbonate influx into the cell (or its equivalent proton secretion) at the contraluminal membrane: (1) Na^+/H^+ exchange, (2) H^+-ATPase, and (3) Na^+-$2HCO_3^-$-co-transport.

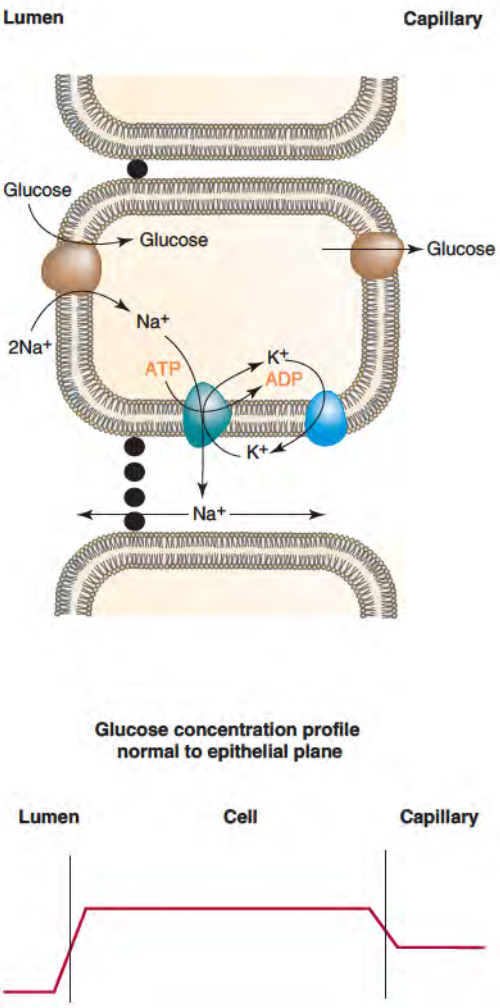

Figure 25.18 Model for epithelial glucose absorption. Note the indirect role of Na^+, K^+-exchanging ATPase.

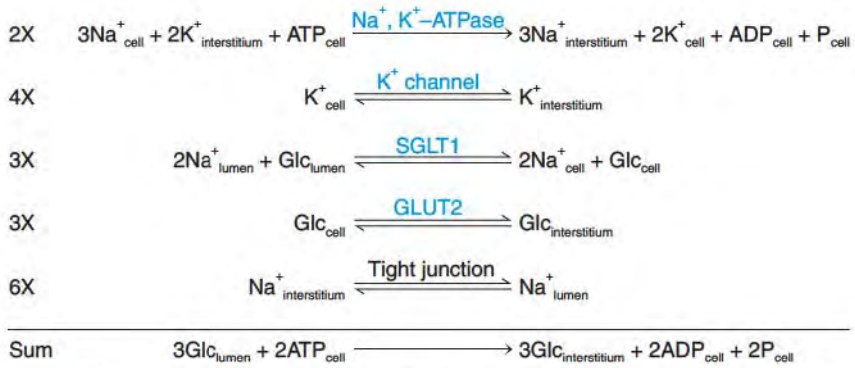

Figure 25.19 Transepithelial glucose transport as translocation reactions across plasma membranes and the tight junction. Transporters SGLT1 (sodium glucose transporter 1) and GLUT2 (glucose transporter 2) mediating Na^+-glucose cotransport and facilitative glucose transport, respectively. Numbers in the left column indicate the minimal turnover of individual reactions to balance the overall reaction.

Serum glucose is about 5 mM so that complete extraction of glucose from chyme can only be achieved by active transport across the epithelium. This vectorial process is the result of several separate membrane events (Figure 25.19). (1) Primary active, ATP-dependent Na^+ efflux at the contraluminal membrane establishes an electrochemical Na^+ gradient across the contraluminal membrane. (2) K^+-efflux via channels in the contraluminal membrane contributes further to the membrane potential. (3) **Secondary active cotransport** of glucose and Na^+ drives glucose uptake from the lumen into the cell. (4) Facilitative glucose movement downhill into the interstitial and capillary space completes the transepithelial glucose absorption. This scenario is possible because of the presence of a cotransporter for glucose and Na^+ in the luminal membrane (**sodium glucose transporter 1** [SGLT1 or SLC5A1]) (p. 489), a facilitative transporter for glucose in the contraluminal membrane (GLUT2 or SLC2A2), and a leaky "tight junction" that allows the electrochemical Na^+ gradient across the contraluminal membrane to spread over the entire plasma membrane.

SGLT1 facilitates a tightly coupled movement of Na^+ and D-glucose (or structurally similar sugars) with a stoichiometry of two Na^+ ions and one glucose molecule. While the cotransporter *per se* facilitates coupled movement of glucose and Na^+ across the membrane equally well in either direction, transport under physiological conditions is from lumen to cell because of the lower Na^+ concentration and the negative potential in the cell. As a result, glucose is concentrated in the cell. Thus, downhill Na^+ movement normally supports concentrative glucose transport. Concentration ratios of up to 20-fold between intracellular and extracellular glucose have been observed in vitro under conditions of blocked efflux of cellular glucose. In some situations, Na^+ uptake via this route is physiologically more important than glucose uptake (Clin. Corr. 25.3).

GLUT2 (p. 489) in the contraluminal membrane is a member of the facilitative **glu**cose **t**ransporter family and accepts many monosaccharides, including glucose. The direction of net flux is determined solely by the monosaccharide concentration gradient. The two glucose transport systems SGLT1 and GLUT2 share glucose as substrate, but differ considerably in amino acid sequence, secondary protein structure, Na^+ as cosubstrate, specificity for other sugars, sensitivity to inhibitors, and biological regulation. Since both SGLT1 and GLUT2 are not inherently directional, active transepithelial glucose transport relies on the Na^+/K^+-exchanging ATPase to continually move Na^+ out of the cell and maintain the electrochemical Na^+ gradient. One advantage of this arrangement for supplying energy to nutrient absorption is that the Na^+/K^+-exchanging ATPase can energize transport of many different nutrient transporters that use Na^+ as cosubstrate.

Gastric Parietal Cells Secrete HCl

The parietal (oxyntic) cells of gastric glands secrete HCl into the gastric lumen. Luminal H^+ concentrations of up to 0.14 M (pH 0.8) have been observed (see Figure 25.14, p. 1040). At plasma pH = 7.4, the parietal cell transports protons against a concentra-

tion gradient of $10^{6.6}$. The free energy required for HCl secretion under these conditions is minimally 38.1 kJ/mol (9.1 kcal/mol) of HCl. This active HCl secretion is achieved through a combination of primary active K^+/H^+ exchange by a K^+/H^+-exchanging ATPase (ATP4) (or gastric proton pump), Cl^- and K^+ channels in the luminal membrane, and Cl^-/HCO_3^- exchange in the contraluminal membrane. The K^+/H^+-exchanging ATPase is unique to the parietal cell and translocates from intracellular vesicles to the luminal membrane for periods of active HCl secretion. This enzyme couples the hydrolysis of ATP to an electrically neutral obligatory exchange of K^+ for H^+, secreting H^+ and moving K^+ into the cell. The stoichiometry appears to be 1 mol of transported H^+ and K^+ for each mole of ATP.

$$ATP_{cell} + H^+_{cell} + K^+_{lumen} \rightarrow ADP_{cell} + P_{i,cell} + H^+_{lumen} + K^+_{cell}$$

As this ATPase generates a very acidic solution, protein reagents that are activated by acid can become specific inhibitors of this enzyme. Figure 25.20 shows the mechanism of a proton pump inhibitor that is sold as antacid.

In the steady state, HCl is elaborated by H^+/K^+-exchanging ATPase only if the luminal membrane is permeable to K^+ and Cl^- and the contraluminal membrane catalyzes an exchange of Cl^- for HCO_3^- (Figure 25.21). This exchange is essential to replenish the cell's Cl^- and prevent accumulation of base within the cell. Thus, under steady-state conditions, secretion of HCl into the gastric lumen is coupled to movement of HCO_3^- into plasma.

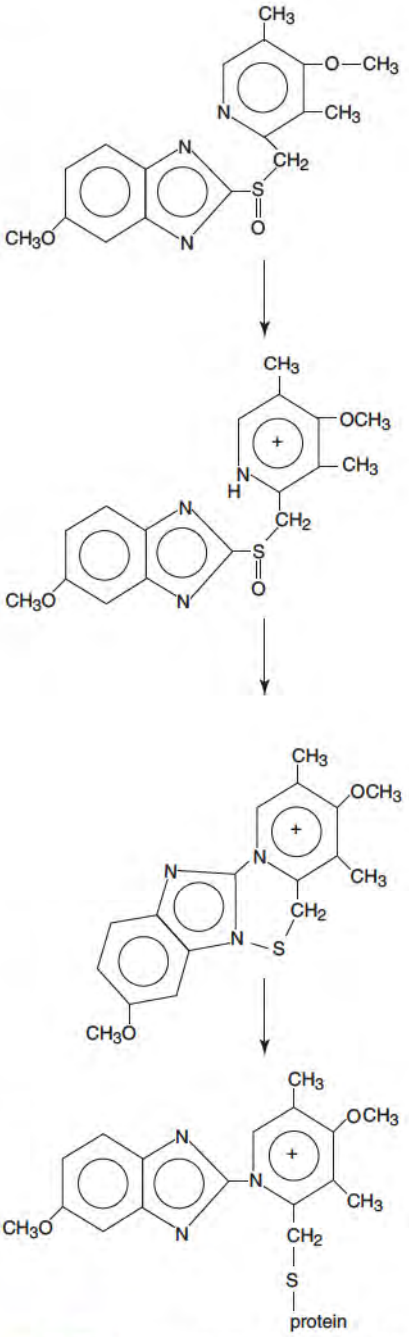

Figure 25.20 **Omeprazole, an inhibitor of K^+/H^+-exchanging ATPase.** This drug accumulates in acidic compartments (pKa ~4) and is converted to a sulfenamide that reacts with cysteine SH groups.

25.4 • DIGESTION AND ABSORPTION OF PROTEINS

Peptidases Assure Efficient Protein Digestion

The total daily protein load to be digested consists of about 70–100 g of dietary proteins and 35–200 g of endogenous proteins from digestive enzymes and sloughed-off cells. Digestion and absorption of proteins are very efficient processes in healthy humans, since only about 1–2 g of nitrogen are lost through feces each day, which is equivalent to 6–12 g of protein.

Except for a short period after birth, oligo- and polypeptides are not absorbed intact in appreciable quantities by the intestine. Proteins are hydrolyzed by a whole range of peptidases, each with specificity for peptide bonds between different amino acids. **Endopeptidases** (proteases) attack internal bonds and liberate large peptide fragments, while exopeptidases cleave off one amino acid at a time from either the carboxyl (carboxypeptidases) or the amino terminus (aminopeptidases). Endopeptidases are important for an initial breakdown of long polypeptides into smaller products, which can then be attacked

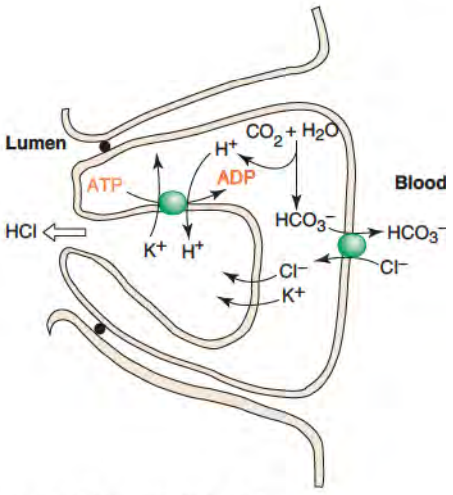

Figure 25.21 **Model for secretion of hydrochloric acid.**

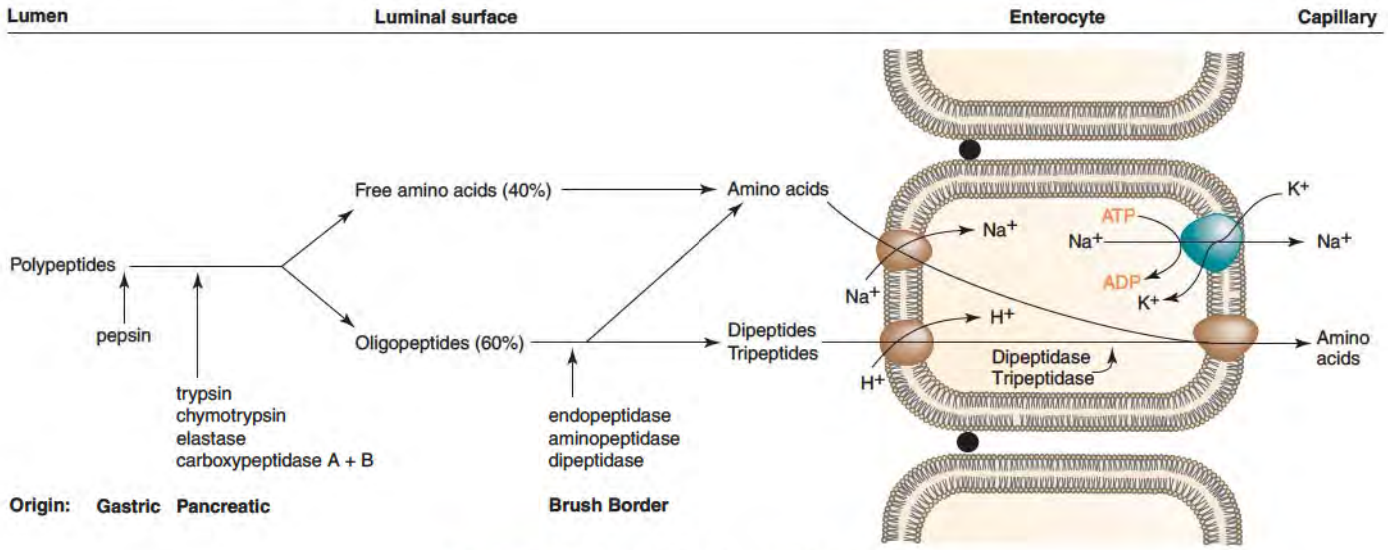

Figure 25.22 Digestion and absorption of proteins.

more efficiently by exopeptidases. The final products are free amino acids and di- and tripeptides, which are absorbed by epithelial cells (Figure 25.22).

Protein digestion can be divided into a gastric, a pancreatic, and an intestinal phase, depending on the source of peptidases.

Pepsins Catalyze Gastric Digestion of Protein

Gastric juice contains HCl at a pH of less than 2 and proteases of the pepsin family. The acid serves to kill off microorganisms and to denature proteins. Denaturation makes proteins more susceptible to hydrolysis by proteases. Pepsins are unusual enzymes in that they are stable and active at acid pH. The catalytic mechanism depends on the carboxylic groups from two aspartic acid residues at the active site (see Figure 25.3, p. 1034). Pepsin A, the major gastric protease, prefers peptide bonds formed by the amino group of hydrophobic and aromatic acids (Phe, Tyr, Trp, and Leu) (Table 25.7).

TABLE 25.7 • Gastric and Pancreatic Peptidases

Enzyme	*Proenzyme*	*Activator*	*Cleavage Point*	*R*

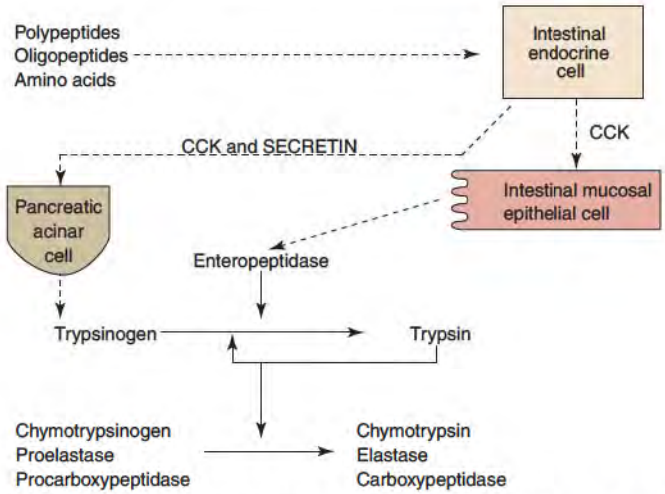

Figure 25.23 Secretion and activation of pancreatic enzymes. Abbreviation: CCK, cholecystokinin. Reproduced with permission from Freeman, H. J., and Kim, Y. S. *Annu. Rev. Med.* 29:102, 1978. Copyright (1978) Annual Reviews, Inc.

Active pepsin is generated from the proenzyme **pepsinogen** by removal of 46 amino acids from the NH_2-terminus. Cleavage between residues 46 and 47 occurs as an intramolecular reaction (autoactivation) below pH 5 or by the action of pepsin. The liberated peptide remains bound to pepsin and acts as pepsin inhibitor above pH 2. This inhibition is released by a drop of the pH below 2 or by further degradation of the peptide by pepsin. Thus, pepsinogen is activated at an exponential rate once the pH becomes acidic. Pepsin cuts proteins mainly into large peptide fragments, but also produces some smaller peptides and free amino acids. These latter products are important for initiation of the pancreatic phase of protein digestion.

Pancreatic Zymogens Are Activated in Small Intestine

Pancreatic juice is rich in proenzymes that are activated after they reach the lumen of the small intestine (Figure 25.23). **Enteropeptidase** (or enterokinase), a protease produced by duodenal epithelial cells, activates pancreatic trypsinogen to trypsin by scission of a hexapeptide from the NH_2-terminus. Trypsin activates more trypsinogen to trypsin and also acts on the other proenzymes, thus liberating the endopeptidases chymotrypsin and elastase and the carboxypeptidases A and B. Pancreatic juice normally contains a 6-kDa trypsin inhibitor protein that inhibits any trypsin formed prematurely within the pancreatic cells or pancreatic ducts (Clin. Corr. 25.4).

CLINICAL CORRELATION 25.4

Trypsin and Pancreatic Autodigestion

Trypsinogen actually refers to a family of proteins (e.g., coded by the genes TRYP 1–7). Premature activation of any of the trypsinogens within the pancreas results in activation of other members of the trypsin family and other types of digestive enzymes. The resulting active enzymes autodigest the pancreatic tissue itself, leading to an acute, painful inflammation of this organ. Clinically, the autodigestion can be detected by increases in serum levels of pancreatic amylase. To prevent premature activation of trypsinogens, pancreatic secretions normally contain a pancreatic secretory trypsin inhibitor (SPINK1). Rare autosomal-dominant mutations N29I and R122H of trypsin-1 (PRSS1 or cationic trypsinogen) and the variant N34S of the pancreatic secretory trypsin inhibitor are associated with childhood or youth onset of acute recurrent pancreatitis. Presumably, these mutations are associated with a greater tendency for autoactivation of trypsinogen and lesser inhibitory activity of the pancreatic secretory trypsin inhibitor, respectively. Digestive enzymes also activate within the pancreas when the ducts are clogged, e.g. when the major excretory duct that is shared with the common bile duct, is blocked by a gall stone (gall stone pancreatitis). Similarly, acinar cell injury, as suggested for chronic alcohol abuse, results in autoactivation of trypsinogen and pancreatitis (alcoholic pancreatitis).

Keim, V. Role of genetic disorders in acute recurrent pancreatitis. *World J. Gastroenterology* 14:1011, 2008; and Apte, M. V., Pirola, R. C., and Wilson, J. S. Molecular mechanisms of alcoholic pancreatitis. *Digestive Diseases* 23:232, 2005.

Specificities of **trypsin**, **chymotrypsin**, and **elastase** are presented in Table 25.7. The enzymes are active only at neutral pH and depend on pancreatic $NaHCO_3$ for neutralization of gastric HCl. Their mechanism of catalysis involves an essential serine residue (p. 343) and is thus similar to serine esterases, such as acetylcholine esterase. The serine proteases and esterases are inhibited by reagents that chemically modify serine in the active site. An example of such an inhibitor is diisopropylphosphofluoridate, which was developed for chemical warfare with acetylcholine esterase as intended target (p. 948).

Peptides generated from ingested proteins are further degraded within the small intestinal lumen by pancreatic carboxypeptidases A and B, which use Zn^{2+} as part of the catalytic mechanism. The combined action of pancreatic proteases and peptidases results in formation of free amino acids and small peptides of 2–8 residues; peptides account for about 60% of the amino nitrogen at this point.

Brush Border and Cytosolic Peptidases Digest Small Peptides

Since pancreatic juice does not contain appreciable aminopeptidase activity, final digestion of di- and oligopeptides depends on enzymes of the small intestine. The luminal surface of epithelial cells is particularly rich in endopeptidase and aminopeptidase activity, and also contains **dipeptidases** (see Table 25.3, p. 1033). Their action at the brush border surface produces free amino acids and di- and tripeptides, which are absorbed via specific amino acid or peptide transport systems. Transported di- and tripeptides are generally hydrolyzed within the intestinal epithelial cell before they leave the cell. This explains why practically only free amino acids are found in the portal blood after a meal. The virtual absence of peptides used to be taken as evidence that luminal protein digestion proceeded all the way to free amino acids before absorption occurred (Clin. Corr. 25.5). However, it is now established that a large portion of dietary amino nitrogen is absorbed in the form of small peptides with subsequent intracellular hydrolysis. Exceptions are di- and tripeptides that contain proline, hydroxyproline, or unusual amino acids, such as β-alanine in carnosine (β-alanylhistidine) or anserine (β-alanyl 1-methylhistidine). These peptides are absorbed and released intact into portal blood. Although unusual, β-alanine is nevertheless part of a normal diet as it is found, for example, in chicken meat.

Amino Acid and Di- and Tripeptide Transporters

The small intestine has a high capacity for absorbing free amino acids and di- and tripeptides. Most L-amino acids can be transported across the epithelium against a concentration gradient, although the need for concentrative transport *in vivo* is not obvious as luminal

CLINICAL CORRELATION 25.5

Gluten Enteropathy

Gluten enteropathy, or celiac disease, is due to intolerance of a protein fraction, termed gluten. Gluten is present in the cereals wheat, barley, and rye, but not rice and maize. The frequency of this disease in Caucasians is estimated as 1 in 250, that is, so prevalent that gluten-free diets can often be ordered. The disease appears to be caused by an enzyme deficiency in a yet to be identified brush border peptidase that results in incomplete digestion of gluten. Specific remaining peptides of 7 to 18 amino acid residues have been recognized, whereby peptides with the motifs of PSQQ or QQQP appear to be toxic to the mucosa. Such toxic peptides are produced at much higher concentrations during the digestion of gluten in celiac patients than in unaffected individuals. The presence of toxic peptides results in an increased permeability of the mucosal barrier and T-cell mediated immune and inflammatory responses to gluten-derived and other peptides that reach the immune cells. The inflammatory response, in turn, reduces the digestive surface area of the small intestinal mucosa and capacity of brush border digestion. Symptoms range from minor gastrointestinal complaints (bloating, diarrhea) to severe malnutrition. They are usually a consequence of reduced small intestinal brush border digestion and bacterial degradation of the remaining nutrients in the colon. Treatment consists of either avoidance of gluten-containing diets or, still experimental, the use of animal intestinal extracts to more completely digest gluten peptides.

Cornell, H. J. and Stelmasiak, T. A unified hypothesis of coeliac disease with implications for management of patients. *Amino Acids* 33:43, 2007.

TABLE 25.8 • Amino Acid Transporters in the Small Intestines

Transporter	*Other name(s)*	*Substrate Specificity*	*Mechanism*	*Disease Due to Loss of Function*
		Luminal Membrane		
SLC1A1	EAAT3	Asp, Glu	Secondary active transport: cotransport with Na^+, countertransport with K^+	Dicarboxylic aminoaciduria
SLC3A1/SLC7A9	rBAT/$b^{0,+}$AT	Lys, Arg, Cys-Cys	Facilitative, concentrating: cotransport with positive charge, countertransport with neutral amino acids	Cystinuria
SLC6A19	B^0AT1, NBB	Phe, Tyr, Met, Val, Leu, Ile	Secondary active transport: cotransport with Na^+	Hartnup disease, neutral aminoaciduria
SLC1A5	ASCT2, ASC	Ala, Ser, Cys	Exchanging: cotransport with Na^+	
SLC6A20	IMINO	Pro, hydroxy-Pro	Secondary active transport: cotransport with Na^+, cotransprot with Cl^- (in some species)	
SLC6A6	BETA	β-Ala, taurine	Secondary active transport: cotransport with Na^+, cotransprot with Cl^- (in some species)	
SLC36A1	PAT1	Gly, Ala, Pro, GABA, D-Ala	Secondary active transport: cotransport with H^+	
SLC15A1	PEPT1	Dipeptides, tripeptides, penicillin	Secondary active transport: cotransport with H^+	
		Contraluminal Membrane		
SLC3A2/SLC7A7	y^+L, y^+LAT 1	Lys, Arg	Exchanging: countertransport with Na^+ plus neutral amino acids	Lysinuric protein intolerance
SLC3A2/SLC7A8	L, LAT 2	Small and large neutral amino acids	Facilitative	
SLC16A10	TAT 1	Phe, Tyr, Trp	Facilitative	

concentrations are usually higher than the plasma levels of 0.1–0.2 mM. The uptake into cells is mediated by several different transporters in the luminal membrane, while the release into blood is mediated by several additional, different transporters in the contraluminal membrane (Table 25.8). Remarkably, several loss-of-function mutations in amino acid transporters were discovered because small intestine and renal proximal tubules share transporter types and renal loss of any particular amino acid transporter produces an easily measured result, namely, amino acid excretion in urine (amino aciduria). Similarly, importance of di- and tripeptide absorption for nutrition was discovered when a loss-of-function mutation in the major neutral amino transporter (neutral aminoaciduria) was not accompanied by an expected deficiency in the corresponding amino acids, suggesting compensation by at least one additional transporter type (Clin. Corr. 25.6).

The mechanism for active absorption of neutral L-amino acids appears to be similar to that discussed for D-glucose (see Figure 25.18, p. 1041). An Na^+-dependent cotransporter from the SLC6 family (also termed NBB for **N**eutral amino acid **B**rush **B**order or B^0AT1) and Na^+-independent, facilitative transporter (SLC3A2/SLC7A8, or L for **L**eucine preferring) have been characterized in the luminal and contraluminal membranes, respectively. The brush border transport of amino acids other than the neutral ones is energized in more complicated ways. For example, acidic amino acids can be concentrated by cotransport with 2 Na^+ ions and countertransport with one K^+ ion (SLC1A1) whereas basic amino acids rely on cotransport of a positive charge and the cell-inside negative potential (SLC3A1/SLC7A9). The amino acids alanine, serine, and cysteine are substrates for several transporters, one of which appears to catalyze an obligatory amino acid/amino acid exchange (SLC1A5).

Molecular analysis has revealed the existence of heteromeric amino acid transporters in which a "heavy" subunit (SLC3 family) directs cellular trafficking of the complex to either luminal or contraluminal membrane and a "light" subunit (SLC7 family) determines amino acid specificity and transport mechanism (Figure 25.24). For example, SLC3A1

TABLE 25.9 • Dietary Carbohydrates

Carbohydrate	*Typical Source*		*Structure*
Fructose	Fruit, honey	α-Fru	Glucose	Fruit, honey, grape	β-Glc	Amylopectin	Potatoes, rice, corn, bread	α-Glc(1 → 4)$_n$ Glc with α-Glc(1 → 6) branches	Amylose	Potatoes, rice, corn, bread	α-Glc(1 → 4)$_n$ Glc	Sucrose	Table sugar, desserts	α-Glc(1 → 2)β-Fru	Trehalose	Young mushrooms	α-Glc(1 → 1)α-Glc	Lactose	Milk, milk products	β-Gal(1 → 4)Glc	Raffinose	Leguminous seeds	α-Gal(1 → 6)α-Glc (1 → 2)β-Fru	

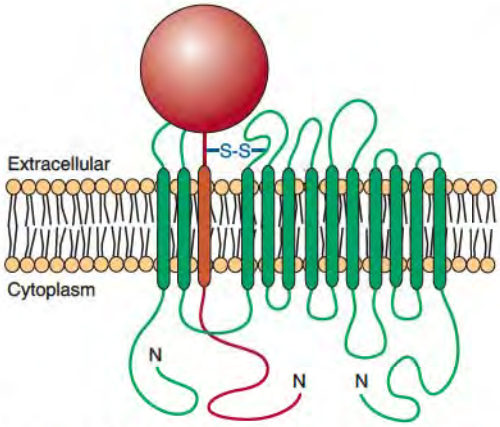

Figure 25.24 Model for heteromeric amino acid transporter. The heavy subunit with 1 transmembrane domaine (dark gray) is linked by a disulfide bridge to the light subunit with 12 transmembrane domains (light gray).
Redrawn from Chillaron, J., Roca, R., Valencia, A., Zorzano, A., and Palacin, M. Heteromeric amino acid transporters: biochemistry, genetics, and physiology. *Am. J. Physiol. Renal Physiol.* 281:F995, 2001.

directs the complex to the luminal membrane while SLC3A2 determines contraluminal location. Loss-of-function mutations of either subunit lead to a transport defect. The ability to form different combinations of heavy and light subunits in different tissues explains the large variability observed for the properties and specificity of amino acid transport.

Di- and tri-peptides are cotransported with H^+ and thus are energized through the proton electrochemical gradient across the luminal membrane (PEPT1, or SLC15A1). This H^+ electrochemical gradient is established by Na^+/H^+ exchange and is thus indirectly powered by Na^+/K^+-exchanging ATPase. The dipeptide transporter also accepts β-lactam antibiotics (aminopenicillins) and is important for absorption of orally administered antibiotics of this class.

25.5 • DIGESTION AND ABSORPTION OF CARBOHYDRATES

Disaccharides and Polysaccharides Require Hydrolysis

Dietary carbohydrates provide a major portion of the daily caloric requirement. They consist of mono-, di-, and polysaccharides (Table 25.9). Major carbohydrates in Western diets are sucrose, starch, and lactose. Monosaccharides, such as glucose and fructose, are absorbed directly. Disaccharides require enzymes of the small intestinal surface for hydrolysis into monosaccharides, whereas polysaccharides depend on pancreatic amylase and intestinal surface enzymes for digestion (Figure 25.25).

Starch, a major nutrient, is a plant storage polysaccharide of over100 kDa. It is a mixture of linear chains of glucose molecules linked by α-1,4-glucosidic bonds (**amylose**) and of branched chains with branch points of α-1,6-glucosidic bonds (amylopectin). The ratio of branch points to 1,4-glucosidic bonds is about 1:20. Glycogen is the animal storage polysaccharide and similar in structure to amylopectin, except that the number of branch points is greater in glycogen.

Hydrated starch and glycogen are digested by the endosaccharidase **α-amylase** of saliva and pancreatic juice (Figure 25.26). Hydration of the polysaccharides occurs during heating and is essential for efficient digestion. Amylase is specific for internal α-1,4-glucosidic bonds; α-1,6 bonds are not attacked nor are α-1,4 bonds of glucose units that serve as branch points. Pancreatic amylase is secreted in large excess relative to starch intake and is more important for digestion than the salivary enzyme. The products are mainly the disaccharide **maltose**, the trisaccharide maltotriose, and the so-called α-limit dextrins that contain on average eight glucose units with one or more α-1,6-glucosidic bonds.

CLINICAL CORRELATION 25.6

Neutral Amino Aciduria: Hartnup Disease

Hartnup disease (OMIM 234500) is an autosomal recessive defect of the Na^+-coupled transporter SCL6A19 that mediates active absorption of neutral amino acids from the lumen of the small intestine and the proximal tubule. Therefore, all patients have neutral amino aciduria. The disease was first described in the family that gave the disease its name as an association of neutral amino aciduria with a pellagra-type skin rash and episodes of cerebellar ataxia. The latter two symptoms are expressions of tryptophan deficiency in plasma and bacterial degradation products of tryptophan in the intestine, respectively. Pellagra-like features (p. 785), point to a decreased availability of tryptophan for conversion to nicotinamide. The clinical symptoms are variable and depend on the amount of protein in the diet. The variability indicates the existence of compensatory mechanisms for neutral amino acid absorption and subsequent studies revealed the existence of intestinal and renal transporters for di- or tripeptides, PEPT1 and PEPT2, respectively. PEPT1 (SLC15A1) is the major intestinal transporter for absorption of small peptide products of digestion.

TABLE 25.10 • Saccharidases of the Surface Membrane of Small Intestine

Enzyme	*Specificity*	*Natural Substrate*	*Product*
exo-1,4-α-Glucosidase (glucoamylase)	α-(1 → 4)Glucose	Amylose	Glucose
Oligo-1,6-glucosidase (isomaltase)	α-(1 → 6)Glucose	Isomaltose, α-dextrin	Glucose
α-Glucosidase (maltase)	α-(1 → 4)Glucose	Maltose, maltotriose	Glucose
Sucrose-α-glucosidase (sucrase)	α-Glucose	Sucrose	Glucose, fructose
α,α-Trehalase	α-(1 → 1)Glucose	Trehalose	Glucose
β-Glucosidase	β-Glucose	Glucosylceramide	Glucose, ceramide
β-Galactosidase (lactase)	β-Galactose	Lactose	Glucose, galactose

Final hydrolysis of di- and oligosaccharides to monosaccharides is carried out by enzymes on the luminal surface of small intestinal epithelial cells (Table 25.10). The surface oligosaccharidases are exoenzymes that cleave off one monosaccharide at a time from the nonreducing end. The capacity of α-glucosidases is normally much greater than needed for completion of digestion of starch. Similarly, there is usually excess capacity for **sucrose** (table sugar) hydrolysis. In contrast, **β-galactosidase** (**lactase**) for hydrolysis of **lactose**, the major milk carbohydrate, can be rate limiting in humans (Clin. Corr. 25.7).

Di-, oligo-, and polysaccharides not hydrolyzed by α-amylase and/or intestinal surface enzymes cannot be absorbed; therefore they reach the lower tract of the intestine, which from the lower ileum on contains bacteria. Bacteria can utilize many of these remaining car-

bohydrates because they possess many more types of saccharidases than humans. Monosaccharides released by bacterial enzymes are predominantly metabolized anaerobically by the bacteria themselves, resulting in degradation products such as short-chain fatty acids, lactate, hydrogen gas (H_2), methane (CH_4), and carbon dioxide (CO_2). In excess, these compounds can cause fluid secretion, increased intestinal motility, and cramps, either because of increased intraluminal osmotic pressure and distension of the gut or because of a direct irritant effect by the bacterial degradation products on the intestinal mucosa.

The flatulence that follows ingestion of leguminous seeds (beans, peas, and soy) is caused by oligosaccharides that cannot be hydrolyzed by human intestinal enzymes. The seeds contain modified sucrose to which one or more galactose moieties are linked. The glycosidic bonds of galactose are in the α configuration, which can be split only by bacterial enzymes. The simplest sugar of this family is raffinose. Trehalose is a disaccharide that occurs in young mushrooms and requires a special **disaccharidase**, **trehalase**, for digestion (see Table 25.9, p. 1048).

Monosaccharide Transporters

The major monosaccharides produced by digestion of di- and polysaccharide are D-glucose, D-galactose, and D-fructose. At least two monosaccharide transporters catalyze monosaccharide uptake from the intestinal lumen into the lining epithelial cells: (1) a Na^+-monosaccharide cotransporter (SGLT1) that mediates active uptake of D-glucose and D-galactose into cells and (2) a Na^+-independent, facilitative monosaccharide transporter with specificity for D-fructose (GLUT5) (p. 489). Another facilitative monosaccharide transporter (GLUT2) accepts all three monosaccharides and is present in the contraluminal plasma membrane. The physiological role of GLUT2 is to facilitate exit of monosaccharides from cells into the interstitial and capillary compartments, thereby completing the absorption process (Figure 25.25, p. 1050). GLUT2 is a member of the widely distributed GLUT family of transporters and present in tissues such as intestine, liver, and kidney that absorb or produce glucose and release it into blood. Properties of intestinal SGLT1 and of GLUT2 are compared in Table 25.11.

25.6 • DIGESTION AND ABSORPTION OF LIPIDS

Digestion of Lipids Requires Overcoming Their Limited Water Solubility

An adult human ingests about 60–150 g of lipid per day. Triacylglycerols constitute more than 90% of this intake. The rest is made up of phospholipids, cholesterol, cholesteryl esters, and free fatty acids. In addition, 1–2 g of cholesterol and 7–22 g of phosphatidylcholine (lecithin) are secreted each day by the liver and reach the small intestine with bile.

The poor water solubility of lipids presents problems for digestion because substrates are not easily accessible to the digestive enzymes in the aqueous phase. In addition, most products of lipid digestion are themselves lipids with poor water solubility so they tend to form aggregates that hinder effective absorption. These problems are overcome by (1) generating/secreting surfactive molecules that increase the interfacial area between aqueous

TABLE 25.11 • Characteristics of Glucose Transporters in the Plasma Membranes of Enterocytes

Characteristic	*Luminal*	*Contraluminal*
Designation	SLC5A1 (SGLT1)	SLC2A2 (GLUT2)

Good substrates	D-Glc, D-Gal, α-methyl-D-Glc	D-Glc, D-Gal, D-Man, 2-deoxy-D-Glc, D-Fru

CLINICAL CORRELATION 25.7

Disaccharidase Deficiency

Intestinal disaccharidase deficiencies are encountered relatively frequently in humans. Deficiency can be present in one or several enzymes for a variety of reasons (genetic defect, physiological decline with age, or the result of injuries to the mucosa). Lactase is the most commonly deficient enzyme. Absolute or relative deficiency is experienced as milk intolerance. Consequences of a lack of lactose hydrolysis in the upper small intestine are inability to absorb lactose, which then becomes available for bacterial fermentation in the lower small intestine. Bacterial fermentation produces gas (distension of gut and flatulence) and osmotically active solutes that draw water into the intestinal lumen (diarrhea). Lactose in yogurt has already been hydrolyzed during the fermentation process of making yogurt. Thus, individuals with lactase deficiency can usually tolerate yogurt better than unfermented dairy products. Lactase is commercially available to pretreat milk so that its lactose is hydrolyzed.

Swallow, D. M. Genetics of lactase persistence and lactose intolerance. *Annu. Rev. Genetics* 37:197, 2003; Solomons, N. W. Fermentation, fermented foods and lactose intolerance. *Eur. J. Clin. Nutrition* 56:S50, 2002; and Lactose intolerance: http://digestive.niddk.nih.gov/ddiseases/pubs/lactoseintolerance/and http://www.lactose.net.

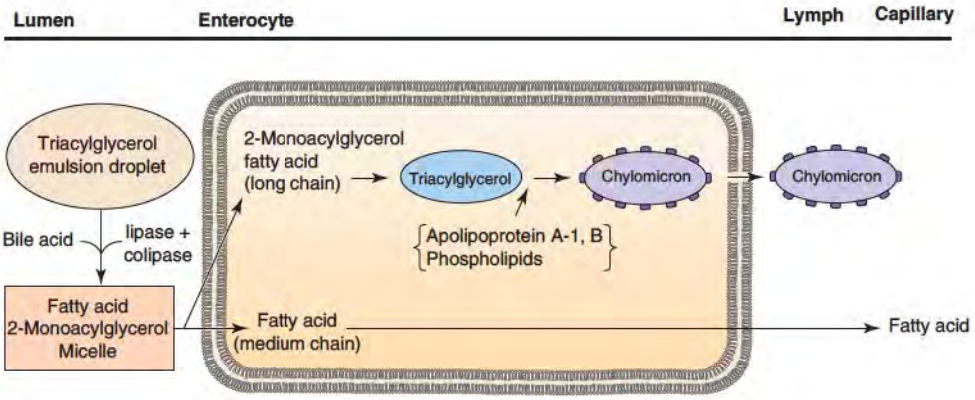

Figure 25.27 Digestion and absorption of lipids.

and lipid phases and (2) "solubilization" of lipids with detergents. Thus changes in the physical state of lipids are intimately connected to chemical changes during digestion and absorption.

At least five phases of lipid digestion can be distinguished (Figure 25.27): (1) hydrolysis of triacylglycerols to free fatty acids and monoacylglycerols within the lumen of the gastrointestinal tract; (2) solubilization of lipids by detergents (bile acids) and transport from the intestinal lumen toward the surface of the lining epithelial cells; (3) uptake of free fatty acids and monoacylglycerols into the epithelial cell and synthesis to triacylglycerols; (4) packaging of newly synthesized triacylglycerols into special lipid-rich globules, called **chylomicrons**; and (5) exocytosis of chylomicrons from the intestinal epithelial cells into lymph.

Lipids Are Digested by Gastric and Pancreatic Lipases

Hydrolysis of triacylglycerols is initiated in the stomach by lingual and gastric **lipases**. Gastric digestion can account for up to 30% of total triacylglycerol hydrolysis. However, the rate of hydrolysis is slow because ingested triacylglycerols form lipid droplets with a limited interfacial area to which lipases can adsorb. Nevertheless, some lipase molecules adsorb and hydrolyze triacylglycerols into fatty acids and diacylglycerols (Figure 25.28), which converts a water-immiscible compound to products with both polar and nonpolar groups. Such surfactive products spontaneously adsorb to water–lipid interfaces and confer a hydrophilic surface to lipid droplets, thereby allowing an increase in interfacial area. At constant volume of the lipid phase, any increase in interfacial area causes dispersion of the lipid phase into smaller droplets (emulsification) and provides more sites for adsorption of lipase molecules. The dispersion of lipids into smaller droplets is also aided by the peristaltic and churning movements of the stomach. Gastric chyme that is released into the duodenum generally contains only **emulsion droplets** of less than two millimeter in diameter.

Pancreatic lipase is the major enzyme for triacylglycerol hydrolysis (Figure 25.29). It hydrolyzes esters in the α-position of glycerol and prefers long-chain fatty acids (longer than 10 carbon atoms). The products are free fatty acids and β-monoacylglycerols. Hydrolysis occurs at the water–lipid interface of emulsion droplets or bile acid **micelles** (p. 465). However, bile acids, which are present in the intestinal lumen, inhibit purified lipase, indi-

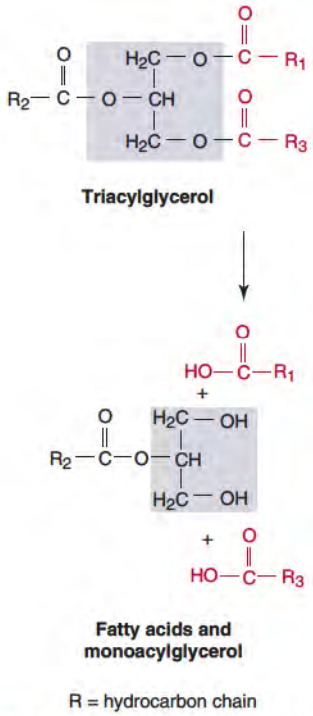

Figure 25.29 Mechanism of action of lipase.

CLINICAL CORRELATION 25.8

Pharmacological Interventions to Prevent Fat Absorption and Obesity

Obesity is a major problem in modern society as food is generally very abundant. Therefore, interest in weight reduction is widespread. Two commercial products exploit the understanding of intestinal lipid absorption for this purpose. Olestra® is a commercial lipid produced by esterification of natural fatty acids with sucrose instead of glycerol (Figure *a*). With six to eight fatty acids covalently linked to sucrose the compound tastes like natural lipids, however, it cannot be hydrolyzed and is excreted unchanged.

Pancreatic lipase is the major enzyme that hydrolyzes dietary triacylglycerols to absorbable fatty acids and glycerol. Orlistat® (Figure *b*) is a non-hydrolyzable analog of a triacylglycerol and a powerful inhibitor of pancreatic lipase. Ingestion of Orlistat® slows down lipid digestion and hence absorption. Benefits derive from some lipid excretion, but also from release of a hormone (peptide YY) when lipids reach the terminal small intestine and colon. Peptide YY is postulated to increase the sensation of satiety and slow down the transit time of food through the gastrointestinal tract.

Olestra is a registered trademark of Proctor and Gamble, and Orlistat of Roche, Basel, Switzerland.

cating a more complex situation *in vivo*. Pancreatic juice contains a small protein (12 kDa) that binds to lipase and the micellar surface and prevents inhibition of lipase by bile acids. This protein has been termed **colipase**. It is secreted as procolipase and depends on tryptic removal of an NH_2-terminal decapeptide for activation. Clin. Corr. 25.8 describes two commercial strategies to reduce lipid absorption as a means to decrease obesity.

Pancreatic juice also contains an unspecific lipid esterase, which acts on cholesteryl esters, monoacylglycerols, or other lipid esters, such as esters of vitamin A with carboxylic acids. In contrast to triacylglycerol lipase, this esterase requires bile acids for activity.

Phospholipids are hydrolyzed by specific phospholipases. Pancreatic juice is especially rich in prophospholipase A_2 (Figure 25.30). Like other pancreatic proenzymes, it is activated by trypsin. Phospholipase A_2 requires bile acids for activity.

Bile Acid Micelles Solubilize Lipids during Digestion

Bile acids are biological detergents synthesized by liver and secreted as conjugates of glycine or taurine with the bile into the duodenum. At physiological pH, they are

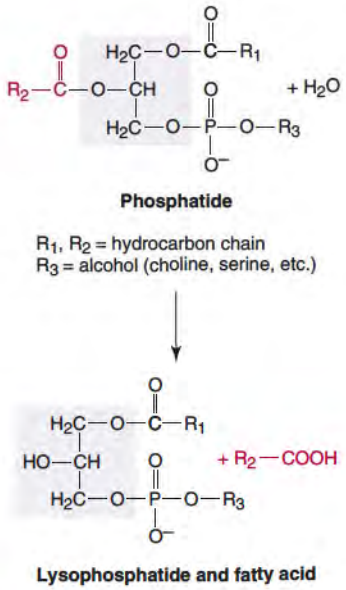

Figure 25.30 Mechanism of action of phospholipase A_2.

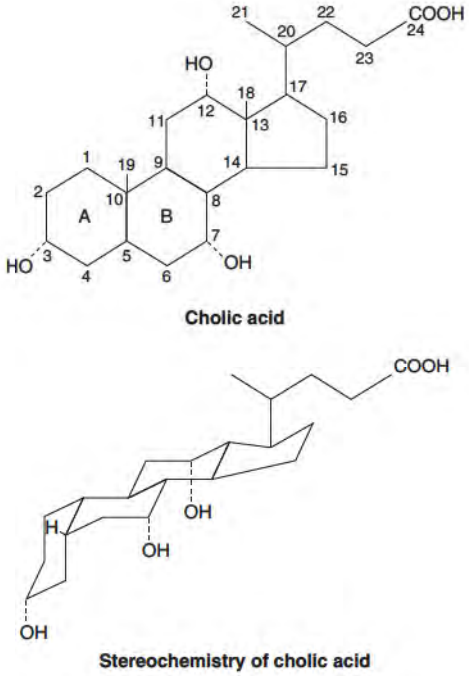

Figure 25.31 Cholic acid, a bile acid.

ionized (anions) so that the terms *bile acids* and *bile salts* are often used interchangeably (Figure 25.31). Bile acids reversibly form thermodynamically stable aggregates, called micelles (p. 465), at concentrations above 2–5 mM and at pH values above the pK (Table 25.12). In other words, bile acid molecules in micelles are in equilibrium with those free in solution. The minimal concentration of a bile acid necessary for micelle formation is its **critical micellar concentration** (Figure 25.32). As equilibrium structure, micelles reach a well-defined size (≤ 4 nm) that depends on the concentrations of bile acids and other lipids but not on mechanical dispersion forces. The difference

between micelles and emulsion droplets becomes obvious on ultracentrifugation of duodenal content: Emulsion droplets collect at the top as oily layer while micelles stay in the clear or slightly turbid subphase.

Major driving forces for micelle formation are the sequestering of apolar, hydrophobic groups away from water and the interaction of polar groups with water molecules. Bile acids have a fused ring system, which is hydrophobic on one side and hydrophilic on the other, and, in addition, a highly polar head group. The geometry of polar and apolar regions in bile acids is very different from that of ionized fatty acids (soap) or phospholipids, and hence their micelles have different geometries. For example, fatty acid or phospholipid micelles are spherical whereas pure bile acid micelles form "sandwich "structures" (Figure 25.33). Micelles, including the ones formed by bile acids, can solubilize other lipids, such as phospholipids and fatty acids, and form "mixed" micelles. Liver actually secretes bile acids together with phospholipids (mainly phosphatidyl choline) and cholesterol. The structure of these mixed micelles of bile acids and phospholipids is that of a rod, in which phospholipids are arranged radially along the length of the rod with the polar groups oriented outward and bile acids acting as wedge between the phospholipids head groups, also with their polar groups facing outward. The rods are capped by the polar groups of bile acids and phospholipids, and they become longer with increasing ratio of phospholipids to bile acids (Figure 25.34). Within the mixed phospholipid-bile acid micelles, other water-insoluble lipids, such as cholesterol, can be accommodated and thereby "solubilized." There are limits to the amounts of phospholipids and cholesterol that can be solubilized by physiological concentrations of bile acids; excess phospholipids form small unilamellar vesicles (20–60 nm in diameter), which can accommodate also some cholesterol. Excess cholesterol that cannot be solubilized by micelles or vesicles has a tendency to come out of solution by crystallization (Clin. Corr. 25.9).

During digestion of triacylglycerol, free fatty acids and monoacylglycerols are released at the surface of fat emulsion droplets and micelles. In contrast to triacylglycerols, which are water insoluble, free fatty acids and monoacylglycerols are slightly water soluble, and molecules at the surface equilibrate with those in solution and in bile acid micelles. Thus the products of triacylglycerol hydrolysis are continually transferred from emulsion droplets to the micelles (see Figure 25.28, p. 1052).

Micelles are the major vehicle for transferring lipids from the lumen to the mucosal surface where absorption occurs. Because the fluid layer near the cell surface is poorly mixed, the major mechanism for solute flux across this unstirred fluid layer is diffusion

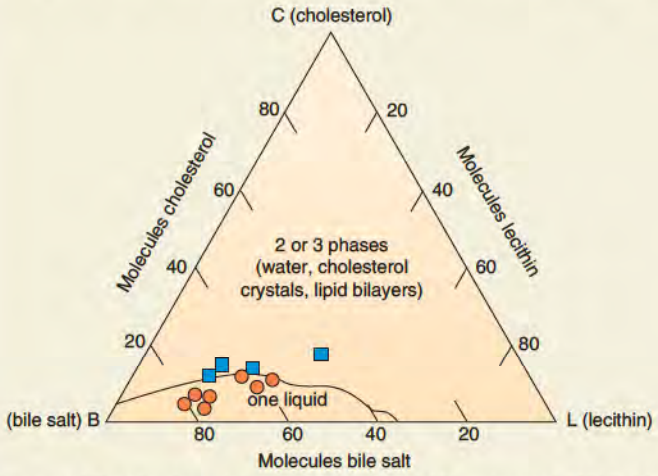
CLINICAL CORRELATION 25.9

Cholesterol Stones

Liver secretes phospholipids, cholesterol, and bile acids into bile. Because of the limited solubility of cholesterol, its secretion can lead to cholesterol stone formation in the gallbladder. Stone formation is a relatively frequent occurrence; up to 20% of North Americans develop stones during their lifetime. Cholesterol is practically insoluble in aqueous solutions. However, it can be incorporated into mixed phospholipid–bile acid micelles and thereby "solubilized" (see figure). Liver can produce bile that is supersaturated with respect to cholesterol. Excess cholesterol tends to come out of solution and crystallize. Supersaturated bile is considered lithogenic, that is, stone forming. Crystal formation usually occurs in the gallbladder, rather than the hepatic bile ducts, because contact time between bile and any crystallization nuclei is greater in the gallbladder. In addition, bile is concentrated here by absorption of electrolytes and water. The bile salts chenodeoxycholate (= chenate, Table 25.12) and its stereoisomer ursodeoxycholate (7-hydroxy group in β position) are available for oral use to dissolve gallstones. Their ingestion increases the bile acid pool and secretion rates by the liver, thereby reducing the cholesterol concentration of bile and allowing cholesterol from gall stones to be solubilized.

The tendency to secrete bile supersaturated with respect to cholesterol is inherited, occurs more frequently in females than in males, and is associated with obesity. Supersaturation also appears to be a function of the size and nature of bile acid pool and secretion rate.



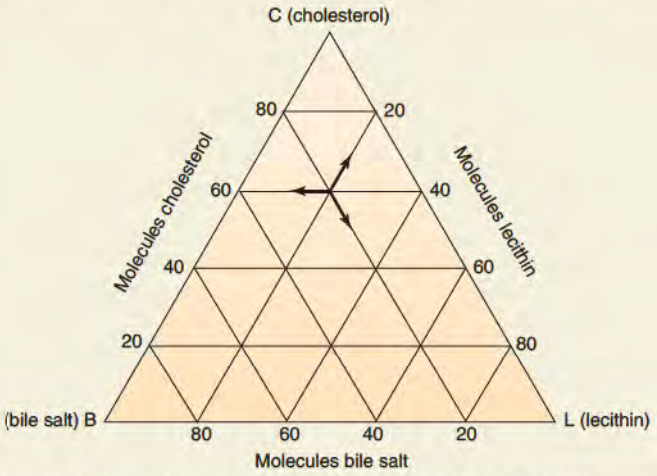


Diagram of the physical states of mixtures of 90% water and 10% lipid. The 10% lipid is made up of bile acids, phosphatidylcholine (lecithin), and cholesterol, and the triangle represents all possible ratios of the three lipid constituents. Each point within the triangle corresponds to a particular composition of the three components, which can be read off the graph as indicated; each point on one of the sides corresponds to a particular composition of just two components. The left triangle contains the composition of gallbladder bile samples from patients without stones (red o) and with cholesterol stones (blue □). Lithogenic bile has a composition that falls outside the "one liquid" area in the lower left corner.

down the concentration gradient. The delivery rate of solutes at the cell surface by diffusion is proportional to the concentration difference between luminal bulk phase and cell surface. Diffusion through an unstirred layer becomes a problem for sparingly soluble or insoluble nutrients, in that reasonable concentration gradients and delivery rates cannot be achieved. Bile acid micelles overcome this problem for lipids by increasing their effective concentration in the unstirred layer. The increase in rate of transport is nearly proportional to the increase in effective concentration and can be 1000-fold over that of individually solubilized fatty acids, in accordance with the different water solubility of fatty acids as micelles and as individual molecules. This relationship between flux and effective concentration holds because the diffusion constant is only slightly smaller for micelles than for lipid molecules in solution. In absence of bile acids, absorption of triacylglycerols does not completely stop, but efficiency is drastically reduced. Residual absorption depends on the slight water solubility of free fatty acids and monoacylglycerols. Unabsorbed lipids reach the lower intestine where a

small part can be metabolized by bacteria. The bulk of unabsorbed lipids, however, is excreted with the stool (steatorrhea).

Micelles also transport cholesterol and the lipid-soluble vitamins A, D, E, and K through the unstirred fluid layers. Bile acid secretion is essential for their absorption.

Most Absorbed Lipids Are Incorporated into Chylomicrons

Uptake of lipids by intestinal epithelial cells occurs by diffusion through the plasma membrane. In addition, long-chain fatty acid uptake is enhanced by a transporter (FATP4, or SLC27A4). Absorption is virtually complete for fatty acids and monoacylglycerols, which are slightly water soluble. It is less efficient for water-insoluble lipids. For example, only 30%–40% of the dietary cholesterol is usually absorbed (Clin. Corr. 25.10).

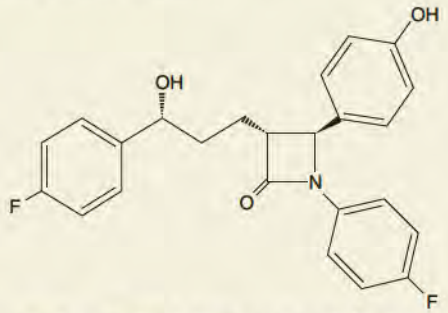
Within the absorbing epithelial cells, the fate of fatty acids depends on chain length (Figure 25.27, page 1052). Fatty acids of short and medium chain length ($\leq$ 10 carbon atoms) pass into portal blood without modification. Long-chain fatty acids ($>$ 12 carbon atoms) or their monoacylglycerols become bound to a cytosolic fatty acid-binding protein (intestinal FAB, FABP2) and are transported to the endoplasmic reticulum, where they are converted into triacylglycerols. Glycerol for this process is derived from the absorbed 2-monoacylglycerols and, to a minor degree, from glucose. Cholesterol is esterified by cholesterol acyltransferase. The newly synthesized triacylglycerols and cholesteryl esters form lipid globules into which phospholipids and **apolipoproteins** adsorb. The globules are called chylomicrons because they can grow up to several micrometers in diameter and leave the intestine through lymph vessels (chyle is milky lymph; the name is derived from the Greek *chylos*, which means "juice"). Chylomicrons are synthesized within the lumen of the endoplasmic reticulum from which they migrate through the Golgi and then in vesicles to the contraluminal membrane. They are released into the intercellular space by fusion of these vesicles with the plasma membrane. Interestingly, chylomicrons do not enter the capillary space and the portal vein; instead they travel through the intestinal lymph vessels (or lacteals) and the thoracic duct to the systemic venous system. The

CLINICAL CORRELATION 25.10

Cholesterol Absorption

Intestinal absorption of dietary and biliary cholesterol occurs via an incompletely understood transport system across the brush border membrane and inside enterocytes. The proteins scavenger receptor B-I (SCARB1) and CD36 appear to mediate brush border uptake of cholesterol, while the Niemann–Pick C1-like protein (NPC1L1) appears to serve to conduct cholesterol to intracellular sites. Knockout of NPC1L1 reduces cholesterol absorption by $>$ 70%. The drug ezetimibe (structure shown here) is approved by the Federal Drug Administration for adjunct therapy with statins to lower serum cholesterol levels. This drug is taken up in the intestine and resecreted after esterification with glucuronic acid in the liver. The glucuronated form is a potent inhibitor of intestinal cholesterol uptake.

A portion of cholesterol taken up by cells is actually returned to the lumen mediated by an ABC transporter (p. 494) consisting of two half-transporters (ABCG5 and ABCG8). The export of sterols by the ABC transporters is particularly important for rejecting plant sterols, and normally, plant sterols are not found in serum. Loss-of-function mutations in either of the half-transporters are associated with increased uptake and plasma levels of the plant sterol sitosterol (phytosterolemia or sitosterolemia).



Structure of ezetimibe [(3*R*,4*S*)-1-(4-fluorophenyl)-3-((3*S*)-3-(4-fluorophenyl)-3-hydroxypropyl)-4-(4-hydroxyphenyl)-2-azetidinone].

Ezetimibe is sold in the U.S.A. as prescription drug ZETIA®, which is a registered trademark of MSP Singapore Company, LLC, and marketed by Merck/Schering-Plough Pharmaceuticals.

CLINICAL CORRELATION 25.11

A-β-Lipoproteinemia

Apolipoprotein B (apoB) is a key component of lipoproteins: A 48-kDa splice variant is used by intestinal epithelial cells in the assembly of chylomicrons, while a 100-kDa variant is important for the assembly of very low density lipoproteins (VLDLs) by the liver. ApoB serves as acceptor for newly synthesized triglycerides that are transferred by microsomal triglyceride transfer protein. Mutations in the gene for this latter enzyme are the basis for a-β-lipoproteinemia characterized by the absence of liver and intestinal lipoproteins from plasma. Serum cholesterol is extremely low in this condition. A-β-lipoproteinemia is associated with severe malabsorption of triacylglycerol and lipid-soluble vitamins (especially tocopherol and vitamin E) and accumulation of apoB in enterocytes and hepatocytes.

Fisher, E. A., and Ginsberg, H. N. Complexity in the secretory pathway: The assembly of apolipoprotein B-containing lipoproteins. *J. Biol. Chem.* 277:17377, 2002; and Hussain, M. M., Iqbal, J., Anwar, K., Rava, P., and Dai, K. Microsomal triglyceride transfer protein: a multifunctional protein. *Frontiers in Bioscience* 8: s500, 2003.

intestinal apolipoproteins are designated A-1 and B48 (Clin. Corr. 25.11); they are different from those of the liver with similar function (p. 724).

While dietary medium-chain fatty acids reach the liver directly with the portal blood, the long-chain fatty acids first reach adipose tissue and muscle via the systemic circulation before coming into contact with the liver. Fat and muscle cells take up large amounts of dietary lipids for storage or metabolism. A bypass of the liver may have evolved to protect this organ from lipid overload after a meal.

The differential handling of medium- and long-chain fatty acids by intestinal cells can be exploited to provide the liver with high-caloric nutrients in the form of fatty acids. Short- and medium-chain fatty acids smell and taste rancid and are not very palatable; however, triacylglycerols that contain these fatty acids are quite palatable and can be used as part of the diet. Short-chain fatty acids are produced physiologically from residual carbohydrates, particularly in the colon, by bacteria.

25.7 • BILE ACID METABOLISM

Bile Acid Chemistry and Synthesis

Bile acids are synthesized in liver cells (hepatocytes) from cholesterol, secreted into bile together with phospholipids, and modified by bacterial enzymes in the intestinal lumen. Primary bile acids synthesized by the liver are **cholic** and **chenodeoxycholic** (chenic) acid. **Secondary bile acids** are derived from primary bile acids by bacterial reduction in position 7 of the ring structure, resulting in **deoxycholate** and **lithocholate**, respectively (see Figure 18.42, p. 728 for structures).

Primary and secondary bile acids are reabsorbed by the intestine (lower ileum) into portal blood, taken up by liver cells, and then resecreted into bile. In liver cells, primary as well as secondary bile acids are linked to either glycine or taurine via an isopeptide bond. These glyco- and tauroconjugates constitute the forms that are secreted into bile. Conjugation is important for converting the mildly acidic carboxyl group to more polar and acidic ones, which is expressed as lower pK value and implies ionization over a wider pH range (Table 25.12). The conjugation is partially reversed within the intestinal lumen by hydrolysis of the isopeptide bond.

Bile Acid Transport

The total amount of conjugated and unconjugated bile acids secreted per day is 20–30 g for an adult. However, the body maintains a pool of only 3–5 g. A small pool is advantageous because bile acids become toxic at high concentrations due to their detergent properties, for example, through their ability to lyse cells. Therefore, to achieve the observed secretion rates, bile acids are reabsorbed by ileal enterocytes, recirculated to the liver and resecreted 4 to 10 times per day. The secretion and reuptake is referred to as the enterohepatic circulation (Figure 25.35). Reabsorption of bile acids is quite efficient since only about 0.8 g of bile acids each day is excreted with the feces. Serum levels of bile acids normally vary with the rate of reabsorption and therefore are highest during a meal. Cholate, deoxycholate, chenodeoxycholate, and their conjugates continuously participate in the enterohepatic circulation. In contrast, most of the lithocholic acid produced by bacterial enzymes is sulfated during the next passage through the liver. The sulfate ester of lithocholic acid is not reabsorbed and therefore excreted in the feces. The transporters mediating enterohepatic circulation of bile acids are shown in Figure 25.36. Ileal absorption of bile acids is mediated by secondary active transport via a luminal Na^+ bile acid cotransport system (apical sodium-dependent bile acid transporter, ASBT, or SLC10A2) with a stoichiometry of 2:1 for Na^+ to bile acid. Bile acids are moved from ileal enterocytes into blood predominantly by exchange for another anion via a specific anion exchanger consisting of two different gene products (OSTα–OSTβ). Uptake of bile acids from blood by liver cells is predominantly by secondary active Na^+-bile acid cotransport (Na^+ taurocholate co-transporting polypeptide, NTCP, or SLC10A1). Unconjugated bile acids can also be taken up from blood by a family of Na^+-independent, organic anion transporters (SLC01A2, SLC01B1, SLC01B3, formerly SLC21 family). In contrast,

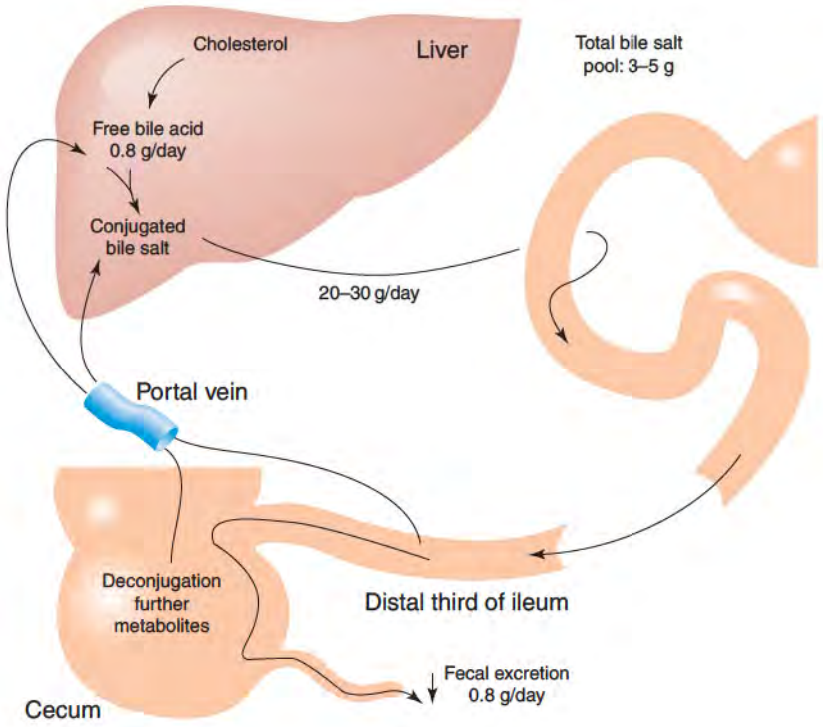

Figure 25.35 Enterohepatic circulation of bile acids. Redrawn from Clark, M. L., and Harries, J. T. In McColl. I., and Sladen, G. E. (Eds.), *Intestinal Absorption in Man.* New York: Academic Press, 1975, 195.

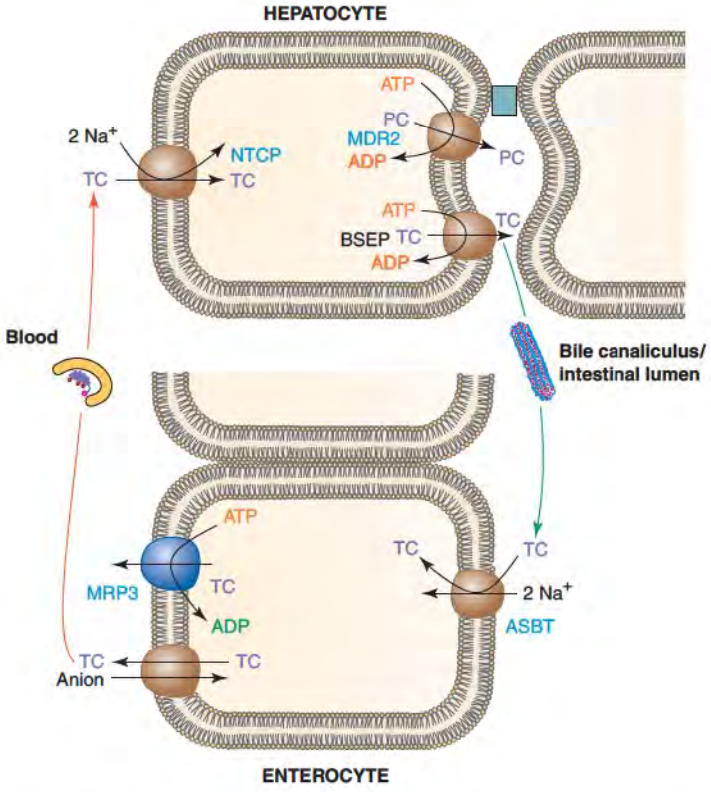

Figure 25.36 Transporters for taurocholate (TC) and phosphatidyl choline (PC) during enterohepatic circulation.

secretion of bile acids by liver cells across the canalicular plasma membrane into bile is by primary active transport (**Bile Salt Export Pump**, **BSEP**, or ABCB11, another member of the ABC transporters; p. 494). Phospholipids, which are secreted simultaneously with bile acids, are transported by the pump MDR2 (ABCB4). To achieve reasonable total bile acid concentrations within cells and in plasma while maintaining low free concentrations to prevent detergent action, bile acids are bound to specific binding proteins in the cytosol of hepatocytes and enterocytes. Albumin functions as such a binding protein for bile acids in plasma.

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. Active forms of most enzymes that digest food may normally be found in all of the following except
- **A.** in soluble form in the lumen of the stomach.
- **B.** in the saliva.
- **C.** attached to the luminal surface of the plasma membrane of intestinal epithelial cells.
- **D.** dissolved in the cytoplasm of intestinal epithelial cells.
- **E.** in zymogen granules of pancreatic exocrine cells.

2. Histamine is a potent secretagogue of
- **A.** amylase by the salivary glands.
- **B.** HCl by the stomach.
- **C.** gastrin by the stomach.
- **D.** hydrolytic enzymes by the pancreas.
- **E.** $NaHCO_3$ by the pancreas.

3. The contraluminal plasma membranes of small intestinal epithelial cells contain
- **A.** aminopeptidases.
- **B.** Na^+/K^+-exchanging ATPase.
- **C.** disaccharidases.
- **D.** GLUT5.
- **E.** Na^+-monosaccharide transport (SGLT1).

4. The enterohepatic circulation of bile acids
- **A.** necessitates participation of secondary active Na^+-bile acid cotransport.
- **B.** results in the reabsorption of only the primary bile acids.
- **C.** maintains the body pool of bile acids at 20–30 g.
- **D.** maintains serum levels of bile acids at a constant value.
- **E.** uses the same transport mechanism to secrete bile acids from the liver to bile as from the enterocyte to the blood.

5. Epithelial cells of the lower ileum express a Cl^-/HCO_3^- exchange coded for by the DRA gene. These cells
- **A.** mediate an electrogenic exchange of 2 luminal Na^+ for 1 cytosolic H^+.
- **B.** absorb Cl^- into the cell in exchange for HCO_3^- moving into the lumen.
- **C.** prevent a metabolic acidosis due to loss of HCl.
- **D.** mediate Na^+ movement out of the cell as Cl^- moves into the cell.
- **E.** mediate Na^+ movement into the cell via a Na^+ channel.

6. Peptidases involved in protein digestion
- **A.** are all endopeptidases.
- **B.** must have a neutral pH.
- **C.** are synthesized in the stomach and pancreas as proenzymes.
- **D.** each have a different activator.
- **E.** all have an essential serine at the active site.

Questions 7 and 8: A young woman finds that every time she eats dairy products she feels highly uncomfortable. Her gut becomes distended, and she has gas and, frequently, diarrhea. A friend suggested that she try yogurt to get calcium, and she is able to tolerate that. These symptoms do not appear when she eats food other than dairy products. Like many adults, she is deficient in an enzyme required for carbohydrate digestion.

7. The most likely enzyme in which she is deficient is
- **A.** α-amylase.
- **B.** β-galactosidase (lactase).
- **C.** α-glucosidase (maltase).
- **D.** sucrose-α-glucosidase (sucrase).
- **E.** α,α-trehalase.

8. Monosaccharides are absorbed from the intestine
- **A.** by a Na^+-dependent cotransporter for glucose and galactose.
- **B.** by a Na^+-independent facilitated transport for fructose.
- **C.** by a Na^+-independent transporter (GLUT2) across the contraluminal membrane.
- **D.** against a concentration gradient if the transporter is Na^+ dependent.
- **E.** all of the above.

Questions 9 and 10: A woman comes to the emergency room with severe abdominal pain in the right upper quadrant as well as severe pain in her back. The pain began several hours after she consumed a meal of fried chicken and cheese-coated french fries. The symptoms indicated gallstones, and this was confirmed by ultrasound. Although surgery might be necessary in the future, conservative treatment was tried first. She was instructed to limit fried foods and high-fat dairy products. She was also given chenodeoxycholate to take orally to try to dissolve the gallstones.

9. Cholesterol stones
- **A.** usually form during passage of bile through the hepatic bile duct.
- **B.** occur when the mixed phospholipid-bile acid micelles are very high in phospholipid.
- **C.** can be dissolved by excess bile acid micelles.
- **D.** rarely occur because cholesterol is not a normal part of bile.
- **E.** are a necessary part of lipid digestion.

10. In the metabolism of bile acids,
- **A.** the liver synthesizes cholic and deoxycholic acids, which are primary bile acids.
- **B.** secondary bile acids are produced by conjugation of primary acids to glycine or taurine.
- **C.** 7-dehydroxylation of bile acids by intestinal bacteria produces secondary bile acids, which have similar detergent and physiological properties as primary bile acids.
- **D.** daily bile acid secretion by the liver is approximately equal to daily bile acid synthesis.
- **E.** conjugation reduces the polarity of bile acids, enhancing interaction with lipids.

Questions 11 and 12: Hartnup disease is a genetic defect in an amino acid transport system. The specific defect is in the neutral amino acid transporter in both intestinal and renal epithelial cells. Clinical symptoms of the disease result from deficiencies of essential amino acids and nicotinamide (because of a deficiency specifically of tryptophan).

11. In addition to tryptophan, which of the following amino acids is likely to be deficient in Hartnup disease?
- **A.** Aspartate
- **B.** Leucine
- **C.** Lysine
- **D.** Proline
- **E.** All of the above

12. Hartnup disease patients are able to get some of the benefit of the protein they consume because
- **A.** only the neutral amino acid carrier is defective.
- **B.** di- and tripeptides from protein digestion are absorbed by a different carrier (PepT1).
- **C.** their endo- and exopeptidases are normal.
- **D.** all of the above.
- **E.** none of the above.

Problems

13. Using known endo- and exopeptidases, suggest a pathway for the complete degradation of the following peptide:

His-Ser-Lys-Ala-Trp-Ile-Asp-Cys-Pro-Arg-His-His-Ala

14. Certain tissues effect Cl^- secretion via a Cl^- channel (CFTR-cystic fibrosis transmembrane regulatory protein). Cholera toxin abnormally opens the channel leading to a loss of NaCl. A relatively inexpensive way to treat cholera is to administer fluids high in Na^+ and glucose. Why is this effective?

Answers

1. E Zymogen granules contain inactive proenzymes or zymogens, which are not activated until after release from the cell (amylase from the pancreas and salivary glands is an exception).

2. B Its binding to H_2 receptors of the stomach causes HCl secretion. A: Acetylcholine is the secretagogue. C: Gastrin itself is a secretagogue. D: Acetylcholine and cholecystokinin are the secretagogues. E. Secretin is the secretagogue.

3. B Only the contraluminal surface contains the Na^+, K^+-ATPase. All other activities are associated with the luminal surface.

4. A There are two different transporters from lumen to enterocyte and blood to hepatocyte. B: Both primary and secondary bile acids (except lithocholic acid) are reabsorbed. C: The body pool is very low (3–5 g); high concentrations are toxic. D: Levels fluctuate and are highest during a meal. E: Secretion from liver to bile is a primary active transport.

5. B The proton gradient generated by an electrically neutral Na^+/H^+ exchange drives this. A: The Na^+/H^+ exchange via the expressed NHE3 transporter is electrically neutral. C: Constant loss of HCl leads to a metabolic alkalosis. D: The direction of Na^+ movement is into the cell with subsequent removal by the Na^+/K^+-ATPase. E: This occurs in the large intestine, not here.

6. C Pepsinogen in the stomach and trypsinogen plus others in the pancreas are proenzymes. A: Carboxy- and aminopeptidases are exopeptidases. B: Pepsin is active at pH 2 and lower. D: Trypsin activates chymotrypsinogen, proelastase, and procarboxypeptidase. E: Trypsin, chymotrypsin, and elastase do, but carboxypeptidase has a different mechanism.

7. B Dairy products contain lactose. Undigested lactose is fermented and the products produce the symptoms. Yogurt fermentation hydrolyzes lactose. A, C, and D: Deficiency of any of these would cause problems with most carbohydrates. E: Trehalose is found in mushrooms, not dairy products.

8. E All of these play an important role in absorbing the monosaccharides from digestion. D: This is especially important for the uptake of most of dietary glucose.

9. C Stones occur when bile is supersaturated (> 1:1 ratio of cholesterol/phospholipid). The ingested bile salts increase the bile salt pool and hence bile salt and phospholipid secretion; this lowers the cholesterol/phospholipid ratio. A: Stones usually form in the gallbladder. B: The problem is too little phospholipid relative to cholesterol. D: Actually, stones are relatively common. Cholesterol is a normal component of bile. E: Bile salts are necessary for lipid digestion but stones are not.

10. C Primary bile acids (cholic and chenodeoxycholic acids) are synthesized in liver. In intestine they may be reduced by bacteria to form the secondary bile acids, deoxycholate and lithocholate. D: Only a small fraction of bile acids escapes reuptake; this must be replaced by synthesis. Both primary and secondary bile acids are reabsorbed and recirculated (enterohepatic circulation). E: Both are conjugated to glycine or taurine, increasing their polarity.

11. B Trp shares a carrier with tyr, phe, val, leu, ile, and met. A: Asp is acidic. C: Lysine is basic. D: Proline is an imino acid. All of these use separate carriers.

12. D The body has at least seven transporters for the various classes of amino acids (see question 11). It also has a carrier for di- and tripeptides. C: Since we cannot absorb intact proteins, the presence of the endo- and exopeptidases is essential to generate smaller fragments.

13. Trypsin cleavage gives (a)His-Ser-Lys + (b)Ala-Trp-Ile-Met-Cys-Gly-Pro-Arg + (c) His-His-Ala. Further degradation of (a) is accomplished by elastase and dipeptidase. Further degradation of (b) would start with chymotrypsin and use dipeptidases, tripeptidase, and carboxypeptidase B. To degrade (c) carboxypeptidase A and dipeptidase would be enough. The point is that several peptidases with varying specificities are required.

14. Cholera toxin activates adenylate cyclase leading to elevated cAMP levels and active protein kinase A. In addition to opening the CFTR Cl^{-1} channel, the Na^+/H^+ exchanger is also inhibited and there is a gross NaCl excretion. The Na^+-glucose cotransport is not affected. The presence of glucose allows uptake of Na^+ to replenish body NaCl.

Key Concepts

- Dietary Reference Intakes (DRIs) are quantitative estimates of nutrient intake to be used for planning and assessing diets for healthy people. There is often a fine line between micronutrient sufficiency and toxicity.
- Vitamin A can occur in several forms and can act as an antioxidant, a glycosyl donor, a hormone, or an essential component of the visual cycle.
- Vitamin D regulates cell growth and differentiation, important metabolic processes, and immune function in addition to its role in calcium homeostasis.
- Vitamin E occurs in multiple forms and affects gene expression through cellular redox signaling pathways in addition to its role as an antioxidant.

- Vitamin K is essential for the biological activity of a number of calcium-dependent enzymes, especially those involved in blood clotting and bone metabolism.
- The biological activity and deficiency symptoms of B vitamins are best understood on the basis of their conversion to coenzymes required in key metabolic processes.
- Vitamin C is an antioxidant, is a cofactor for some mixed function oxidases, and aids in iron absorption.
- Both dietary calcium and bone serve as sources of calcium to maintain serum calcium levels required for the activity of some enzymes, blood coagulation, muscle contractility, and nerve function.
- Magnesium is required for neuromuscular transmission and for many enzyme activities, especially those utilizing an ATP–Mg^{++} complex.
- Iron deficiency causes anemia and decreased immunocompetence.

26.1 • INTRODUCTION

Micronutrients play a vital role in human metabolism, as they are involved in almost every biochemical reaction pathway. However, the science of nutrition is concerned not only with the biochemistry of the nutrients but with also whether they are present in adequate amounts in the diet. The American diet is undoubtedly the best it has ever been. Our current food supply provides an abundant variety of foods all year long, and deficiency diseases have become medical curiosities. However, our diet is far from optimal. The old adage is that we can get everything we need from a balanced diet. Unfortunately, many Americans do not consume a balanced diet. Foods of high caloric density and low nutrient density (often referred to as empty calories or junk food) are abundant and popular, and our nutritional status suffers because of these food choices. Obviously then, neither alarm nor complacency is justified. We need to know how to evaluate the adequacy of our diet.

26.2 • ASSESSMENT OF MALNUTRITION

There are three increasingly stringent criteria for measuring **malnutrition**.

1. Dietary intake studies, which are usually based on a 24-h recall, are the least stringent. Twenty-four-h recalls tend to overestimate the number of people with deficient diets. In addition, poor dietary intake alone is usually not a problem in this country unless the situation is compounded by increased need.

2. Biochemical assays, either direct or indirect, are a more useful indicator of nutritional status. At their best, they indicate **subclinical nutritional deficiencies**, which can be treated before deficiency diseases develop. However, all biochemical assays are not equally valid, an unfortunate fact that is not sufficiently recognized. Changes in biochemical parameters due to stress need to be interpreted with caution. The distribution of many nutrients in the body changes dramatically in a stress situation such as illness, injury, and pregnancy. A drop in level of a nutrient in one tissue compartment (usually blood) need not signal a deficiency or an increased requirement. It could simply reflect a normal metabolic adjustment to stress.

3. The most stringent criterion is the appearance of **clinical symptoms**. However, it is desirable to intervene long before symptoms became apparent.

The question remains: When should dietary surveys or biochemical assays be interpreted to indicate the need for nutritional intervention? Dietary surveys are seldom a valid indication of general malnutrition unless the average intake for a population group falls significantly below the Estimated Average Requirement (EAR) for one or more nutrients. However, by looking at the percentage of people within a population group who have suboptimal intake, it is possible to identify high-risk population groups that should be monitored more closely. Biochemical assays can definitely identify subclinical cases of malnutrition where nutritional intervention is desirable provided (1) the assay has been shown to be reliable, (2) the deficiency can be verified by a second assay, and (3) there is no unusual stress situation that may alter micronutrient distribution. In assessing nutritional status, it is important to be aware of those population groups at risk, the most reliable biochemical assays for monitoring nutritional status, and the symptoms of deficiencies.

26.3 • DIETARY REFERENCE INTAKES

Dietary Reference Intakes (DRIs) are quantitative estimates of nutrient intakes to be used for planning and assessing diets for healthy people and refer to either RDAs or AIs, depending on the nutrient (Figure 26.1). In assessing quantitative standards for nutrient intake the Food and Nutrition Board of the National Research Council considers the amount of nutrients and food components required for preventing deficiency diseases and, where the data are definitive, for promoting optimal health. The first step is determining the **Estimated Average Requirement (EAR)**, the amount of nutrient estimated to meet the nutrient requirement of half of the healthy individuals in an age and gender group. The **Recommended Dietary Allowance (RDA)** is normally set at two standard deviations above the EAR and is assumed to be the dietary intake amount that is sufficient to meet the nutrient requirement of nearly all (97%–98%) healthy individuals in a group. If a nutrient is considered essential but the experimental data are inadequate for determining an EAR, an **Adequate Intake (AI)** is set rather than an RDA. The AI is believed to cover the needs of all individuals in a group, but uncertainty of the data prevent being able to specify with certainty the percentage of individuals covered by this intake. AIs are often based on approximations of nutrient intake by a group of individuals. For example, AIs for young infants are often based on the daily mean nutrient intake supplied by human milk for healthy, full-term infants who are exclusively breast-fed. Finally, for most nutrients the Food and Nutrition Board sets a **Tolerable Upper Intake Level (UL)**. The UL is defined as the highest level of daily nutrient intake that is likely to pose no risks of adverse health effects to almost all individuals in the general population. The RDAs, AIs, and ULs are designed to be of use in planning and evaluating diets for individuals. The EAR is designed to be used in setting goals for nutrient intake and assessing the prevalence of inadequate intake in a population group.

These determinations are relatively easy to make for those nutrients associated with dramatic deficiency diseases, for example, vitamin C and scurvy. Measures that are more indirect must be used in other instances, such as tissue saturation or extrapolation from animal studies. The Food and Nutrition Board normally meets every 6 to 10 years to consider currently available information and update their recommendations.

DRIs serve as a useful general guide in evaluating adequacy of individual diets. However, the DRIs have several limitations.

1. DRIs are designed to meet the needs of healthy people and do not take into account special needs arising from infections, metabolic disorders, or chronic diseases.
2. Since present knowledge of nutritional needs is incomplete, there may be unrecognized nutritional needs. To provide for these needs, the DRIs should be met from as varied a selection of foods as possible. No single food can be considered complete, even if it meets the DRI for all known nutrients. This is important, especially in light of the current practice of fortifying foods of otherwise low nutritional value.
3. As currently formulated, DRIs may not define the "optimal" level of any nutrient, since optimal amounts are difficult to define. Because of information suggesting that optimal intake of certain micronutrients may reduce heart disease and cancer risk, the DRIs for these nutrients have recently been increased slightly; however, some experts feel that the current DRIs may not be sufficient to promote optimal health.

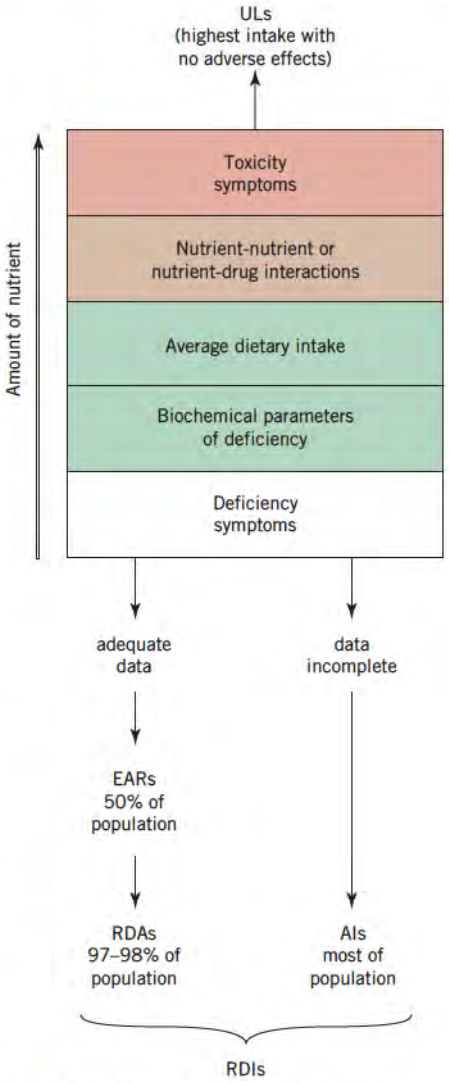

Figure 26.1 Dietary reference intakes. A schematic representation of the relationship between EAR (Estimated Average Requirement, the amount of nutrient estimated to meet the needs of 50% of a population group), RDA (Recommended Dietary Allowance; the amount of nutrient estimated to meet the needs of 97-98% of a population group), AI (Adequate Intake, the amount of nutrient estimated to meet the needs of most of a population group), DRI (Dietary Reference Intake, either RDA or AI, depending on the nutrient), and UL (Tolerable Upper Intake Level, highest level of nutrient intake that is likely to pose no risk of adverse health effects to almost all individuals in the general population).

26.4 • FAT-SOLUBLE VITAMINS

Vitamin A Is Derived from Plant Carotenoids

The active forms of vitamin A are retinol, retinal (retinaldehyde), and retinoic acid. Their precursors are synthesized by plants as the carotenoids (Figure 26.2), some of which are cleaved to retinol and stored in the liver as retinol palmitate. Liver, egg yolk, butter, and whole milk are good sources of retinol. Dark green and yellow vegetables are generally good

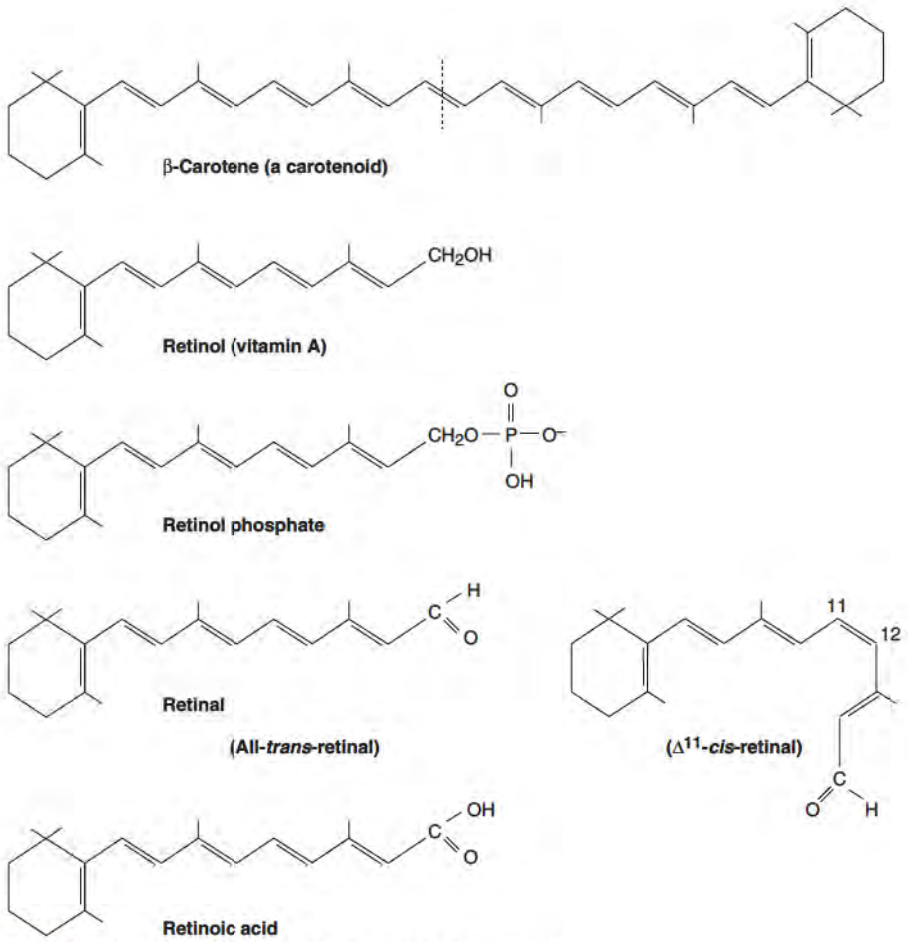

Figure 26.2 **Structures of vitamin A and related compounds.**

sources of the carotenoids. Conversion of carotenoids to retinol is rarely 100%, so the vitamin A potency of various foods is expressed in terms of milligrams per day of retinol activity equivalents (1 RAE is equal to 1 μg retinol, 12 μg of **β-carotene**, and 24 μg of α-carotene or β-cryptoxanthin). The carotenoids are major sources of vitamin A in the American diet because they can be cleaved to retinol and converted to other vitamin A metabolites in the body (Figure 26.2). Carotenoids are also thought to function as antioxidants, although they may have additional metabolic functions.

Only in recent years has the biochemistry of vitamin A become well understood (Figure 26.3). β-Carotene and some other carotenoids have an important role as antioxidants. At the low oxygen tensions prevalent in the body, β-carotene is a very effective antioxidant and may reduce the risk of those cancers initiated by free radicals and other strong oxidants. Several epidemiologic studies suggested that adequate dietary β-carotene may be important in reducing the risk of lung cancer, especially in people who smoke. However, supplemental β-carotene did not provide any detectable benefit and may have actually increased cancer risk for smokers in several multicenter prospective studies. This illustrates the danger of making dietary recommendations on epidemiologic studies alone.

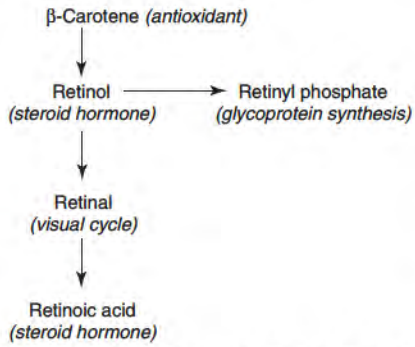

Figure 26.3 **Vitamin A metabolism and function.**

Retinol is converted to **retinyl phosphate**, which appears to serve as a glycosyl donor in the synthesis of some glycoproteins and mucopolysaccharides in much the same manner as **dolichol phosphate** (p. 660). It is essential for the synthesis of glycoproteins needed for normal growth regulation and for mucus secretion. Retinoic acid binds to **retinoic acid receptors** (**RARs**) and retinoid X receptors (RXRs), which then bind to DNA and modulate the synthesis of proteins involved in the regulation of cell growth and differentiation. Thus, it can be considered to act like a steroid hormone in regulating growth and differentiation.

In the Δ^{11}-*cis*-retinal form, **vitamin A** becomes reversibly associated with visual proteins (the **opsins**). When light strikes the retina, a number of complex biochemical changes take place, resulting in generation of a nerve impulse, conversion of the *cis*-retinal to the all-*trans* form, and its dissociation from the visual protein (p. 962). Regeneration of functional visual pigments requires isomerization back to the Δ^{11}-*cis* form (Figure 26.4). In addition to the direct role of vitamin A in the visual cycle, clinical studies suggest that the carotenoids lutein and zeaxanthin reduce the risk of macular degeneration.

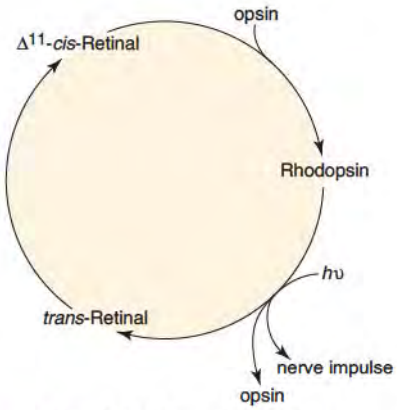

Figure 26.4 **Role of vitamin A in vision.**

On the basis of what is known about the biochemical mechanisms of vitamin A action, its biological effects are easy to understand. For example, retinyl phosphate is required for the synthesis of glycoproteins (an important component of mucus), and lack of mucus secretion leads to a drying of epithelial tissues. Retinol and/or retinoic acid down-regulate the synthesis of **keratin**, and excess keratin synthesis leaves a horny keratinized surface in place of the normal moist and pliable epithelium. Thus, vitamin A is required for maintenance of healthy epithelial tissue. In addition, retinol and/or retinoic acid are required for the synthesis of the iron transport protein transferrin. Thus, vitamin A deficiency can lead to anemia from impaired transport of iron.

Vitamin A-deficient animals are more susceptible to infections and cancer. Decreased resistance to infection may be due to keratinization of mucosal cells lining the respiratory, gastrointestinal, and genitourinary tracts. Fissures readily develop in the mucosal membranes, allowing microorganisms to enter. Vitamin A deficiency may also impair the immune system. The protective effect of vitamin A against many forms of cancer may result from the antioxidant potential of carotenoids and the effects of retinol and retinoic acid in regulating cell growth.

Since vitamin A is stored in the liver, deficiency can develop only over prolonged periods of inadequate intake. Mild vitamin A deficiency is characterized by follicular hyperkeratosis (rough keratinized skin resembling goosebumps), **anemia** (biochemically equivalent to iron deficiency anemia, but in the presence of adequate iron intake), and increased susceptibility to infection and cancer. **Night blindness** is an early symptom of deficiency. Severe deficiency leads to progressive keratinization of the cornea, known as xerophthalmia in its most advanced stages. Infection usually sets in, with resulting hemorrhaging of the eye and permanent loss of vision.

For most people, (unless they happen to eat liver) dark green and yellow vegetables are the most important dietary sources of vitamin A. Unfortunately, these foods are most often missing from the American diet. Dietary surveys indicate that 40%–60% of the population consumes less than two-thirds of the RDA for vitamin A. Clinical symptoms of vitamin A deficiency are rare in the general population, but are a fairly common consequence of severe liver damage or diseases that cause fat malabsorption (Clin. Corr. 26.1).

Vitamin A accumulates in the liver. Excess intake over prolonged periods can be toxic. Doses of 25,000–50,000 g/day of vitamin A over months or years are toxic for many children and adults. The usual symptoms include bone pain, scaly dermatitis, enlargement of liver and spleen, nausea, and diarrhea. It is virtually impossible to ingest toxic amounts of vitamin A from normal foods unless one eats polar bear liver (6000 μg/serving) regularly. Most instances of vitamin A toxicity are caused by massive doses of vitamin A supplements. Fortunately, this practice is relatively rare because of increased public awareness of vitamin A toxicity.

Vitamin D Synthesis Requires Sunlight

Technically, **vitamin D** should be considered a pro-hormone rather than a vitamin. **Cholecalciferol** ($\mathbf{D_3}$) is produced in skin by UV irradiation of 7-dehyrocholesterol (p. 719 for a discussion of the synthesis of vitamin D). Thus, as long as the body is exposed to adequate sunlight, there is little or no dietary requirement for vitamin D. The best dietary sources of vitamin D_3 are saltwater fish (especially salmon, sardines, and herring), liver, and egg yolk. Milk, butter, and other foods are routinely fortified with ergocalciferol (D_2) prepared by

CLINICAL CORRELATION 26.1

Nutritional Considerations in Cystic Fibrosis

Patients with malabsorption diseases often develop malnutrition. Cystic fibrosis (CF) is the most common lethal inherited disease among Caucasians (affecting about 1 in 3500 newborns) and results from a mutation in the gene for the cystic fibrosis transmembrane conductance regulator, a cAMP-regulated chloride channel. This mutation leads to a generalized dysfunction of the exocrine glands that causes formation of viscid mucus, which progressively plugs their ducts. Obstruction of the bronchi and bronchioles leads to pulmonary infections, which are usually the direct cause of death. In many cases, however, the exocrine cells of the pancreas are also affected, leading to a deficiency of pancreatic enzymes and sometimes a partial obstruction of the common bile duct.

Deficiency of pancreatic lipase and bile salts leads to severe malabsorption of fat and fat-soluble vitamins. Calcium tends to form insoluble salts with the long-chain fatty acids, which accumulate in the intestine. Starches and proteins are also trapped in the fatty bolus of partially digested foods. This physical entrapment, along with the deficiencies of pancreatic amylase and pancreatic proteases, can lead to severe protein–calorie malnutrition, which increase the risk of death in patients with cystic fibrosis. Excessive mucus secretion on the luminal surface of the intestine may also interfere with the absorption of several micronutrients, including iron.

Fortunately, microsphere preparations of pancreatic enzymes are now available that greatly alleviate many of these malabsorption problems. With these preparations, protein and carbohydrate absorption are returned to near normal. Fat absorption is improved greatly but not normalized, since deficiencies of bile salts and excess mucus secretion persist. Because dietary fat is a major source of calories, these patients have difficulty obtaining sufficient calories from a normal diet. This is complicated by increased protein and energy needs because of the chronic infections often seen in these patients. Thus, the current recommendations are for energy intakes ranging from 110%–200% of the RDA to combat the poor growth and increased susceptibility to infection. The recommendation is for high-energy high-protein diets without any restriction of dietary fat (50% carbohydrate, 15% protein, and 35% fat). If caloric intake from the normal diet is inadequate, dietary supplements or enteral feeding may be used. The dietary supplements usually contain easily digested carbohydrates and milk protein mixtures. Medium-chain triglycerides are sometimes used as a partial fat replacement since they can be absorbed directly through the intestinal mucosa in the absence of bile salts and pancreatic lipase.

Since some fat malabsorption is present, deficiencies of fat-soluble vitamins often occur. Children aged 2–8 years need a standard adult multiple-vitamin preparation containing 400 IU of vitamin D and 5000 IU of vitamin A/day. Older children, adolescents, and adults need a standard multivitamin at a dose of 1–2/day. If serum vitamin A or vitamin E levels become low, water-miscible vitamin preparations should be used. Vitamin K deficiency has not been adequately studied, but supplementation is usually recommended, especially when on antibiotics or if cholestatic liver disease is present. Iron deficiency is common but iron supplementation is not usually recommended because of concern that higher iron levels in the blood might encourage systemic bacterial infections. Calcium levels in the blood are usually normal. However, since calcium absorption is probably suboptimal, it is important to ensure that the diet provides at least RDA levels of calcium.

Assoc.* 108:832, 2008.

irradiating ergosterol from yeast (Figure 26.5). Vitamin D potency is measured in terms of micrograms cholecalciferol (1 μg cholecalciferol, or ergocalciferol, = 40 IU). There has been some recent controversy about whether ergocalciferol is as biologically potent as cholecalciferol, but that has not yet been resolved.

Both cholecalciferol and ergocalciferol are metabolized in liver where **25-hydroxycholecalciferol [25-(OH)D]** is formed (Figure 26.5). This is the major circulating derivative of vitamin D, and is converted into the biologically active **1-α,25-dihydroxycholecalciferol (calcitriol)** by the enzyme 25-hydroxyvitamin D-1 α-hydroxylase (Figure 26.5). It used to be thought that this reaction occurred exclusively in the proximal convoluted tubules of kidney (Clin. Corr. 26.2, p. 1070). The kidney does appear to be the major source of 1-α,25-dihydroxycholecalciferol [1, 25-$(OH)_2$D] in the blood. However, it is now recognized that many other tissues including colon, prostate, breast, brain, β-islet cells of the pancreas, vascular smooth muscle cells and macrophages can also produce 1,25-$(OH)_2$D. These cells also have vitamin D receptors, so the 1,25-$(OH)_2$D that they produce acts in a paracrine fashion, making little if any contribution to circulating 1,25-$(OH)_2$D levels in the bloodstream.

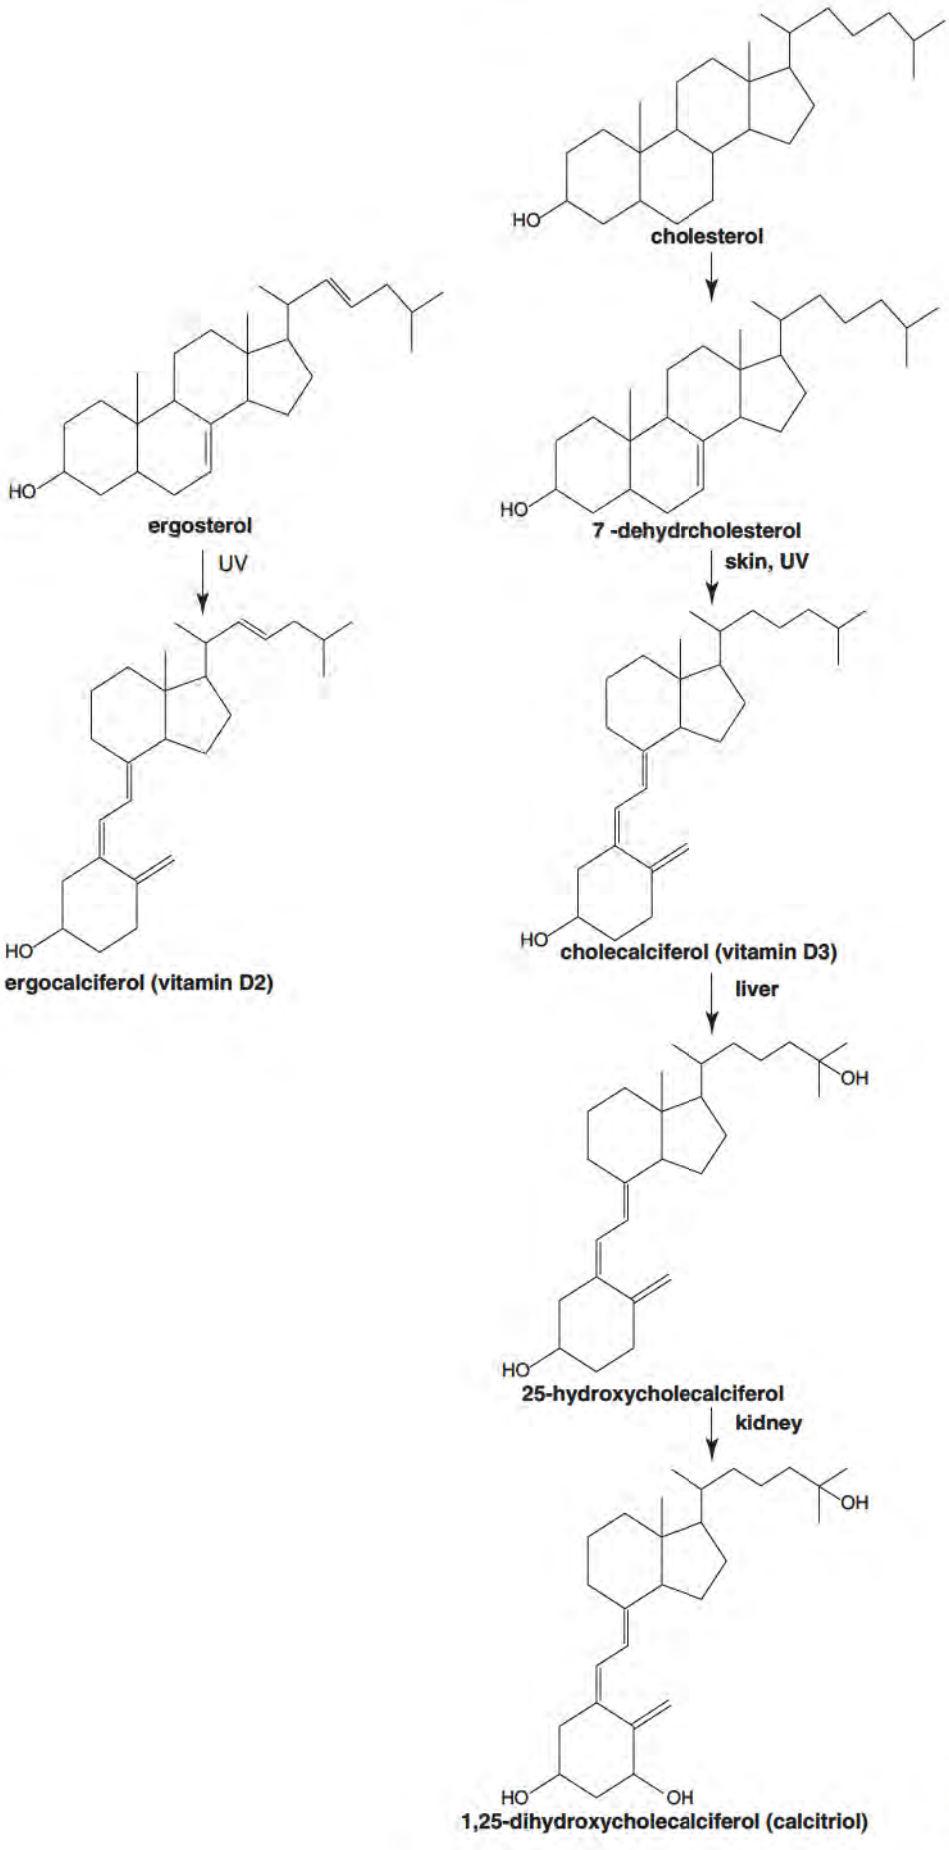

Figure 26.5 **Structures of vitamin D_3 and related metabolites.**

CLINICAL CORRELATION 26.2

Renal Osteodystrophy

In chronic renal failure, a complicated chain of events leads to renal osteodystrophy. The renal failure results in an inability to produce 1,25-$(OH)_2$D, and thus bone calcium becomes the only important source of serum calcium. In the later stages, the situation is complicated by increased renal retention of phosphate and the resulting hyperphosphatemia. The serum phosphate levels are often high enough to cause metastatic calcification (i.e., calcification of soft tissue), which tends to lower serum calcium levels further (the solubility product of calcium phosphate in the serum is very low and a high serum level of one component necessarily causes a decreased concentration of the other). The hyperphosphatemia and hypocalcemia stimulate parathyroid hormone secretion, which further accelerates the rate of bone loss. The result is bone loss and metastatic calcification. Administration of high doses of vitamin D or its active metabolites would not be sufficient since the combination of hyperphosphatemia and hypercalcemia would only lead to more extensive metastatic calcification. The readjustment of serum calcium levels by high calcium diets and/or vitamin D supplementation must be accompanied by phosphate reduction therapies. It is difficult to reduce dietary phosphate sufficiently because most protein sources are also high in phosphate. In this regard, vegetable proteins are a better choice than animal proteins because a significant portion of the phosphate in vegetable protein is in the form of phytates and are unavailable for absorption. It is also important to avoid processed, fast, and convenience foods because phosphate is also added to those foods. For example, sodium phosphate is often added to processed meats to keep the meat from drying out. Because it is so difficult to achieve sufficient phosphate restriction in the diet, phosphate binders are often used to make dietary phosphate unavailable for absorption. Calcium acetate and a cationic polymer called Sevelamer hydrochloride are the most commonly used phosphate binders at present. Orally administered 1,25-$(OH)_2$D is effective at stimulating calcium absorption in the mucosa but does not enter the peripheral circulation in significant amounts. Thus, in severe hyperparathyroidism intravenous 1,25-$(OH)_2$D may be necessary. Research is in progress with calciumimetic agents that bind to a calcium sensor located on the extracellular membrane of the parathyroid gland and decrease parathyroid hormone production and release.

Phosphorous homeostasis in normal health and in chronic kidney disease patients with special emphasis on dietary phosphorous intake. *Seminars in Dialysis* 20:295, 2007.

Traditionally, vitamin D has been thought to primarily play a role in maintaining calcium homeostasis (Figure 26.6). 1,25-$(OH)_2$D production by the kidney is increased when calcium levels are low, and it acts in concert with **parathyroid hormone** (**PTH**), which is also produced in response to low serum calcium. High PTH levels stimulate production of 1,25-(OH)D whereas low PTH amounts cause formation of 24,25-$(OH)_2$D by the kidney. The 1,25-$(OH)_2$ D acts as a typical steroid hormone in intestinal mucosal cells, where it induces synthesis of a calcium transport protein, TRPV5, and a calcium-binding protein, calbindin, that are required for calcium transport. In bone 1,25-$(OH)_2$D and PTH act synergistically to promote bone resorption (demineralization) by stimulating osteoblast formation and activity. Finally, PTH and 1,25-$(OH)_2$D inhibit calcium excretion in the kidney by stimulating calcium reabsorption in the distal renal tubules. 24,25-$(OH)_2$D was thought to be inactive, but recent studies with knockout mice lacking the 24-hydroxylase enzyme have shown that 24,25-$(OH)_2$D plays an essential but ill-defined role in bone metabolism. Calcitonin is produced when serum calcium levels are high (usually right after a meal) and lowers serum calcium levels by blocking bone resorption and stimulating calcium excretion by the kidney.

The response of calcium metabolism to several different physiological situations is summarized in Figure 26.6. The response to low serum calcium levels is characterized by elevation of PTH and 1,25-$(OH)_2$D, which act to enhance calcium absorption and bone resorption and to inhibit calcium excretion (Figure 26.6*a*). High serum calcium levels block production of PTH. The low PTH levels cause 25-(OH)D to be converted to 24,25-$(OH)_2$D instead of 1, 25-$(OH)_2$D. In the absence of PTH and 1,25-$(OH)_2$D bone resorption is inhibited and calcium excretion is enhanced. High serum calcium levels also stimulate production of **calcitonin**, which contributes to the inhibition of bone resorption and the increase in calcium excretion. Finally, the high levels of both serum calcium and phosphate increase the rate of bone mineralization (Figure 26.6*b*). Thus, bone is a very important reservoir of the calcium and phosphate needed to maintain homeostasis of serum levels. When dietary vitamin D and calcium are adequate, no net loss of bone

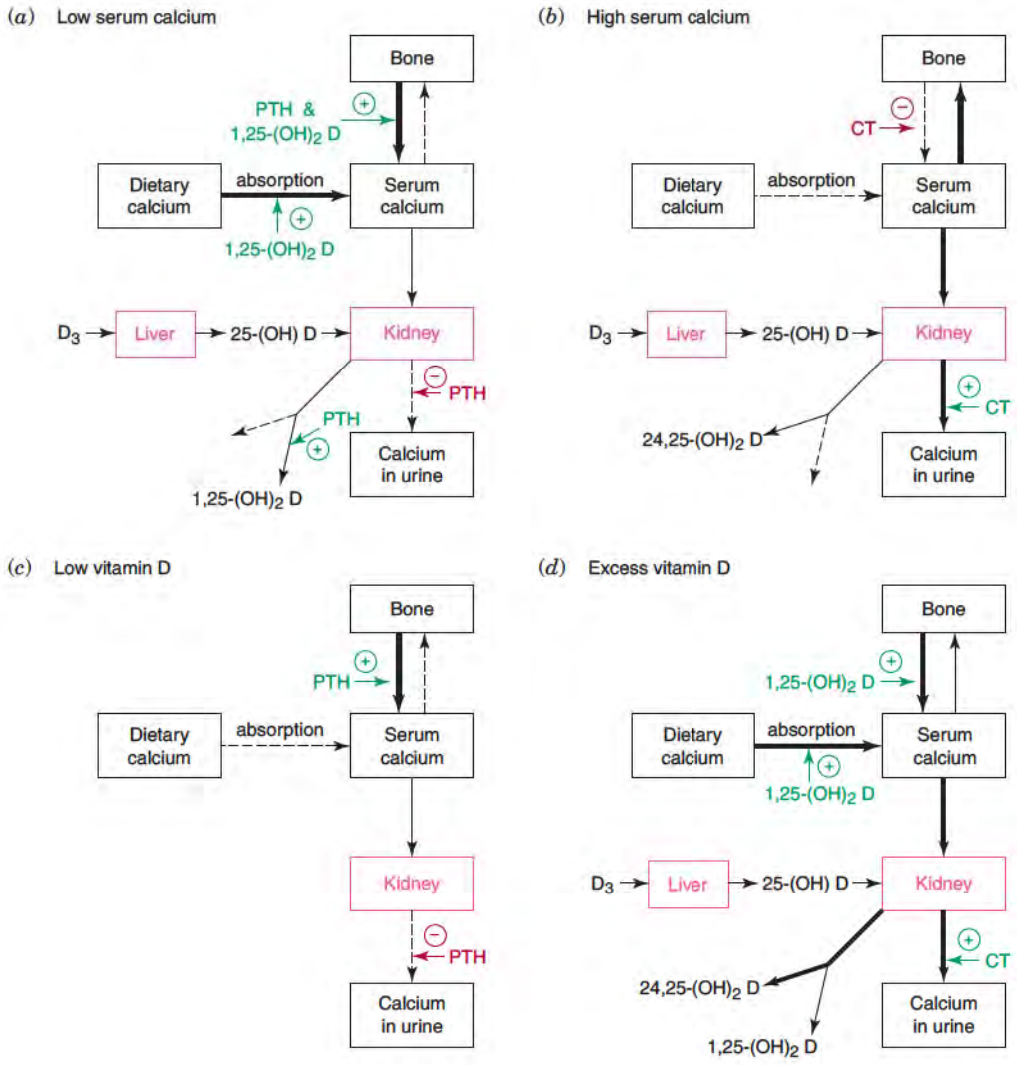

Figure 26.6 Vitamin D and calcium homeostasis.
The dominant pathways of calcium metabolism under each set of metabolic conditions are shown with heavy arrows. Effect of various hormones is shown by red arrows for stimulation or blue arrows for repression. Abbreviations: PTH, parathyroid hormone; CT, calcitonin; D, cholecalciferol; 25-(OH) D, 25-hydroxycholecalciferol; 1, 25-$(OH)_2$D, 1-α, 25-dihydroxycholecalciferol; and 24, 25-$(OH)_2$D, 24, 25-dihydroxycholecalciferol.

calcium occurs. However, when dietary calcium is low, PTH and 1,25-$(OH)_2$D cause net demineralization of bone to maintain normal serum calcium levels. Vitamin D deficiency also causes net demineralization of bone due to elevation of PTH (Figure 26.6*c*).

The most commonly recognized symptoms of vitamin D deficiency are rickets in young children and osteomalacia in adults. Rickets is characterized by continued formation of osteoid matrix and cartilage that are improperly mineralized resulting in soft, pliable bones. In adults, demineralization of preexisting bone causes it to become softer and more susceptible to fracture. **Osteomalacia** is easily distinguishable from the more common osteoporosis, by the fact that the osteoid matrix remains intact in the former but not in the latter. Because of fortification of dairy products with vitamin D, rickets and osteomalacia are very rare and are most often seen in low-income groups, the elderly (who often also have minimal exposure to sunlight), strict vegetarians (especially if their diet is also low in calcium and high in fiber), and chronic alcoholics.

However, we now know that vitamin D is involved in much more than regulation of calcium homeostasis. Receptors for 1,25-$(OH)_2$D occur in many tissues and most of those tissues have the ability to produce 1,25-$(OH)_2$D in a paracrine fashion from 25-(OH)D. It now appears that vitamin D also plays an important role in regulating cell proliferation, the functioning of the adaptive and innate immune system, secretion of insulin by the pancreatic β-cells, regulation of blood pressure and normal neuromuscular function. Recent research suggests that inadequate vitamin D intake may increase the risk of certain types of cancer (particularly breast, colon, and prostate), hypertension, and autoimmune diseases (particularly multiple sclerosis, rheumatoid arthritis, Crohn disease, and type I diabetes).

TABLE 26.1 • Recommended Serum Levels of 25-Hydroxy Vitamin D

Serum Levels of 25-Hydroxy Vitamin D	
Toxicity	> 150 ng/ml (150 nmol/liter)
Sufficiency	≥ 30 ng/ml (75 nmol/liter)
Relative insufficiency	21-29 ng/ml (52 to 72 nmol/liter)
Deficiency	≤ 20 ng/ml (50 nmol/liter)

Because many tissues can make 1,25-$(OH)_2$D from 25-(OH)D, blood levels of vitamin 25-(OH)D are now considered the best indicators of vitamin D sufficiency (Table 26.1). Most experts now define vitamin D deficiency as 25-(OH)D levels of 20 ng/ml or less, vitamin D insufficiency as 25-(OH)D levels of 21–29 ng/ml, and vitamin D sufficiency as 25-(OH)D levels >30 ng/ml. Based on these standards, a large percentage of North Americans and Europeans are vitamin D deficient and recommendations for increasing the RDIs for vitamin D are being considered. The current RDIs are 200 IU (5 μg/day) up to age 50, 400 IU (10 μg/day) from age 51 to 70, and 600 IU (15 μg/day) over 71. Many experts are now recommending that without adequate sun exposure the RDIs for children and adults be increased to at least 800 to 1000 IU (20–25 μg/day). Vitamin D deficiency can also result from fat malabsorption or severe liver and kidney disease (see Clin. Corrs. 26.1, p. 1068, and 26.2, p. 1070). Certain drugs also interfere with vitamin D metabolism. For example, corticosteroids stimulate the conversion of vitamin D to inactive metabolites and cause bone demineralization when used for long periods.

Vitamin D can be toxic in high doses. The tolerable upper intake level (UL) for adults is 2000 IU/day (50 μg/day). The mechanism of vitamin D toxicity is summarized in Figure 26.6*d*. Enhanced calcium absorption and bone resorption cause hypercalcemia, which can lead to metastatic calcification. The enhanced bone resorption causes demineralization similar to that of vitamin D deficiency. Finally, the high serum calcium leads directly to hypercalciuria, which predisposes to formation of renal stones.

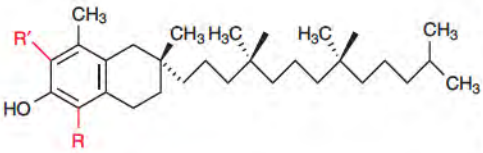
Vitamin E Is a Mixture of Tocopherols and Tocotrienols

Vitamin E occurs in the diet as a mixture of several closely related compounds, called tocopherols and **tocotrienols** (Figure 26.7). All of the tocopherols and tocotrienols are important naturally occurring antioxidants. Due to their lipophilic character, they accumulate in circulating lipoproteins, cellular membranes, and fat deposits, where they act as scavengers for free radicals, protecting unsaturated fatty acids (especially in membranes) from peroxidation reactions. ***α*-Tocopherol** is the most potent scavenger of reactive oxygen species, but γ-tocopherol is a more potent scavenger of reactive nitrogen species. ***γ*-Tocopherol** also appears to inactivate fat-soluble electrophilic mutagens, thus complementing glutathione, which inactivates electrophilic mutagens in the aqueous compartments of the cell. The tocopherols appear to play a role in cellular respiration, either by stabilizing ubiquinone or by helping transfer electrons to ubiquinone (p. 563). Tocopherols and tocotrienols also prevent oxidation of LDL, which may be important in reducing the risk of cardiovascular disease since the oxidized form of LDL is atherogenic. Although many of the biological properties of the tocopherols are the result of their antioxidant potential, some of their benefits appear to be due to effects on enzyme activity or transcription. For example, they appear to enhance heme synthesis by increasing the levels of δ-aminolevulinic acid (ALA) synthase and ALA dehydratase. Recent studies have shown that vitamin E is required for maintaining normal immune function, particularly in the elderly, and may be important in preventing macular degeneration and cognitive decline. Finally, neurological symptoms have been reported following prolonged vitamin E deficiency associated with malabsorption diseases.

Setting the recommended intake levels of vitamin E has been hampered by the difficulty of producing severe vitamin E deficiency in humans. It is generally assumed that the vitamin E content of the American diet is sufficient, since no major vitamin E deficiency diseases have been found. However, vitamin E requirements increase as intake of polyunsaturated fatty acids increases. While the recent emphasis on high polyunsaturated fat diets to reduce serum cholesterol may be of benefit in controlling heart disease, the propensity of polyunsaturated fats to form free radicals on exposure to oxygen may lead to increased cancer risk. It is prudent to increase vitamin E intake for diets rich in polyunsaturated fats.

The controversy about the relationship between vitamin E and cardiovascular disease risk illustrates the difficulty in characterizing the role of vitamins in promoting optimal health, as opposed to preventing deficiency diseases. On one hand relationships between nutrient status and disease risk suggested by biochemical and epidemiologic studies are often not borne out by large-scale intervention trials. On the other hand intervention trials are not generally designed to identify the high-risk population groups that would benefit most from optimal nutrient intake. For example, vitamin E prevents the oxidation of LDL particles to a more atherogenic

Tocopherols



Tocotrienols

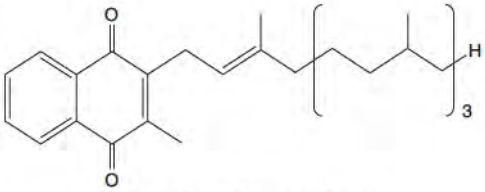
form, so it was logical that vitamin E supplementation might decrease the risk of atherosclerosis. Epidemiologic studies suggested that people consuming 100 mg/day of vitamin E had reduced risk of myocardial infarction. However, large, randomized, double-blind, placebo-controlled intervention trials with supplemental α-tocopherol failed to show any significant reduction in mortality from cardiovascular disease. This could indicate that α-tocopherol can prevent atherosclerosis in the early stages, but is ineffective in the more advanced clinical conditions represented in the clinical trials. Alternatively, it could indicate that γ-tocopherol, or some other tocopherol or tocotrienol found in food, is more effective than α-tocopherol in preventing atherosclerosis, since high levels of supplemental α-tocopherol are known to interfere with utilization of other forms of vitamin E. More importantly, most large-scale intervention trials performed to date have ignored the effects of genetic polymorphisms on disease prevention. (The effect of polymorphisms on nutritional status is discussed in more detail in Section 26.13.) For example, the haptoglobin 2-2 polymorphism is associated with increased production of oxygen free radicals and lower endogenous serum levels of vitamins E and C. Recent randomized, double-blind, placebo controlled clinical trials show an association between the haptoglobin 2-2 polymorphism and preventive effects of vitamin E supplementation against myocardial infarction and cardiovascular death.

Because the α-tocopherol transfer protein in the liver specifically binds to the natural *RRR*-α-tocopherol, it is retained by the body 4–6 times longer than the synthetic all rac or d, l form of α-tocopherol. The specificity of this protein for α-tocopherol also explains why high intakes of α-tocopherol interfere with the utilization of γ-tocopherol. Vitamin E appears to be the least toxic of the fat-soluble vitamins. The UL for vitamin E has been set at 1000 mg/day, primarily because high levels of vitamin could potentiate the effects of blood-thinning medications such as dicumarol.

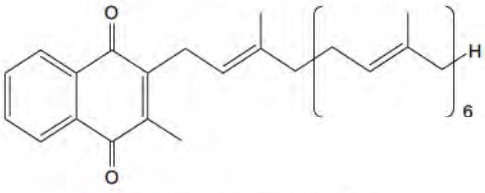
Vitamin K Is a Quinone Derivative

Vitamin K is found naturally as K_1 (**phytylmenaquinone**) in green vegetables and K_2 (multiprenylmenaquinone), which is synthesized by intestinal bacteria (Figure 26.8). The body converts synthetic menaquinone (Menadione) and a number of water-soluble analogs to a biologically active form of vitamin K.

Vitamin K is required for conversion of glutamic acid residues to **γ-carboxyglutamic acid** residues in several precursor proteins (Figure 26.9). The γ-carboxyglutamic acid residues are good chelators and allow the proteins to bind Ca^{2+}, which is required for their biological activity. In the carboxylase reaction, the active hydroquinone form of vitamin K is converted



Vitamin K_1 (phytylmenaquinone)



Vitamin K_2 (multiprenylmenaquinone)

Figure 26.8 The structures of vitamin K_1 (phytylmenaquinone) and K_2 (multiprenylmenaquinone).

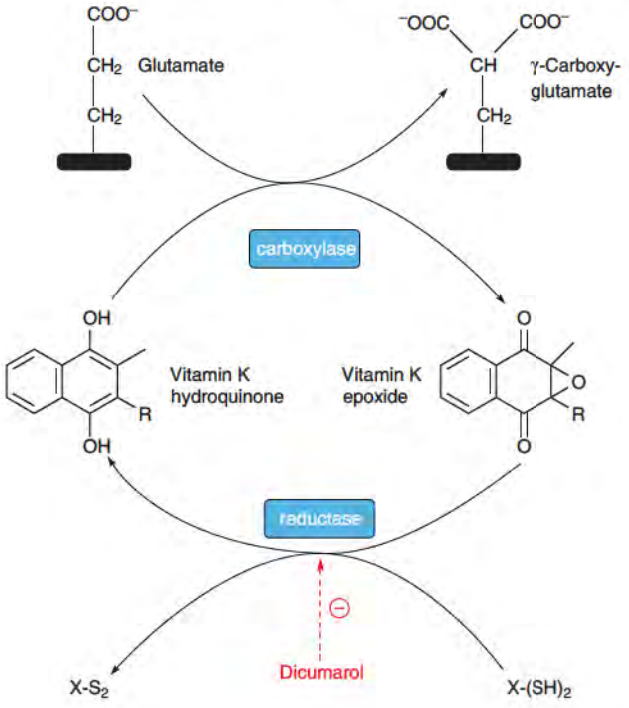


Figure 26.9 Function of vitamin K. Vitamin K is required for the conversion of glutamic acid residues to γ-carboxyglutamic acid residues by the enzyme vitamin K-dependent carboxylase.
In the process, the hydroquinone form of vitamin K is converted to the inactive 2, 3-epoxide form. Conversion of the 2,3-epoxide back to the active hydroquinone requires a dithiol-dependent reductase that is inhibited by dicumarol.

to an inactive 2,3-epoxide form (Figure 26.9). Regeneration of active vitamin K requires vitamin K epoxide reductase, which is inhibited by coumarin-type drugs like **dicumarol**. There are seven proteins involved in blood coagulation that require vitamin K-dependent activation, so vitamin K is essential for blood clotting. The mechanism of activation has been most clearly delineated for prothrombin (p. 964). The γ-carboxyglutamic acid residues allow prothrombin to bind Ca^{2+}, and the prothrombin–Ca^{2+} complex binds to the negatively charged phospholipid surfaces of the platelets and endothelial cells at the site of the injury, where the proteolytic conversion of prothrombin to thrombin occurs.

Vitamin K is also essential for the synthesis of γ-carboxyglutamic acid residues in three proteins found in bone. For example, **osteocalcin** accounts for 15%–20% of the noncollagen protein in the bone, and the presence of γ-carboxyglutamic acid residues are required for its binding to hydroxyapatite crystals in the bone. The physiological role of osteocalcin and the other γ-carboxylated bone proteins is not clear, but they do appear to be required for normal bone mineralization. Under carboxylated osteocalcin is associated with low bone density and increased risk of fracture. A protein called Gas6, which is a ligand for several receptor protein kinases and is involved in cell cycle regulation, has been shown to require vitamin K-dependent γ-carboxylation for activity. The physiological significance of this observation is not known in most tissues. However, carboxylation of Gas6 and a protein called matrix Gla protein (MGP) appears to be important in preventing vascular calcification.

Vitamin K_1 preferentially accumulates in the liver, where the clotting factors are formed. Vitamin K_2 preferentially accumulates in the peripheral tissues, and higher vitamin K intakes appear to be required for saturation of peripheral tissues with vitamin K_2. The most easily detectable symptom in humans of vitamin K deficiency is increased coagulation time, which reflects the requirement of vitamin K_1 for normal blood coagulation. Because of the higher requirements of vitamin K_2 in peripheral tissues, the RDI for vitamin K has recently been increased. Since vitamin K is synthesized by intestinal bacteria, deficiencies have long been assumed to be rare. However, intestinally synthesized vitamin K may not be efficiently absorbed and marginal vitamin K deficiencies, especially deficiencies that could interfere with bone mineralization, may be more common than originally thought. The most common deficiency occurs in newborn infants (Clin. Corr. 26.3), especially those of mothers on anticonvulsant therapy (Clin. Corr. 26.4). Vitamin K deficiency also occurs in

CLINICAL CORRELATION 26.3

Nutritional Considerations in Newborn Infants

Newborn infants are at special nutritional risk because of very rapid growth and needs for many nutrients are high. Some micronutrients (such as vitamins E and K) do not cross the placental membrane well, and tissue stores are low in the newborn. The gastrointestinal (GI) tract may not be fully developed, leading to malabsorption problems (particularly with respect to the fat-soluble vitamins). The GI tract is also sterile at birth and the intestinal flora that normally provide significant amounts of certain vitamins (especially vitamin K) take several days to become established. If the infant is born prematurely, the nutritional risk is slightly greater, since the GI tract will be less well developed and the tissue stores will be less.

The most serious nutritional complication appears to be hemorrhagic disease. Newborns, especially premature infants, have low tissue stores of vitamin K and lack the intestinal flora necessary to synthesize the vitamin. Breast milk is a relatively poor source of vitamin K. Approximately 1 out of 400 live births shows some signs of hemorrhagic disease, which can be prevented by 0.5–1 mg of the vitamin given at birth.

Most newborn infants have sufficient reserves of iron to last 3–4 months. Since cow's milk and breast milk contain little iron, supplementation with iron is usually initiated at an early age by the introduction of iron-fortified cereal. Vitamin D levels are also low in breast milk and supplementation with 200 IU/day of vitamin D is usually recommended. When infants must be maintained on assisted ventilation with high oxygen concentrations, supplemental vitamin E may reduce the risk of bronchopulmonary dysplasia and retrolental fibroplasia, potential complications of oxygen therapy. The anemia of prematurity may respond to supplemental folate and vitamin B_{12}.

In summary, supplemental vitamin K is given at birth to prevent hemorrhagic disease. Breast-fed infants are usually provided with supplemental vitamin D, with iron being introduced along with solid foods. Bottle-fed infants are provided with supplemental iron. If infants must be maintained on oxygen, supplemental vitamin E may be beneficial.

Child Nurs.* 29:312, 2004; and Collier, S., Fulhan, J., and Duggan, C. Nutrition for the pediatric office: Update on vitamins, infant feeding and food allergies. *Curr. Opin. Pediatr.* 16:314, 2004.

CLINICAL CORRELATION 26.4

Anticonvulsant Drugs and Vitamin Requirements

Anticonvulsant drugs such as phenobarbital or diphenylhydantoin (DPH) are an excellent example of drug–nutrient interactions that are of concern to physicians. Metabolic bone disease appears to be the most significant side effect of prolonged anticonvulsant therapy. Whereas children and adults who take these drugs seldom develop rickets or severe osteomalacia, up to 65% of those on long-term therapy have abnormally low serum calcium and phosphorus, abnormally high serum alkaline phosphatase, and some bone loss. Vitamin D supplements appear to correct both the hypocalcemia and osteopenia. Anticonvulsants also tend to increase needs for vitamin K, leading to an increased incidence of hemorrhagic disease in infants born to mothers on anticonvulsants. Anticonvulsants appear to increase the need for folic acid and B_6. Low serum folate levels occur in 75% of patients on anticonvulsants, and megaloblastic anemia may occur in as many as 50% without supplementation. This is of particular concern for women of childbearing age. When infants are exposed to antiepileptic drugs in utero, the risk of congenital malformations, particularly neural tube defects, is doubled compared to the general population. The recommended daily allowance of folic acid is 600 μg/day for pregnant women, and the need may be greater for patients on anticonvulsants. Since folates may speed up the metabolism of some anticonvulsants, it is important that excess folic acid not be given.

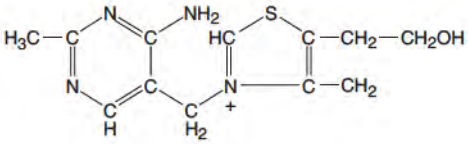
patients with **obstructive jaundice** and other diseases leading to severe fat malabsorption (see Clin. Corr. 26.1, p. 1068) and patients on long-term antibiotic therapy (which may destroy vitamin K-synthesizing organisms in the intestine). Deficiency is sometimes seen in the elderly, who are prone to fat malabsorption.



Thiamin

Figure 26.10 Structure of thiamin.

26.5 • WATER-SOLUBLE VITAMINS

Water-soluble vitamins differ from fat-soluble vitamins in several respects. Most are readily excreted once their concentration surpasses the renal threshold so toxicities are rare. Their metabolic stores are labile and depletion can often occur in a matter of weeks or months, so deficiencies occur relatively quickly on an inadequate diet. Since water-soluble vitamins are coenzymes for many common biochemical reactions, it is often possible to assay vitamin status by measuring one or more enzyme activities in isolated red blood cells. These assays are especially useful if one measures the endogenous activity and the stimulation of that activity by addition of the active coenzyme derived from the vitamin.

Most water-soluble vitamins are converted to coenzymes that are used in pathways for energy generation or hematopoiesis. Deficiencies of the energy-releasing vitamins produce a number of overlapping symptoms and show up first in rapidly growing tissues. Typical symptoms include dermatitis, glossitis (swelling and reddening of the tongue), cheilitis at the corners of the lips, and diarrhea. In many cases, nervous tissue is also involved due to its high-energy demand or specific effects of the vitamin. Common neurological symptoms include peripheral neuropathy (tingling of nerves at the extremities), depression, mental confusion, lack of motor coordination, and malaise. Demyelination and degeneration of nervous tissues may also occur. These deficiency symptoms are so common and overlapping that they can be considered as properties of the energy-releasing vitamins as a class, rather than being specific for any one.

26.6 • ENERGY-RELEASING WATER-SOLUBLE VITAMINS

Thiamin Forms the Coenzyme Thiamin Pyrophosphate

Thiamin (Figure 26.10) is rapidly converted to **thiamin pyrophosphate** (**TPP**) (also referred to as thiamin diphosphate [TDP]), a coenzyme required for the pyruvate dehydrogenase and ***α*-ketoglutarate dehydrogenase** reactions (Figure 26.11), and thiamin triphosphate, which is localized in peripheral nerve membranes and appears to function in transmission

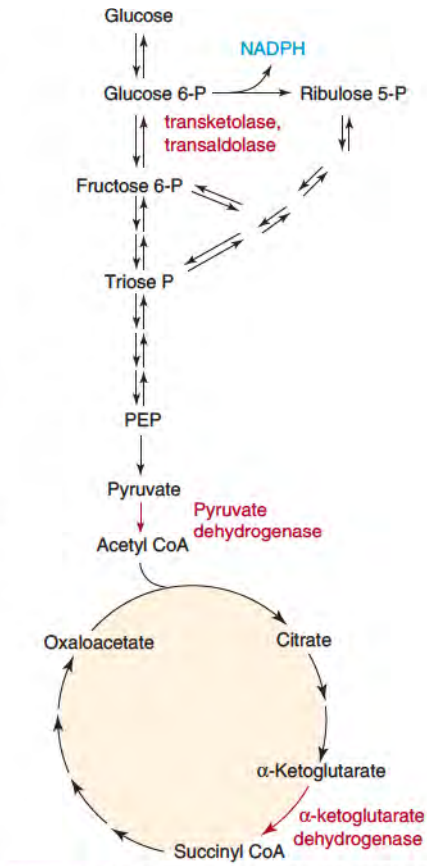


Figure 26.11 Summary of important reactions involving thiamin pyrophosphate.
Reactions involving thiamin pyrophosphate are indicated in red.

of nerve impulses. Loss of pyruvate dehydrogenase activity compromises cellular energy generation and causes an accumulation of pyruvate and lactate. Loss of α-ketoglutarate dehydrogenase activity causes reduced oxidative decarboxylation of α-keto acids (p. 554). Symptoms of thiamin deficiency involving neural tissue may result from the direct role of thiamin triphosphate in nerve transmission or from the accumulation of pyruvate and lactate in neural tissue. Thiamin pyrophosphate is also required for the transketolase and transaldolase reactions of the pentose phosphate pathway. Red blood cell transketolase is commonly used for measuring thiamin status in the body.

Symptoms of mild **thiamin deficiency** include loss of appetite, constipation, nausea, mental depression, peripheral neuropathy, irritability, and fatigue. These symptoms are most often seen in the elderly and low-income groups on restricted diets. Mental confusion, ataxia (unsteady gait while walking and general inability to achieve fine control of motor functions), and ophthalmoplegia (loss of eye coordination) are symptoms of moderately severe thiamin deficiency. This set of symptoms is referred to as Wernicke–Korsakoff syndrome, and is most commonly seen in chronic alcoholics (Clin. Corr. 26.5). Severe thiamin deficiency is known as beriberi. Dry beriberi is characterized by advanced neuromuscular symptoms, including muscular atrophy and weakness. When this is coupled with edema, the disease is called wet beriberi. Both forms of beriberi can be associated with an unusual type of heart failure characterized by high cardiac output. Beriberi occurs primarily in populations that rely exclusively on polished rice for food, although cardiac failure is sometimes seen in alcoholics as well. Coffee and tea contain substances that destroy thiamin, but this is not a problem with normal consumption. Routine enrichment of cereals has assured that most Americans have an adequate intake of thiamin on a mixed diet.

CLINICAL CORRELATION 26.5

Nutritional Considerations in Alcoholics

Chronic alcoholics run considerable risk of neurologic symptoms associated with thiamin or pyridoxine deficiencies and hematological problems associated with folate or pyridoxine deficiencies. The deficiencies are not necessarily due to poor diet alone, although it is often a strong contributing factor. Alcohol causes pathological alterations of the gastrointestinal tract that directly interfere with absorption of certain nutrients. The severe liver damage associated with chronic alcoholism appears to interfere with storage and activation of nutrients and vitamins.

Up to 40% of hospitalized alcoholics have megaloblastic erythropoiesis due to folate deficiency. Alcohol interferes with folate absorption and alcoholic cirrhosis impairs folate storage. Another 30% of hospitalized alcoholics have sideroblastic anemia or identifiable sideroblasts in erythroid marrow cells characteristic of pyridoxine deficiency. Some alcoholics develop a peripheral neuropathy that responds to pyridoxine supplementation. This problem may result from impaired activation or increased degradation of pyridoxine. In particular, acetaldehyde (a product of alcohol metabolism) displaces pyridoxal phosphate from its carrier protein in the plasma, causing it to be rapidly degraded to inactive compounds and excreted.

The most dramatic disorder is the Wernicke–Korsakoff syndrome. The symptoms include mental disturbances, ataxia (unsteady gait and lack of fine motor coordination), and uncoordinated eye movements. Congestive heart failure similar to that seen with beriberi may also occur. While this syndrome may only account for 1%–3% of alcohol-related neurologic disorders, the response to supplemental thiamin is dramatic. The thiamin deficiency probably arises from impaired absorption, although alcoholic cirrhosis may also affect storage of thiamin in the liver.

Deficiencies of most water-soluble vitamins can occur and cases of alcoholic scurvy and pellagra are occasionally reported. Chronic ethanol consumption causes redistribution of vitamin A stores in the body. Liver stores are rapidly depleted while levels of vitamin A in the serum and other tissues may be normal or slightly elevated. Apparently, ethanol causes increased mobilization of vitamin A from the liver and increased catabolism of liver vitamin A to inactive metabolites by the hepatic cytochrome P450 system. Alcoholic patients have decreased bone density and an increased incidence of osteoporosis. This probably relates to a defect in the 25-hydroxylation step in the liver and an increased rate of metabolism of vitamin D to inactive products by the cytochrome P450 system. Alcoholics generally have decreased serum levels of zinc, calcium, and magnesium due to poor dietary intake and increased urinary losses. Iron-deficiency anemia is very rare unless there is gastrointestinal bleeding or chronic infection. In fact, excess iron is a more common problem with alcoholics. Many alcoholic beverages contain relatively high iron levels, and alcohol may enhance iron absorption.

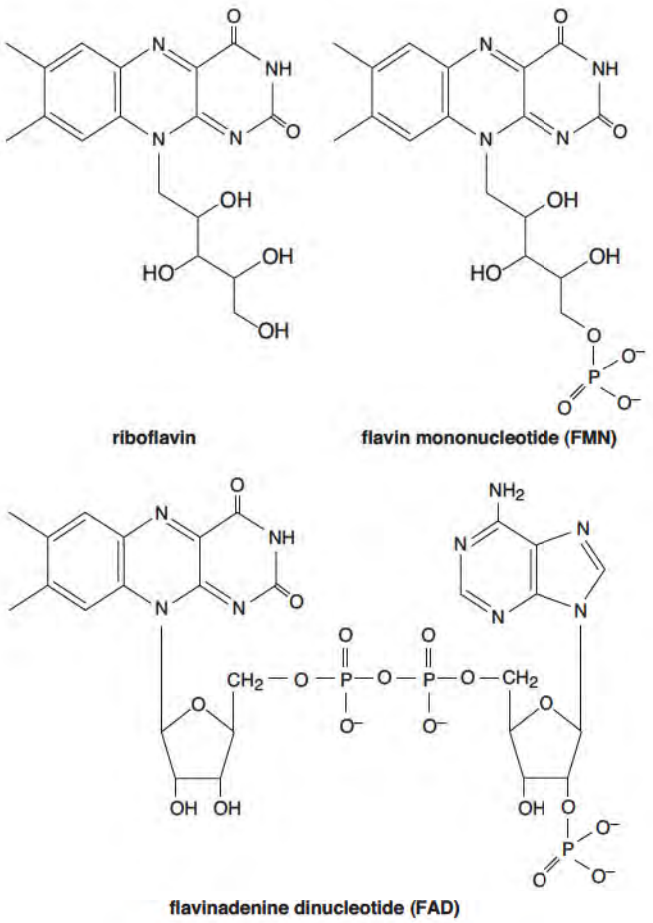

Figure 26.12 **Structures of riboflavin, flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD).**

Riboflavin Forms the Coenzymes FAD and FMN

Riboflavin (Figure 26.12) is the precursor of **flavin adenine dinucleotide** (**FAD**) and **flavin mononucleotide** (**FMN**), both of which are coenzymes in a wide variety of redox reactions essential for energy production and cellular respiration. Riboflavin is also required for iron mobilization, and riboflavin deficiency can contribute to anemia when iron intake is low. Characteristic symptoms of riboflavin deficiency are angular cheilitis, glossitis, and scaly dermatitis (especially around the nasolabial folds and scrotal areas). The best enzyme for assaying riboflavin status is erythrocyte glutathione reductase. Foods rich in riboflavin include milk, meat, eggs, and cereal products. Riboflavin deficiencies are quite rare in this country, and are usually seen in chronic alcoholics. Hypothyroidism slows the conversion of riboflavin to FMN and FAD, but it is not known whether this affects riboflavin requirements.

Niacin Forms the Coenzymes NAD and NADP

Niacin (Figure 26.13) is not a vitamin in the strictest sense of the word, since niacin can be synthesized from tryptophan (Figure 26.14). However, conversion of tryptophan to niacin is relatively inefficient (60 mg of tryptophan is required for the production of 1 mg of niacin) and occurs only after all of the body requirements for tryptophan (protein synthesis, production of serotonin and melatonin, and energy production) have been met. Since synthesis of niacin requires pyridoxine, riboflavin and iron (Figure 26.14), it is also very inefficient on a marginal diet. Dietary niacin (nicotinic acid) and niacinamide (nicotinamide) are both converted to the ubiquitous oxidation–reduction coenzymes NAD and NADP (Figure 26.14). These coenzymes are electron acceptors or hydrogen donors in many redox reactions and cellular respiration. NAD is also required for the poly-ADP-ribose polymerase reaction, which is part of the cellular DNA damage recognition system and regulates DNA replication, DNA repair, and cell cycle progression.

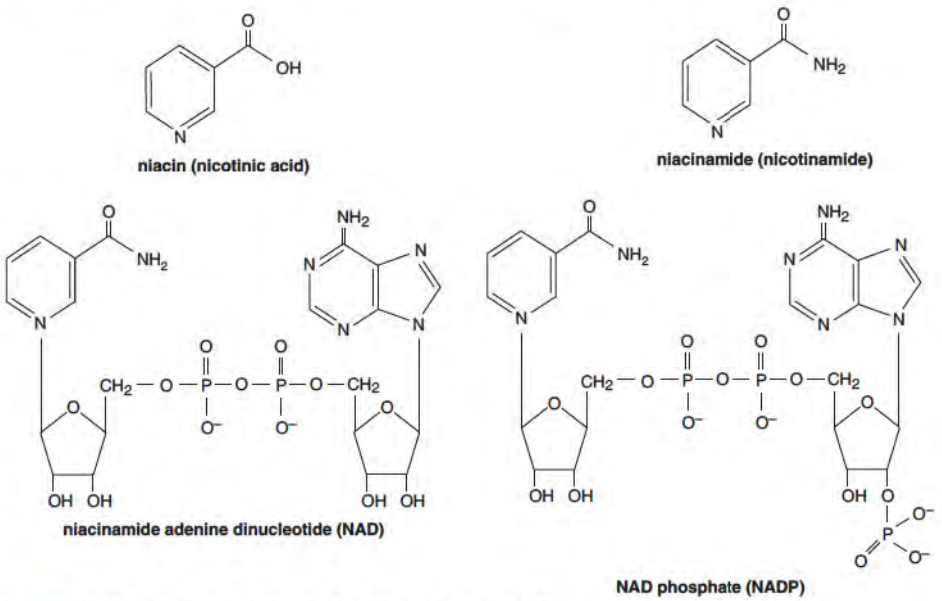

Figure 26.13 **Structures of niacin and related metabolites**

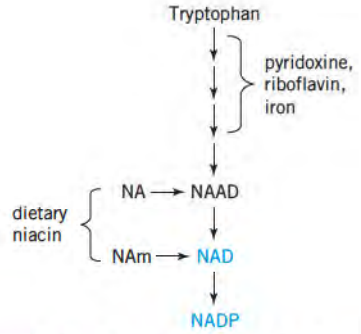

Figure 26.14 **Formation of NAD and NADP.** Pathways for formation of NAD and NADP. Abbreviations: NA = nicotinic acid; NAm = nicotinamide; and NAAD = nicotinic acid adenine dinucleotide.

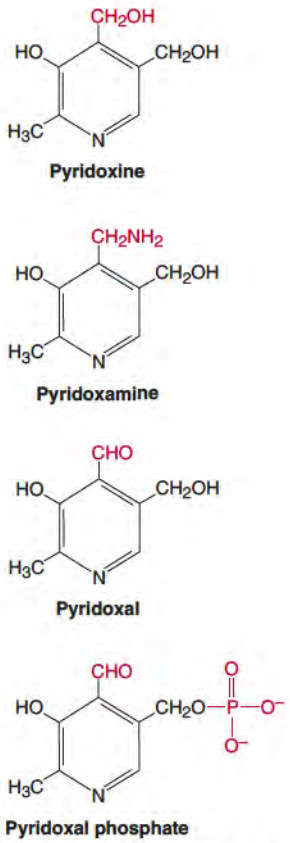

Figure 26.15 **Structures of vitamin B_6.**

Borderline **niacin deficiency** results in a glossitis (redness) of the tongue, somewhat similar to riboflavin deficiency. Pronounced deficiency leads to pellagra, which is characterized by the three Ds: dermatitis, diarrhea, and dementia. The dermatitis is usually seen only in skin areas exposed to sunlight and is symmetric. The neurologic symptoms are associated with actual degeneration of nervous tissue. Because of food fortification, pellagra is a medical curiosity in the developed world, being primarily seen in alcoholics, patients with severe malabsorption, and elderly on very restricted diets. Pregnancy, lactation, and chronic illness lead to increased needs for niacin, but a varied diet usually provides sufficient amounts. The richest sources of niacin are meats, peanuts and other legumes, and enriched cereals.

Nicotinic acid in pharmacologic doses (1.4–4 g/day) is used to lower LDL cholesterol and triglycerides, and increase HDL cholesterol levels. The decrease in LDL cholesterol and triglycerides appears to be due to a direct, noncompetitive inhibition by niacin of liver diacylglycerol acyltransferase-2, a key enzyme in triglyceride synthesis. The decreased hepatic triglyceride synthesis results in intracellular apo B degradation and decreased secretion of VLDL particles. The increased HDL levels appear to be due to an effect of niacin on a hepatic apo AI receptor, which inhibits removal of HDL particles from the circulation. Side effects of niacin therapy include flushing of the skin, hyperuricemia, and elevation of liver enzymes. The flushing of the skin can be avoided by using niacinamide or slow-release preparations of nicotinic acid, but careful monitoring of the patient for hepatic alterations is still required.

Pyridoxine (Vitamin B_6) Forms the Coenzyme Pyridoxal Phosphate

Pyridoxine, **pyridoxamine**, and **pyridoxal**, are naturally occurring forms of vitamin B_6 (Figure 26.15). They are efficiently converted to pyridoxal phosphate, which is required for the synthesis, catabolism, and interconversion of amino acids. **Pyridoxal phosphate** is essential for the transaminase reactions that allow the interconversion of amino acids and their entry into energy generating pathways (p. 754) and can, therefore, be considered an energy-releasing vitamin. Some symptoms of severe deficiency are similar to those of the other energy-releasing vitamins. It is also required for the synthesis of the neurotransmitters serotonin, norepinephrine, epinephrine, and γ-aminobutyrate (GABA) and for synthesis of the sphingolipids necessary for myelin formation. This may explain the irritability, nervousness, and depression seen with mild deficiency and the peripheral neuropathy and convulsions observed with severe deficiency. It is required for synthesis of δ-aminolevulinic

acid, a precursor of heme, and B_6 deficiencies can cause sideroblastic microcytic anemia. Pyridoxal phosphate is covalently linked to a lysine residue of glycogen phosphorylase, which stabilizes the enzyme. This may explain the decreased glucose tolerance associated with deficiency, although B_6 appears to have some direct effects on the glucocorticoid receptor as well. Pyridoxal phosphate is also required for the conversion of homocysteine to cysteine. Hyperhomocysteinemia is associated with increased risk for cardiovascular disease and cognitive decline in the elderly (see Section 26.7, p. 1079).

The dietary requirement for B_6 is roughly proportional to the protein content of the diet. The requirement is increased during pregnancy and lactation, and it may increase with age. Vitamin B_6 is widespread in foods, but meat, vegetables, whole-grain cereals, and egg yolks are among the richest sources. It had been assumed that the average American diet was adequate in B_6 and it was, therefore, not routinely added to flour and other fortified foods. However, recent nutritional surveys have found that a significant fraction of the US population consumes less than the recommended intake for B_6.

Pantothenic Acid and Biotin Form Coenzymes Involved in Energy Metabolism

Pantothenic acid is a component of **coenzyme A (CoA)** and the phosphopantotheine moiety of fatty acid synthase and is required for metabolism of fat, protein, and carbohydrate via the citric acid cycle and for fatty acid and cholesterol synthesis. More than 70 enzymes have been described to date that utilize CoA or its derivatives. Therefore, one would expect pantothenic acid deficiency to be a serious concern in humans. This is not the case since (1) pantothenic acid is very widespread in natural foods, probably reflecting its widespread metabolic role and (2) when pantothenic acid deficiency does occur, it is usually associated with multiple nutrient deficiencies, thus making it difficult to discern symptoms specific to the pantothenic acid deficiency.

Biotin is covalently bound to an ϵ-amino group of a lysine residue in pyruvate carboxylase, acetyl-CoA carboxylase, propionyl-CoA carboxylase, and β-methylcrotonyl-CoA carboxylase. Biotin occurs in peanuts, chocolate, and eggs and is synthesized by intestinal bacteria. However, the biotin synthesized by intestinal bacteria may not be present in a location or a form that can contribute significantly to absorbed biotin.

α-Lipoic Acid Plays Multiple Roles in the Body

α-Lipoic acid is an essential coenzyme for the pyruvate dehydrogenase, α-ketoglutarate dehydrogenase and branched-chain α-keto acid dehydrogenase reactions, so it plays a major role in energy generation via the citric acid cycle. In cells it is reduced to dihydrolipoic acid, which is a potent antioxidant. Finally, α-lipoic acid increases the activity of adenylate kinase, PPAR-α, and PPAR-γ by unknown mechanisms. The effects on PPAR-α and PPAR-γ may explain clinical studies showing that α-lipoic acid supplementation appears to improve glucose utilization and decrease insulin resistance in patients with metabolic syndrome and type 2 diabetes.

26.7 • HEMATOPOIETIC WATER-SOLUBLE VITAMINS

Folic Acid Functions as Tetrahydrofolate in One-Carbon Metabolism

The simplest form of **folic acid** is pteroylmonoglutamic acid. Folic acid in the diet usually occurs as **polyglutamate derivatives** with from 2 to 7 glutamic acid residues joined in γ-peptide linkages (Figure 26.16). An enzyme called **folylpoly-γ-glutamate carboxylase II (glutamate conjugase)** removes the extra glutamate in the intestine. The monoglutaminated folic acid is then taken up by the reduced folate carrier (RFC) in intestinal mucosal cells. The monoglutaminated folic acid in the blood is taken into cells via the folate receptor (FR) α and

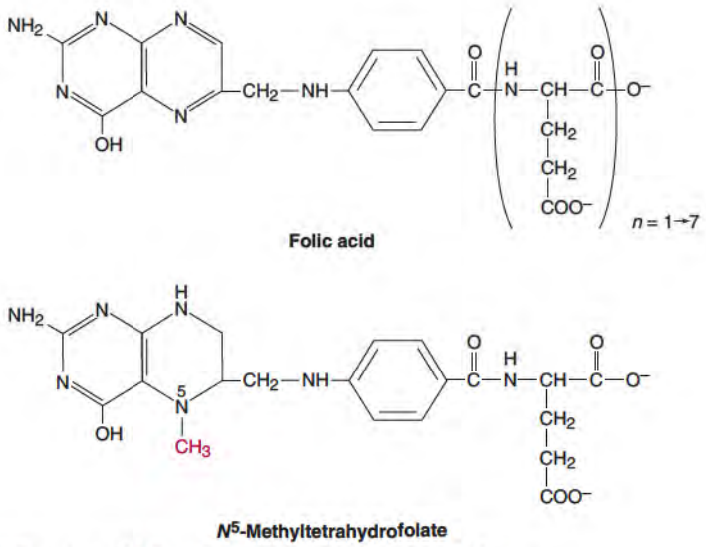

Figure 26.16 Structure of folic acid and N^5-methyltetrahydrofolate.

the polyglutamate tail is added by folylpoly-γ-glutamate synthetase. The polygluamated folic acid is then reduced to **tetrahydrofolate** polyglutamate by **dihydrofolate reductase (DHFR)** (Figure 26.17). Inside cells tetrahydrofolates are present primarily as polyglutamates, which appear to be the biologically active form. Tetrahydrofolate polyglutamate is also stored in liver.

Tetrahydrofolate is a one-carbon carrier that facilitates interconversion of methenyl, formyl, formimino, methylene, and methyl groups (Figure 26.18). This occurs at the expense of pyridine nucleotide reduction or oxidation and while the carbon moiety is attached to THF. The interconversions permit use of a carbon that is removed in one oxidation state from a molecule for addition in a different oxidation state to a different molecule.

The various one-carbon tetrahydrofolate derivatives are used in the synthesis of serine, glycine, purines, and dTMP (see Figure 26.17). N^5-methyl tetrahydrofolate is also required for the B_{12}-dependent conversion of homocysteine to methionine. Homocysteine is a nonessential amino acid that is toxic when it accumulates within the cell. Methionine is a precursor to *S*-adenosyl methionine which is required for cellular methylation reactions,

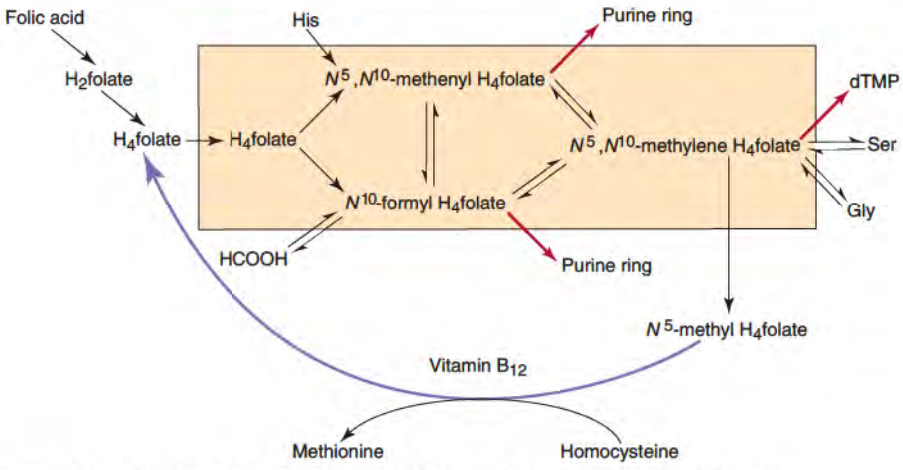

Figure 26.17 Metabolic roles of folic acid and vitamin B_{12} in one-carbon metabolism.
Metabolic interconversions of folic acid and its derivatives are indicated with black arrows. Pathways relying exclusively on folate are shown with red arrows. The important B_{12}-dependent reaction converting N^5-methyl tetrahydrofolate (H_4folate) back to H_4folate is shown with a blue arrow. The box encloses the 'pool' of one-carbon derivatives of H_4folate.

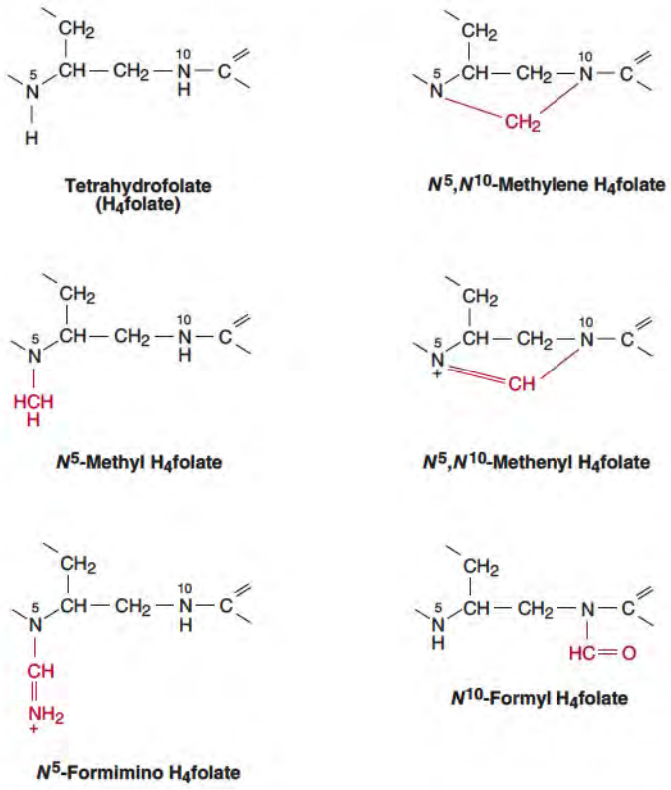

Figure 26.18 Active center of tetrahydrofolate. N5 is the site of attachment of methyl and formimino groups; N10 is the site for formyl; methylene and methenyl groups form bridges between N5 and N10.

including choline biosynthesis and methylation of DNA and histones. Thus, adequate folate status is not only required for DNA synthesis and cellular proliferation, but is also required for normal regulation of gene expression.

Folate deficiency inhibits DNA synthesis by decreasing the availability of purines and dTMP. This leads to arrest of cells in S phase (p. 1004), a characteristic megaloblastic change in size and shape of the nuclei and a slower maturation of red blood cells, causing production of abnormally large macrocytic red blood cells with fragile membranes. Thus a macrocytic anemia associated with megaloblastic changes in the bone marrow is characteristic of folate deficiency. Folate deficiency in pregnant women increases the risk of birth defects, especially neural tube defects (Clin. Corr. 26.6), either due to effects on cell division or gene regulation during development. In addition, hyperhomocysteinemia is fairly common in the elderly population and may be due to inadequate intake and/or decreased utilization of folate, vitamin B_6, and vitamin B_{12}. Hyperhomocysteinemia is associated with increased risk for cardiovascular disease and cognitive decline in the elderly and usually responds to supplementation with folic acid, vitamin B_6, and vitamin B_{12}. Finally, folate deficiency appears to be associated with several forms of cancer, especially colon and cervical cancer.

Folate deficiency is caused by inadequate intake, increased need, impaired absorption, increased demand, and impaired metabolism. Some dietary surveys suggest that inadequate intake may be more common than previously supposed. As with most other vitamins, inadequate intake is probably not sufficient to trigger symptoms of folate deficiency in the absence of increased requirements or decreased utilization. For example, gene polymorphisms that increase the need for folate may be common (Clin. Corr. 26.6). Increased need also occurs during pregnancy and lactation. By the third trimester the folic acid requirement has almost doubled. In the United States, 20%–25% of otherwise normal pregnant women have low serum folate, but actual megaloblastic anemia is rare and is usually seen only after multiple pregnancies. However, inadequate folate levels during the early stages of pregnancy increase the risk for neural tube defects, a type of birth defect. Normal diets seldom supply the 600 μg/day of folate needed during pregnancy. Thus, enriched grain products are now fortified with folic acid at a concentration of 1.4 μg/g of product. This level of fortification was designed to increase average intake of folic acid by 100 μg/day. Since fortification, the incidence of neural

CLINICAL CORRELATION 26.6

Gene Polymorphisms and Folic Acid Requirement

Folic acid supplementation lowers the risk of neural tube defects and decreases serum homocysteine levels; this may lower the risk of heart disease. These data lead to an increase in the RDA for folic acid and to fortification of grain products with folic acid. Yet even on a marginal diet, not all adults have elevated homocysteine levels and not all mothers give birth to babies with neural tube defects. What determines these individual responses to inadequate folate intake? There is a common genetic polymorphism in the gene for 5,10-methylenetetrahydrofolate reductase (MTHFR) that produces the 5-methyltetrahydrofolate required for the conversion of homocysteine to methionine (see Figure 26.17, p. 1080). A C677T (OMIM 607093) single nucleotide polymorphism (SNP) results in a substitution of valine for alanine that lowers specific activity and reduces stability of the enzyme. Approximately 12% of the Caucasians and Asians are homozygous (T/T) and 50% are heterozygous (C/T) for this polymorphism. Plasma folate concentrations are significantly lower and plasma homocysteine levels are significantly higher in T/T individuals consuming diets low in folate. When coupled with low folate intake, the T/T genotype may account for 15% of neural tube defects. In addition, older individuals with the T/T genotype and low folate intake appear to be at increased risk of colon cancer. An active investigation of genetic polymorphisms in the other genes involved in folate metabolism is underway. Polymorphisms have been described in a number of other genes involved in tetrahydrofolate one-carbon metabolism, but none of them have been definitively shown to increase the risk of neural tube defects to date. However, absorption of folate by the intestine may be lower in mothers with a history of neural tube defect pregnancies than in control mothers. The genetics of this effect has not yet been determined.

Bailey, L. B., and Gregory, J. F. Polymorphisms of methylenetetrahydrofolate reductase and other enzymes: Metabolic significance, risks, and impact on folate requirement. *J. Nutr.* 129:919, 1999; Fang, J. Y., and Xiao, S. D. Folic acid, polymorphism of methyl-group metabolism genes, and DNA methylation in relation to GI carcinogenesis. *J. Gastroenterol.* 38:821, 2003; and Beaudin, A. E., and Stover, P. J. tube defects has decreased by 19%. Addition of an extra 200 μg/day would offer much greater protection against neural tube defects and hyperhomocysteinemia, but this level of folic acid supplementation could mask the symptoms of vitamin B_{12} deficiency as described below. Thus, most physicians routinely recommend supplementation for women during the child-bearing years and for the elderly. Folate deficiency is also common in alcoholics (see Clin. Corr. 26.5, p. 1076) and in those with malabsorption diseases.

Anticonvulsants and oral contraceptives may interfere with folate absorption, and anticonvulsants appear to increase catabolism of folates (see Clin. Corr. 26.4, p. 1075). Long-term use of these drugs can lead to folate deficiency unless adequate supplementation is provided. For example, 20% of patients using oral contraceptives develop megaloblastic changes in the cervicovaginal epithelium, and 20%–30% show low serum folate.

Vitamin B_{12} (Cobalamin) Contains Cobalt in a Tetrapyrrole Ring

Pernicious anemia, a megaloblastic anemia associated with neurological deterioration caused by progressive demyelination of nervous tissue, was invariably fatal until 1926 when liver extracts were shown to be curative. Subsequent work showed the need for both an **extrinsic factor** present in liver and an **intrinsic factor** produced by the body; **vitamin B_{12}** was the extrinsic factor. Vitamin B_{12} contains **cobalt** in a coordination state of six, coordinated in four positions by a tetrapyrrole (corrin) ring, in one position by a benzimidazole nitrogen, and in the sixth position by one of several different ligands (Figure 26.19). The crystalline forms of B_{12} used in supplementation are usually hydroxycobalamin or cyanocobalamin. B_{12} in foods usually occurs bound to protein in the methyl or 5′-deoxyadenosyl form. To be utilized, the B_{12} must be released from the protein by acid hydrolysis in the stomach or trypsin digestion in the intestine. It then combines with the intrinsic factor, a protein secreted by the stomach; this carries it to the ileum for absorption.

Vitamin B_{12} participates in only two chemical reactions in humans. The methyl derivative of B_{12} is required for **methionine synthase**, in which homocysteine is methylated to methionine. The 5-deoxyadenosyl derivative is required for **methylmalonyl-CoA mutase**, which converts methylmalonyl CoA to succinyl CoA, a key reaction in catabolism of valine, isoleucine, methionine, threonine, odd chain fatty acids, thymine, and the side chain of cholesterol. As might be expected, B_{12} deficiency causes the accumulation of both homocysteine and methylmalonic acid.

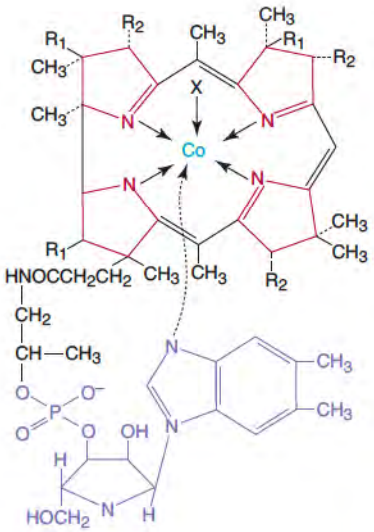

Figure 26.19 Structure of vitamin B_{12} (cobalamine).

The megaloblastic anemia associated with B_{12} deficiency is thought to reflect the effect of B_{12} on folate metabolism. B_{12}- dependent methionine synthesis (homocysteine + N^5-methyl THF –> methionine + THF) is the only pathway by which N^5-methyltetrahydrofolate can return to the tetrahydrofolate pool (see Figure 26.17, p. 1080). Thus, in B_{12} deficiency essentially all of the folate becomes "trapped" as the N^5-methyl derivative, causing a buildup of N^5-methyltetrahydrofolate and a deficiency of the tetrahydrofolate derivatives needed for purine and dTMP biosynthesis. By replenishing the tetrahydrofolate pool, large amounts of supplemental folate can overcome the megaloblastic anemia, but not the neurological problems. This is the crux of the current debate on the optimal levels for folate fortification of foods. It is the megaloblastic anemia that usually brings the patient into the doctor's office. Thus, by masking the anemia, routine fortification of foods with high levels of folate could prevent detection of B_{12} deficiency until the neurological damage had become irreversible.

It has been proposed that the demyelination associated with B_{12} deficiency is caused by methylmalonyl CoA accumulation in two ways. (1) Methylmalonyl CoA is a competitive inhibitor of malonyl CoA in fatty acid biosynthesis. Because the myelin sheath is continually turning over, any severe inhibition of fatty acid biosynthesis will lead to its degeneration. (2) Methylmalonyl CoA can substitute for malonyl CoA in fatty acid synthesis leading to synthesis of branched-chain fatty acids, which may disrupt membrane structure. However, the neurologic symptoms of B_{12} deficiency cannot be fully explained by either mechanism, since accumulation of both methylmalonic acid and homocysteine is required for demyelination. Recent studies have shown that B_{12} deficiency is associated with increased expression of tumor necrosis factor α (TNF-α) and nerve growth factor (NGF) and decreased expression of epidermal growth factor (EGF) and interleukin 6 (IL-6) in cerebrospinal fluid, but the mechanism of these changes and their effect on neural function remain unknown.

Vitamin B_{12} is widespread in foods of animal origin, especially meats. Since the liver stores up to a 6-year supply of vitamin B_{12}, deficiencies of B_{12} are rare except in older people who produce insufficient intrinsic factor and/or HCl in the stomach (Clin. Corr. 26.7), patients with severe malabsorption diseases (see Clin. Corr. 26.1, p. 1068) and long-term vegetarians.

CLINICAL CORRELATION 26.7

Nutritional Needs of Elderly Persons

If current trends continue, one out of five Americans will be over the age of 65 by the year 2030. With this projected aging of the American population, there has been increased interest in defining the nutritional needs of the elderly. Recent research shows altered needs of elderly persons for several essential nutrients. For example, the absorption and utilization of vitamin B_6 decreases with age. Dietary surveys have consistently shown that B_6 is a problem nutrient for many Americans, and the elderly are no exception. Many older Americans get less than 50% of the RDA for B_6 from their diet. Vitamin B_{12} deficiency is also more prevalent in the elderly. Many older adults develop atrophic gastritis (decreased acid production in the stomach) and decreased production of intrinsic factor, which lead to poor absorption of B_{12}. The blood level of homocysteine, a possible risk factor for atherosclerosis, dementia, and Alzheimer disease, is often elevated in the elderly. Homocysteine is a by-product of DNA methylation and is normally metabolized to methionine or cysteine in reactions requiring folic acid, B_{12} and B_6 (see Figure 26.17, p. 1080). Simple supplementation with those B vitamins is generally sufficient to normalize homocysteine levels. Vitamin D can be a problem as well. Many elderly do not spend much time in the sunlight, and the conversion of 7-dehydrocholesterol to vitamin D in the skin and 25-(OH)D to 1,25-$(OH)_2$D in the kidney decreases with age. These factors lead to significant deficiencies of 1,25-$(OH)_2$D in the elderly, which can cause a negative calcium balance. These changes may contribute to osteoporosis.

There is some evidence for increased need for chromium and zinc as well. Many elderly appear to have difficulty converting dietary chromium to the biologically active chromodulin. Chromium deficiency could contribute to type 2 diabetes. Similarly, most elderly consume between one-half and two-thirds the RDA for zinc, and conditions such as atrophic gastritis can interfere with zinc absorption. Symptoms of zinc deficiency include loss of taste acuity, dermatitis, and a weakened immune system. All of these symptoms are common in the elderly population, and zinc deficiency may contribute.

Not all of the news is bad, however. Vitamin A absorption increases with age and its clearance by the liver decreases, so vitamin A remains in the circulation for a longer time. Not only does the need for vitamin A decrease as we age, but the elderly also need to be particularly careful to avoid vitamin A toxicity. Although this does not restrict their choice of foods or multivitamin supplements, they should generally avoid separate vitamin A supplements.

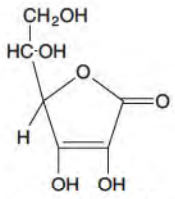
26.8 • OTHER WATER-SOLUBLE VITAMINS

Ascorbic Acid Functions in Reduction and Hydroxylation Reactions



ascorbic acid

Figure 26.20 **Structure of vitamin C (ascorbic acid).**

Vitamin C or ascorbic acid (Figure 26.20) is a cofactor for mixed function oxidases involved in the hydroxylation of lysine and proline, synthesis of carnitine, and synthesis of norepinephrine. Hydroxylation of lysine and proline is required for protocollagen to cross-link properly into normal collagen fibrils. Vitamin C is required for maintenance of normal connective tissue and for wound healing. It is also necessary for bone formation, since the organic matrix of bone tissue consists largely of collagen. Collagen is also a component of the ground substance surrounding capillary walls, so vitamin C deficiency causes capillary fragility. Carnitine is required for transport of long-chain fatty acids into the mitochondria (p. 691), and decreased carnitine levels may be responsible for the fatigue associated with vitamin C deficiency. Since vitamin C is concentrated in the adrenal gland, it may be required for hydroxylation reactions in synthesis of some corticosteroids especially in periods of stress. Vitamin C also appears to modulate signal transduction pathways and gene expression affecting vascular endothelial cells. Finally, ascorbic acid also acts as a nonenzymatic reducing agent. For example, it aids in **absorption of iron** by reducing it to the ferrous state in the stomach. It spares vitamin A, vitamin E, and some B vitamins by protecting them from oxidation. It enhances utilization of folic acid, either by aiding conversion of folate to tetrahydrofolate or formation of polyglutamate derivatives of tetrahydrofolate.

Symptoms of mild **vitamin C deficiency** include capillary fragility, which leads to easy bruising and formation of petechiae (small, pinpoint hemorrhages in skin) and decreased immunocompetence. Scurvy, a more severe form of deficiency, is associated with decreased wound healing, osteoporosis, hemorrhaging, and anemia. Osteoporosis results from the inability to maintain the collagenous organic matrix of the bone, which leads to demineralization. Anemia results from extensive hemorrhaging coupled with defects in iron absorption and folate metabolism.

Vitamin C is readily absorbed so that deficiency invariably results from poor diet and/or increased need. In severe stress or trauma there is a rapid drop in serum vitamin C levels, and most of the body's supply of vitamin C is mobilized to the adrenals and/or the traumatized area. It is not clear whether this represents an increased demand for vitamin C or merely a normal redistribution to those areas where it is needed most. Nor is it clear whether the lowered serum levels of vitamin C impair its functions in other tissues in the body. The current consensus seems to be that the lowered serum vitamin C levels indicate an increased demand, but there is little agreement as to how much.

Smoking causes lower serum levels of vitamin C. In fact, the RDAs for smokers are 110–125 mg of vitamin C/day versus 75–90 mg/day for nonsmoking adults. Aspirin appears to block uptake of vitamin C by white blood cells. Oral contraceptives and corticosteroids also lower serum levels of vitamin C. The possibility of marginal vitamin C deficiency should be considered with any patient using these drugs over a long period, especially if dietary intake of vitamin C is suboptimal.

The use of megadoses of vitamin C to prevent and cure the common cold has generated considerable controversy. While vitamin C supplementation does not appear to prevent the common cold, it may moderate the symptoms or shorten the duration. It has been suggested that vitamin C is required for normal leukocyte function or that it decreases histamine levels. Although megadoses of vitamin C are probably no more harmful than the widely used over-the-counter cold medications, some potential side effects of high vitamin C intake should be considered. For example, oxalate is a major metabolite of ascorbic acid. Thus, high ascorbate intakes could theoretically lead to the formation of oxalate kidney stones in predisposed individuals. However, most studies have shown that excess vitamin C is primarily excreted as ascorbate rather than oxalate. Pregnant mothers taking megadoses of vitamin C may give birth to infants with abnormally high vitamin C requirements, but this is easily treated. The UL for vitamin C has been set at 2000 mg/day because higher levels can cause diarrhea in some individuals.

Choline and Carnitine Perform Several Functions

Choline and carnitine have traditionally been considered as nonessential because they can be synthesized *de novo*. However, choline has recently been reclassified as essential and carnitine as conditionally essential. Choline (Figure 26.21) is required for synthesis and release of **acetylcholine**, an important neurotransmitter involved in memory storage, motor control, and other functions. It is also a precursor for synthesis of the phospholipids **phosphatidylcholine** (lecithin) and **sphingomyelin**, which are important for membrane function, intracellular signaling, and hepatic export of very low-density lipoproteins. Phosphatidylcholine is also important in removal of cholesterol from tissues, as it is a substrate for lecithin-cholesterol acyltransferase in reverse cholesterol transport (p. 725). Finally, choline is a precursor for the methyl donor betaine.

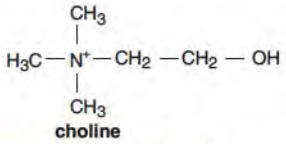


Figure 26.21 **Structure of choline.**

Studies in rodents indicate that choline deficiency increases the risk of liver cancer and memory deficits in aged animals, but these effects have not been demonstrated in humans. Both choline and betaine supplementation appear to lower serum homocysteine levels in humans. However, current data are insufficient to draw firm conclusions about whether choline and/or betaine supplementation have any effects on cardiovascular risk.

A significant portion of the daily choline requirement can be met by the endogenous conversion of phosphatidylethanolamine to phosphatidylcholine by the liver enzyme phosphatidylethanolamine *N*-methyltransferase (PEMT). Because choline can be synthesized *de novo* and is abundant in food, choline deficiency is very rare. Hepatic complications (fatty livers and elevated serum alanine aminotransferase) that respond to choline supplementation have been observed in patients on total parenteral nutrition solutions devoid of choline, with small intestinal bypass, and with liver cirrhosis. Choline is critical during fetal development because it affects DNA methylation, which influences neural cell precursor cell proliferation and apoptosis. Fortunately, PEMT expression is increased severalfold during pregnancy.

Carnitine (Figure 26.22) is required for transport of fatty acids across the mitochondrial membrane, so it is essential for normal fatty acid metabolism (p. 691). In muscle an enzyme called carnitine acyltransferase uses carnitine to convert acetyl CoA to acetylcarnitine, releasing free coenzyme A in the process. This is important because the supply of mitochondrial coenzyme A is very limited and acetyl CoA synthesis by pyruvate dehydrogenase during high intensity exercise is much more rapid than the citric acid cycle can utilize This would quickly deplete the coenzyme A supply and shut down the pyruvate dehydrogenase reaction in the absence of the carnitine acyltransferase reaction. Thus, in exercising muscle, carnitine is essential for both fatty acid and carbohydrate metabolism.

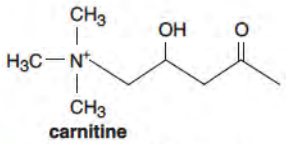

Figure 26.22 **Structure of carnitine.**

Because carnitine can be synthesized *de novo,* it is nonessential for normal healthy adults. However, it is considered conditionally essential overall because human genetic disorders of carnitine metabolism have been described and some of them respond to carnitine supplementation. Carnitine is a popular dietary supplement for athletes. However, for supplemental carnitine to have any effect on muscle carnitine levels it must be administered along with sufficient carbohydrate to significantly increase serum insulin levels. Most carnitine supplements on the market do not have any effect on muscle carnitine levels.

26.9 • MACROMINERALS

Calcium Has Many Physiological Roles

Calcium is the most abundant mineral in the body. Most is in bone, but the small amount of Ca^{2+} outside of bone functions in a variety of essential processes. It is required for many enzymes; it mediates some hormonal responses; and it is essential for blood coagulation, muscle contractility, and normal neuromuscular irritability. In fact, only a relatively narrow range of serum Ca^{2+} levels is compatible with life. Since maintenance of constant serum levels is so vital, an elaborate homeostatic control system has evolved (see Figure 26.6, p. 1071). Low serum Ca^{2+} stimulates formation of 1,25-dihydroxycholecalciferol, which enhances intestinal Ca^{2+} absorption and, with parathyroid hormone, stimulates bone resorption. Thus, long-term dietary Ca^{2+} insufficiency almost always results in net loss of calcium from the bones.

Dietary Ca^{2+} requirements, however, vary considerably from individual to individual due to the existence of other factors that affect availability of Ca^{2+}. For example, vitamin D is required for optimal utilization of calcium, while excess dietary protein may cause more rapid excretion of Ca^{2+}. Exercise facilitates calcium utilization for bone formation. Calcium balance studies carried out on Peruvian Indians, who have extensive exposure to sunlight, get extensive exercise, and subsist on low-protein vegetarian diets, indicate a need for only 300–400 mg Ca^{2+}/day. However, similar studies carried out in this country consistently show higher requirements and the RDA has been set at 1000–1300 mg/day.

Symptoms of **Ca^{2+} deficiency** resemble those of vitamin D deficiency, but other symptoms such as muscle cramps are possible with marginal deficiencies. A significant portion of low-income children and adult females in this country do not consume adequate Ca^{2+}. This is of particular concern because these are the population groups with particularly high needs for Ca^{2+}. For this reason, the U.S. Congress has established the WIC (Women and Infant Children) program to assure adequate protein, Ca^{2+}, and iron for indigent families with pregnant/lactating mothers or with young infants.

Dietary surveys show that 34%–47% of the population over 60 years of age consumes less than the EAR for Ca^{2+}. This is the group most at risk of developing osteoporosis, characterized by loss of bone organic matrix and progressive demineralization. Causes of osteoporosis are multifactorial and largely unknown, but it is likely that part of the problem has to do with Ca^{2+} metabolism (Clin. Corr. 26.8). Recent studies suggest that inadequate intake of Ca^{2+} may result in elevated blood pressure. This is of great concern because most low-sodium diets (which are recommended for patients with high blood pressure) severely limit dairy products, the main source of Ca^{2+} for Americans.

Magnesium Is Required by Many Enzymes

Magnesium is required for many enzyme activities, particularly those utilizing an ATP–Mg^{2+} complex, and for neuromuscular transmission. Mg^{2+} content is significantly reduced during processing of food items, and recent dietary surveys have shown that the average

CLINICAL CORRELATION 26.8

Diet and Osteoporosis

There is strong consensus that the years from age 10 to 35, when bone density is reaching its maximum, are the most important for reducing the risk of osteoporosis. The maximum bone density obtained during these years depends on both calcium intake and exercise, and dense bones are less likely to become seriously depleted of calcium following menopause. Unfortunately, most American women consume far too little calcium during these years. The RDA for calcium is 1300 mg/day (4 or more glasses of milk/day) for women from age 11 to 18, 1000 mg/day (3 or more glasses of milk/day) for women from 19 to 50, and 1200 mg/day (4 glasses of milk/day) for women over 50. Some experts think that calcium requirements for postmenopausal women should be even higher. In 1994, an NIH consensus panel on osteoporosis recommended that postmenopausal women consume up to 1500 mg of calcium/day. Unfortunately, the median calcium intake for women 19 and older is only about 500 mg/day, and with the recent concern about the fat content of dairy products, calcium intakes appear to be decreasing rather than increasing. Thus, it is clear that increased calcium intake should be encouraged in this group. Even with drug therapy to prevent osteoporosis, calcium intake should not be ignored. Recent studies have shown that calcium intakes in the range of 1000–1500 mg/day make drug or estrogen therapy more effective at preserving bone mass.

Although most of the focus is on calcium intake, we need to remember that bones are not made of calcium alone. If the diet is deficient in other nutrients, the utilization of calcium for bone formation will be impaired. Vitamin C is needed to form the bone matrix, and magnesium and phosphorus are important components of bone structure. Vitamin K and a variety of trace minerals, including copper, zinc, manganese, and boron, are important for bone formation. Thus, calcium supplements may not be optimally utilized if the overall diet is inadequate. Vitamin D is required for absorption and utilization of calcium. It deserves special mention as it may be a problem for the elderly (see Clin. Corr. 28.7, p. 1083), and some experts feel that the current recommendation for vitamin D intake in adults may be too low. Finally, an adequate exercise program is just as important as drug therapy and an adequate diet for preventing the loss of bone density.

Heaney, R. P. Calcium in the prevention and treatment of osteoporosis. *J. Internal Med.* 231:169, 1992; National Institutes of Health. Optimal Calcium Intake. NIH Consensus Statement. 12 (November 4), 1994; and Murphy, N. M. and Carroll, P. The effect of physical activity and its interaction with nutrition on bone health. *Proc. Nutr. Soc.* 62:829, 2003.

Mg^{2+} intake in Western countries is often below the EAR. Deficiency occurs in alcoholism, with use of certain diuretics and in metabolic acidosis. The main symptoms of **Mg^{2+} deficiency** are weakness, tremors, and cardiac arrhythmia. Supplemental Mg^{2+} may help prevent formation of calcium oxalate stones in the kidney. Mg^{2+} supplementation has also been shown to lower blood pressure in several clinical studies, and there is an inverse effect between dietary Mg^{2+} intake and the risk of stroke.

26.10 • TRACE MINERALS

Iron Deficiency Causes Anemia and Decreased Immunocompetence

Iron is a component of heme in hemoglobin and myoglobin, which are essential for O_2 transport; the cytochromes, which are involved in mitochondrial electron transport; the **P_{450} enzymes**, which are involved in hydroxylation reactions; and the lysosomal enzyme myeloperoxidase, which is required for killing of bacteria and other pathogens by neutrophils. **Nonheme iron proteins** such as ribonucleotide reductase are also involved in a number of redox reactions. Thus, iron is required for O_2 transport, energy metabolism, cell proliferation, and immune defense against pathogens. Total body iron in human adults is 3–4 g. Two-thirds of that is incorporated into the heme moiety of erythrocytes. Erythrocytes normally live only 120 days; this means that erythrocytes containing approximately 20 mg of iron are destroyed by the reticuloendothelial system each day. Fortunately, almost all of that iron is reutilized. The only net loss of iron for males and postmenopausal women is shedding of intestinal and skin cells, which amounts to about 1–2 mg/day. Blood loss due to menstruation and disease and increase of blood volume in children increases the need for iron in those population groups. Assuming a 10%–15% efficiency of absorption, an RDA of 8 mg/day for normal adult males and 18 mg/day for menstruating females has been set. For pregnant females it is 27 mg/day. Although 8 mg/day of iron can easily be obtained from a normal diet, 18 mg is marginal at best and 27 mg can almost never be obtained. The best dietary sources are meats, dried legumes, dried fruits, and enriched cereal products.

While iron is absolutely essential for life, it is also extremely toxic. **Free iron** can generate dangerous free radicals through the Fenton reaction, and free iron in the circulation can support the growth of microbial pathogens and increase the risk of systemic infections. Thus, iron is sequestered in the cell by **ferritin** and in the bloodstream by **transferrin**. **Apoferritin** (the term given to ferritin before it binds iron) is a complex of 24 subunits with a capacity for binding 4500 iron atoms. Each apoferritin molecule is a mixture of two very similar subunits. Apoferritin in every tissue contains some of both subunits, but the H form predominates in nucleated blood cells and heart, while the L subunit predominates in the liver and spleen. Transferrin is a single polypeptide with two binding sites. Once cellular iron exceeds the binding capacity of apoferritin the excess iron is deposited on the outside of ferritin in an amorphous mixture of iron hydroxide, iron phosphate, and proteins called hemosiderin in the liver, heart, pancreas, and pituitary, leading to organ dysfunction.

Because the loss of iron (tissue shedding and blood loss) occurs in an unregulated fashion, regulation of iron homeostasis occurs almost entirely at the level of iron uptake and delivery to the bloodstream by the intestine. The uptake of iron by the small intestine is summarized in Figure 26.23. Heme iron is taken up most efficiently by the intestine, but the mechanism of heme iron uptake is not clear at present. The digestion of nonheme iron proteins in the intestinal lumen releases iron in the +3 state. For the remainder of iron metabolism its oxidation state is critical. Iron is transported across cell membranes in the +2 state and is stored or transported in the +3 state. Thus, **ferrireductases** and **ferroxidases** play an important role in iron metabolism. In the intestine Fe^{3+} is reduced to Fe^{2+} by the ferrireductase duodenal cytochrome b (Dcytb). Ascorbate is the primary source of reducing equivalents for Dcytb, so the absorption of nonheme iron is significantly enhanced when foods containing vitamin C are consumed at the same time.

Fe^{2+} is transported into the intestinal mucosal cells by a transporter called **divalent metal transporter (DMT-1)**. As the name suggests, DMT-1 can also transport several other

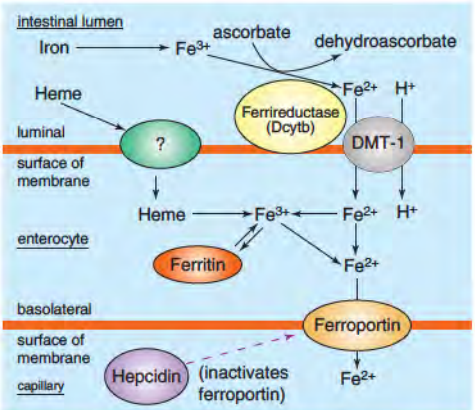

Figure 26.23 Uptake and export of iron by the intestine. Abbreviations: Dcytb, intestinal ferrireductase duodenal cytochrome b; and DMT-1, divalent metal transporter 1.

TABLE 26.2 • Regulation of Key Enzymes Involved in Iron Homeostasis

Protein	*Regulatory Mechanism*	*Function*
Proteins whose expression increases when iron is scarce		
Intestinal DMT-1	IRE in 3′ UTR	Intestinal absorption of iron
Ferroportin	Hepcidin-dependent degradation when iron high	Export of iron from intestine
Ceruloplasmin	?	Conversion of Fe^{2+} to Fe^{3+}

Hepcidin	Expression stimulated by HJV, HFE and TfR2	Facilitates ferroportin degradation
Aminolevulinic acid synthase	IRE in 5′ UTR	Porphyrin biosynthesis

transition metals that occur naturally in the +2 state such as zinc, copper, and manganese. A large excess of any one of these essential trace metals in the diet can create a deficiency of the others. Iron transport by DMT-1 requires co-transport of protons, so it is most active in the upper portion of the duodenum where stomach acid empties into the intestine. This is why antacids and H2 histamine blockers interfere with iron absorption.

Because of the cytotoxicity of free iron, most of it is sequestered by binding to ferritin once it enters the intestinal mucosal cell. In addition to its role in protecting the cell from the cytotoxic effects of iron, the sequestration of iron by ferritin in the intestinal mucosal cell reduces the net delivery of iron to the circulation, and the sequestration of iron by ferritin in the liver removes iron from the circulation under conditions of iron excess. The H subunit of ferritin has the ferroxidase activity required for binding of iron by the ferritin complex. Release of iron into the circulation requires another ferrireductase to reduce it to the +2 state and a transporter called ferroportin. Levels of ferroportin are controlled by a peptide produced by the liver called **hepcidin**, which binds to ferroportin triggering its tyrosine phosphorylation, internalization, and ubiquitin-mediated degradation in proteasomes. When iron is in excess, hepcidin levels are increased, leading to down-regulation of ferroportin and decreasing iron transport into the circulation by the intestinal mucosal cells, by the liver and by macrophages in the reticuloendothelial system.

The key enzymes in this transport process are coordinately regulated to maintain iron homeostasis (Table 26.2). When iron levels are low, DMT-1 expression is up-regulated and ferritin expression is down-regulated. In addition hepcidin expression is down-regulated; this results in stabilization and accumulation of ferroportin. These effects combine to increase uptake, decrease sequestration, and increase export of iron by intestinal mucosal cells. In contrast, when iron levels are high, DMT-1 expression is down-regulated and both ferritin and hepcidin expression are up-regulated. This decreases export of iron by intestinal mucosal cells and increases retention of iron stores by the liver.

Transport of iron in the bloodstream is summarized in Figure 26.24. Once Fe^{2+} enters the circulation it is oxidized to the +3 state by two ferroxidases called **hephaestin** and **ceruloplasmin**. Both hephaestin and ceruloplasmin are involved in oxidation of Fe^{2+} to Fe^{3+} in the intestine, but hepatocytes and macrophages appear to use ceruloplasmin exclusively. Ceruloplasmin and hephaestin are copper-containing enzymes; this is thought to be the reason that anemia is one symptom of copper deficiency (Clin. Corr. 26.9). Fe^{3+} is sequestered and transported through the bloodstream by transferrin. Transferrin levels are increased under conditions of iron deficiency and decreased under conditions of iron excess, but transferrin levels are generally in excess so this effect is much less important than the regulation of the other proteins involved in maintaining iron homeostasis.

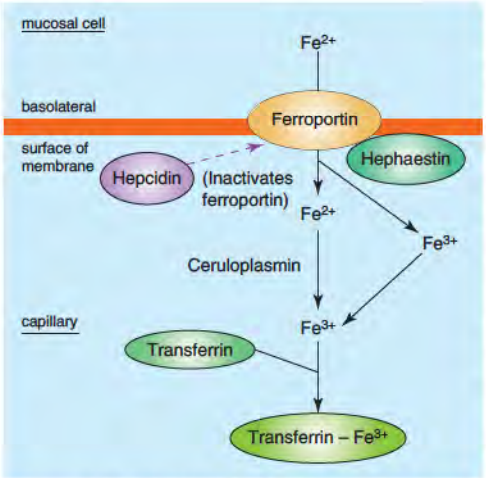

Figure 26.24 **Transport of iron in the circulation.**

CLINICAL CORRELATION 26.9

Ceruloplasmin and Iron Metabolism

A deficiency, but not the absence of ceruloplasmin, a copper-containing protein, is associated with Wilson disease because the ATP7B copper transporter, which is defective in Wilson disease (OMIM 27900), is essential for copper delivery to ceruloplasmin and copper-deficient ceruloplasmin is unstable. Because there was no evidence for significant impairment of mobilization of iron in Wilson disease, it was formerly thought that the ferroxidase activity of ceruloplasmin was not physiologically important. However, a very rare genetic defect in ceruloplasmin biosynthesis, where the protein was virtually absent in serum, leads to a marked elevation of liver-iron content and serum ferritin levels. These patients develop diabetes mellitus, retinal degeneration, and central nervous system changes. The diabetes and central nervous system findings are associated with increased iron in the pancreas and brain, respectively.

Iron-deficiency anemia is not associated with ceruloplasmin deficiency because the intestine has a second ferroxidase called hephaestin. However, both ceruloplasmin and hephaestin are copper-containing enzymes, so copper deficiency can lead to an iron-deficiency anemia. In addition, transcription of the ceruloplasmin gene in iron deficiency increases fourfold. Thus, in contrast to earlier considerations, it appears that ceruloplasmin has a significant role in iron metabolism.

As shown in Figure 26.25, transferrin is taken up by cells by binding to transferrin receptor 1 (TfR1). The transferrin–receptor complex clusters in clathrin-coated pits and is taken up by endocytosis. As the interior of the endosome is acidified, Fe^{3+} is released from transferrin and reduced by a ferrireductase called Streap3; the resulting Fe^{2+} is transported into the cytosol by DMT-1. In this case the activity of DMT-1 is optimal because of the low pH of the endosome. At the end of this process the transferrin receptor is recycled to the cell surface. Expression of TfR1 is increased under conditions of iron deficiency and decreased under conditions of iron excess. There is a homologous protein called transferrin receptor 2 (TfR2), but it appears to serve primarily as an iron sensor and its level is increased under conditions of iron excess. Cytosolic Fe^{2+} is transported into the mitochondria by a transporter called mitoferrin and inserted into protoporphyrin IX to form heme by the enzyme ferrochelatase (p. 796).

Regulation of key enzymes involved in iron homeostasis is summarized in Table 26.2. Several of these enzymes are regulated at a translational level by **iron responsive elements (IREs)** and **iron responsive proteins (IRPs)** (Figure 26.26). Iron responsive elements are stem-loop structures in either the 3′- or the 5′- untranslated regions of mRNAs for proteins involved in iron homeostasis. Iron-responsive proteins 1 and 2 (IRP1 and IRP2) are proteins that bind to the IREs. When the IRE is located in the 3′ untranslated region, such as with transferrin receptor mRNA, binding of an IRP stabilizes the mRNA and enhances its

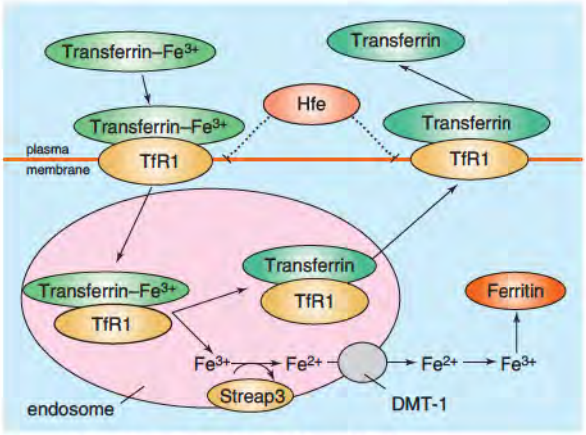

Figure 26.25 **Cellular uptake of transferrin**

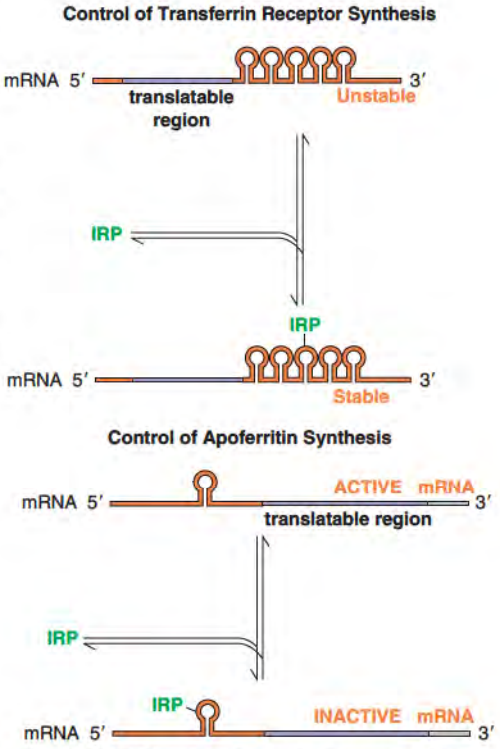

Figure 26.26 **Control of transferrin and apoferritin synthesis by iron responsive elements (IREs) and iron responsive proteins (IRPs).** A: Control of transferrin receptor synthesis; B: Control of apoferritin synthesis

translation. When the IRE is located in the 5′ untranslated region, such as with apoferritin, binding of an IRP interferes with ribosome loading and results in inhibition of translation.

IRP1 has a very interesting mechanism of regulation in response to iron levels. When iron is abundant, it contains an iron–sulfur cluster and has aconitase activity, but no IRE-binding activity. When iron is scarce, it loses the iron–sulfur cluster and undergoes a conformational change that results in loss of aconitase activity and gain of IRE-binding activity. The net result of these effects is that expression of enzymes like the transferrin receptor, which has IREs in the 3′ untranslated region of its mRNA, is increased when iron is scarce, and expression of enzymes like apoferritin, which has an IRE in the 5′ untranslated region of its mRNA, is decreased when iron is scarce. IRP2 is regulated in a more classical manner. IRP2 levels are increased when iron is scarce and decreased when iron is abundant, but the mechanism of this regulation is not clear.

Synthesis of hepcidin by the liver is another key control point for iron homeostasis (Figure 26.27). Hepcidin synthesis is stimulated by the proteins hemojuvelin (HJV), transferrin receptor-2 (TfR2) and the major histocompatibility class I-like molecule HFE. Synthesis of these three proteins is, in turn, up-regulated when iron is abundant. Mutations in any of the three can lead to an iron overload disease called hemochromatosis (Clin. Corr. 26.10) because hepcidin is not available to downregulate ferroportin levels under conditions of iron excess. Iron deficiency anemia can lead to hypoxia and increased erythropoiesis, and both of those lead to decreased hepcidin expression which up-regulates ferroportin levels and increases iron availability. Finally, infection and inflammation result in increased hepcidin levels via the effects of cytokines such as interleukin 6 (IL-6). This results in sequestration of iron in the tissues and reduces the risk of systemic infections.

The best-known symptom of **iron deficiency** is a microcytic hypochromic **anemia** (Clin. Corr. 26.11). Iron deficiency is also associated with decreased immunocompetence. Dietary surveys indicate that 95% or more of children and menstruating females do not obtain adequate dietary iron. Biochemical measurements reveal a 10%–25% incidence of

CLINICAL CORRELATION 26.10

Hemochromatosis

Hemochromatosis is primarily a genetic disease of iron overload. Patients with a predisposition to hemochromatosis develop iron deposits in the liver, heart, and endocrine tissue even though they have normal intakes of dietary iron. Eventually, those iron deposits can lead to cirrhosis, cardiomyopathy, diabetes, and other endocrine disorders. In most cases the iron overload is secondary to decreased hepcidin expression, which leads to an inability to appropriately downregulate ferroportin expression when iron is in excess. The regulation of hepcidin expression is summarized in Figure 26.27, p. 1090. The most common form of hemochromatosis (OMIM 235200) is caused by a homozygous Cys282Tyr mutation in HFE. Approximately 9% of the U.S. population is heterozygous and 0.25% is homozygous for this mutation. Hemochromatosis caused by this genetic defect is relatively mild, with onset at middle age, and penetrance is incomplete, with many patients being affected to only a modest degree.

As might be expected mutations in most of the other genes involved in regulation of hepcidin (see Figure 26.27, p. 1090) can also cause hemochomatosis, but those mutations are much rarer than the HFE polymorphism. Hemochromatosis caused by a homozygous deletion of TfR2 is somewhat more severe than the homozygous HFE mutation. Homozygous mutations in hemjuvelin or hepcidin cause a very severe form of hemochromatosis, called juvenile hemochromatosis. Untreated patients with juvenile hemochromatosis usually develop iron overload and damage to their liver and other organs in their teens. Finally, mutations in ferroportin are of two types. Loss-of-function mutations lead to anemia, whereas missense mutations that lead to an inability of ferroportin to interact with hepcidin lead to hemochromatosis.

Treatment for hemochromatosis consists of regular phlebotomy, which is effective at preventing the symptoms of hemochromatosis if started early enough. People with hereditary hemochromatosis are also generally advised to avoid foods and supplements containing high levels of iron or vitamin C. Unfortunately, many people don't realize that they have hereditary hemochromatosis until the symptoms are well advanced. This has lead to a public health policy debate about iron fortification of foods. Iron fortification of foods was instituted to prevent iron deficiency in young children and pregnant women, and it has been effective for that purpose. However, in countries like Sweden where 42% of the average dietary intake of iron is derived from iron-fortified foods, 5% of males have elevated serum iron values and 2% have iron stores indicative of early-stage hemochromatosis.

Iron-overload disease in HFE hereditary hemochromatosis. *N. Engl. J. Med.* 358:221, 2008.

CLINICAL CORRELATION 26.11

Clinical Tests for Iron-Deficiency Anemia and Hemochromatosis

There are a number of clinical tests that can be used to determine iron status. Anemia in general leads to a decrease in hemoglobin (normal = 12.1–15.1 gm/dL for females and 13.8–17.2 gm/dL for males) and hematocrit (% of red blood cells found in whole blood; normal = 36.1%–44.3% for females and 40.7%–50.3% for males). Iron-deficiency anemia is characterized as a microcytic hypochromic anemia, meaning that the red cells are smaller and paler than normal due to their decreased hemoglobin content. Small amounts of ferritin end up in the circulation due to normal cellular turnover (normal = 12–150 ng/mL for females and 12–300 ng/mL for males), and serum ferritin levels are proportional to cellular ferritin levels. Serum ferritin is almost nonexistent in iron deficiency and increases with cellular iron load. Serum iron (normal = 60–170 mcg/dl) and total iron-binding capacity (TIBC) of serum transferrin (240–450 mcg/dl) are often measured and used to calculate percentage saturation of transferrin (normal = 20%–50%), a very sensitive indicator of iron status.

Iron-deficiency anemia is generally diagnosed on the basis of low hemoglobin and hematocrit levels couple with a microcytic, hypochromic morphology of the red blood cells. Serum iron, serum ferritin, and TIBC may be used as confirming tests. Serum iron and TIBC are most often used to diagnose hemochromatosis. In hemochromatosis, serum iron is high, TIBC is low or normal, and transferrin saturation is high.

Serum transferrin levels can also be measured, but are most frequently used to measure a patient's liver function or nutritional status. Because it is made in the liver, transferrin will be low with liver disease. Transferrin levels also drop when there is not enough protein in the diet, so this test can be used to monitor nutritional state.

iron deficiency anemia in this same group. Iron-deficiency anemia is also a problem with the elderly (see Clin. Corr. 26.7, p 1083) due to poor dietary intake and increased frequency of achlorhydria, which decreases the intestinal uptake of iron by DMT-1.

Because iron-deficiency anemia is widespread, government programs of nutritional intervention such as the WIC program have emphasized iron-rich foods. However, since recent studies have suggested that excess iron intake may increase the risk of cardiovascular disease, iron supplementation and the consumption of iron-fortified foods may be inappropriate for adult men and postmenopausal women. **Excess iron** can lead to the rare condition **hemochromatosis** in which iron deposits are found in abnormally high levels in many tissues and cause liver, pancreatic, and cardiac dysfunction as well as pigmentation of the skin (Clin. Corr. 26.10). Hemochromatosis is also occasionally seen in chronic hemolytic anemias that require frequent blood transfusions such as β-thalassemia and in liver disease.

Iodine Is Incorporated into Thyroid Hormones

Dietary **iodine** is efficiently absorbed and transported to the **thyroid gland**, where it is stored and used for synthesis of triiodothyronine and thyroxine. These hormones function in regulating the **basal metabolic rate** of adults and the growth and development of children. Adequate maternal thyroid levels are particularly important for fetal brain development. Saltwater fish are the best natural food sources of iodine, and in the past population groups living in inland areas suffered from the endemic deficiency disease goiter, an enlargement (sometimes massive) of the thyroid gland. Since iodine has been routinely added to table salt, goiter has become relatively rare. However, in some inland areas, mild forms of goiter still occur in up to 5% of the population.

Zinc Is Required by Many Proteins

Zinc is part of the catalytic center of over 300 metalloenzymes, including RNA and DNA polymerases, alkaline phosphatase, and carbonic anhydrase. In addition, it forms zinc fingers (Zn^{2+} coordinated to four amino acid side chains), which provide structural stability to another 300–700 proteins. Zinc fingers facilitate binding of proteins to DNA and are common motifs in transcription factors and nuclear hormone receptors. They are also important for protein–protein interactions and are found in many signal transduction proteins. Zinc also binds to the metal response element (MRE) of MRE-binding transcription factor-1 (MTF-1) and controls gene expression in a manner analogous to the effect of iron

on binding of IRPs to IREs. Finally, relatively large amounts of loosely bound zinc are also found in vesicular structures including synaptic vesicles of nerve terminals and β-cells of the islets of Langerhans, suggesting that zinc plays a much broader physiological role than might be suggested by its presence in zinc metalloproteins.

Intracellular zinc levels are controlled in part by a group of 14 transporters called ZIPs which transport zinc into cells and 10 transporters called ZnTs which control the efflux of zinc from the cytosol to either intracellular vesicles or extracellular space. Most of the intracellular zinc is tightly bound to cysteine residues in metallothioneins and related proteins. When these cysteines are oxidized, free zinc is released into the cytosol. Thus, intracellular levels of free zinc are closely linked to the redox state of the cell and may be part of the redox signaling pathway.

Zinc deficiency in children is usually marked by poor growth and impairment of sexual development. In both children and adults zinc deficiency results in poor wound healing and dermatitis. Zinc is present in gustin, a salivary polypeptide that appears to be necessary for normal development of taste buds, so zinc deficiency leads to decreased taste acuity. Zinc is required for cytokine production by monocytes and T-cells. Thus, zinc deficiency is associated with impaired immune function. Zinc is required for the activity of porphobilinogen synthase. In lead poisoning, lead replaces the zinc, which leads to anemia and accumulation of γ-aminolevulinic acid (p. 793).

Dietary surveys indicate that zinc intake may be marginal for many individuals, and zinc supplementation has been shown to improve immune status in the elderly. Severe zinc deficiency is seen primarily in alcoholics (especially if they have cirrhosis), patients with chronic renal disease or severe malabsorption diseases, and occasionally in people after long-term parenteral nutrition (TPN). The most characteristic early symptom of zinc-deficient patients on TPN is dermatitis. Zinc is occasionally used therapeutically to promote wound healing and may be of some use in treating gastric ulcers.

Copper Is a Cofactor for Important Enzymes

Important **copper**-containing enzymes include ceruloplasmin and hephaestin (oxidize iron to facilitate its binding to transferrin), cytochrome c oxidase (electron transport), dopamine β-hydroxylase (norepinephrine synthesis), lysyl oxidase (collagen cross-linking), superoxide dismutase (disproportionation of superoxide), tyrosinase (pigment formation), peptidylglycine α-amidating monoxygenase (neurotransmitter metabolism) and C_{18}, Δ^9 desaturase (addition of double bonds to long-chain fatty acids). The C_{18},Δ^9 desaturase is responsible for converting stearic acid (a C_{18} saturated fatty acid) to oleic acid (a C_{18} monounsaturated fatty acid). This may explain why dietary stearic acid does not raise blood cholesterol like the other saturated fatty acids. Symptoms of **copper deficiency** include anemia, hypercholesterolemia, demineralization of bones, leukopenia, fragility of large arteries, and dem yelination of neural tissue. Anemia may reflect the reduced ceruloplasmin and hephaestin activity. Bone demineralization and blood vessel fragility can be directly traced to defects in collagen and elastin formation. Hypercholesterolemia may be related to an increase in the ratio of saturated to monounsaturated fatty acids of the C_{18} series due to reduced activity of the C_{18},Δ^9 desaturase.

Cellular uptake of copper is catalyzed by a high-affinity **copper transporter** called **CTR1**. In mice genetic inactivation of CTR1 is embryonic lethal. Copper efflux from cells is catalyzed by two copper transporting ATPases, **ATP-7A** and **ATP-7B**. ATP-7A is found in most tissues except liver and is essential for exit of copper from intestinal cells. ATP-7B is found in greatest abundance in the liver and brain and is responsible for exit of copper from those tissues. Intracellular copper concentrations regulate the cellular location of both ATP-7A and ATP-7B. When copper levels are low, both ATP-7A and ATP-7B are localized primarily within the *trans* Golgi network. However, when copper levels are high, ATP-7A is transferred to the basolateral surface and plasma membrane of intestinal mucosal cells for transport of copper into the bloodstream and ATP7B is transferred to the bile canaliculus for excretion of copper into the bile. Copper deficiency is relatively rare and is usually seen only because of excess zinc intake (zinc and copper compete for absorption) and in Menkes syndrome, a relatively rare X-linked hereditary disease associated with

CLINICAL CORRELATION 26.12

Diseases of Copper Metabolism

Menkes disease (OMIM 309400) is an X-linked disorder characterized by global copper deficiency. It is caused by mutations in the ATP7A copper transporter that interfere with the ability of intestinal mucosal cells to transport copper into the bloodstream. The symptoms of Menkes disease are mental retardation, growth retardation, hypothermia, loose skin and joints, hypopigmentation, and kinky hair and are caused by the inability to load copper-dependent enzymes with copper. Patients with severe loss of ATP7A activity develop symptoms by 2–3 months and seldom live beyond 3 years. Treatment consists of administration of a copper–histidine complex and is only modestly successful.

Wilson disease is an autosomal recessive disease characterized by copper overload, particularly in the liver and the brain. It is caused by mutations in the ATP7B copper transporter that prevent the liver and neurological tissue from getting rid of excess copper. The accumulation of copper in the liver leads to cirrhosis, chronic hepatitis, and eventually liver failure. The accumulation of copper in the brain leads to parkinsonian symptoms, seizures and psychiatric symptoms. Copper also accumulates as a characteristic gold-brown ring, called the Kayser–Fleischer ring, around the periphery of the cornea. Treatment of Wilson disease consists of limiting copper-rich foods and increasing dietary zinc intake to reduce dietary copper absorption and use of copper chelating agents such as penicillamine and trientine to increase copper excretion from body. These treatments are very effective if begun early enough.

Ala, A., Walker, A. P., Ashkan, K., Dooley, J. S., and Schilsky, M. L. Wilson disease. *Lancet* 369:397, 2007; de Bie, P., Muller, P., Wijmenga, C., and Klamp, L. W. J. Molecular pathogenesis of Wilson and Menkes disease: Correlation of mutations with molecular defects and disease phenotypes. *J. Med. Genet.* 44:673, 2007.

a defect in the ATP-7A copper transporter. Wilson disease, an autosomal recessive disease that leads to copper overload, is associated with a defect in the ATP-7B copper transporter (Clin. Corr. 26.12).

Chromium Is a Component of Chromodulin

Chromium is a component of the low-molecular-weight protein **chromodulin**, which potentiates the effects of insulin by facilitating insulin binding to its receptor and receptor kinase signaling. The chief symptom of chromium deficiency is impaired glucose tolerance, a result of decreased insulin effectiveness. Chromium deficiency appears to be rare in healthy adults. However, diabetes causes increased urinary loss of chromium, which can lead to chromium deficiency over time. Supplementation with chromium appears to improve glycemic control in patients with type 2 diabetes.

Selenium Is Found in Selenoproteins

Selenium is incorporated into approximately 25 selenoproteins in humans including **glutathione peroxidase**, phospholipid-hydroperoxide, **thioredoxin reductase**, iodothyronine deiodinase, selenoprotein P, sperm capsule selenoprotein GPx4, and muscle selenoprotein W. These proteins contain one or more selenocysteine residues, which are incorporated during translation (p. 212). The incorporation of selenocysteine into protein requires a unique selenocystyl-tRNA that binds to UGA codons in mRNAs that also have a stem-loop structure called a Sec-insertion sequence (SECIS) in the 3′-untranslated region. The selenocysteine is synthesized directly on the tRNA from selenide, ATP, and seryl-tRNA.

Glutathione peroxidase destroys peroxides in the cytosol (p. 789), which complements the effect of vitamin E since vitamin E is limited primarily to the membrane. Phospholipid-hydroperoxide glutathione peroxidase catalyzes reductive destruction of phospholipid and cholesterol ester hydroperoxides in oxidized low-density lipoproteins. Iodothyronine deiodinase catalyzes the conversion of thyroxine (T_4) to the active thyroid hormone 3,3′,5-triiodothyronine (T_3). Selenoprotein P is an extracellular protein that delivers selenium to extrahepatic tissues. Selenoprotein GPx4 is important for sperm motility, and selenoprotein W appears to be essential for muscle metabolism. Selenium is one of the few nutrients not removed by the milling of flour and is usually thought to be present in adequate amounts in the diet. Selenium levels are very low in the soil in certain parts of the country, however; and foods raised in these regions are low in selenium. Fortunately, this effect is minimized by the current food distribution system, which assures that the foods marketed

in any one area are derived from a variety of different geographical regions. Clinical studies have suggested that supplementation with selenium may reduce the risk of lung, breast, and bladder cancers.

Manganese, Molybdenum, Fluoride, and Boron Are Essential Trace Elements

Manganese is a component of arginase, glutamine synthetase, Mn superoxide dismutase, and phosphoenolpyruvate decarboxylase and activates a number of other enzymes. **Molybdenum** is present in xanthine oxidase (p. 816). **Fluoride** strengthens bones and teeth and is usually added to drinking water. **Boron** appears to be important role in bone formation, nerve function, and immune response.

26.11 • THE AMERICAN DIET: FACT AND FALLACY

Much has been said about the supposed deterioration of the American diet. Americans are eating much more processed food than did their ancestors. These foods have a higher caloric density and a lower nutrient density than the foods they replace. However, they are almost uniformly enriched with iron, thiamin, riboflavin, niacin, and low levels of folic acid. In many cases they are even fortified (usually as much for sales promotion as for nutritional reasons) with as many as 11–15 vitamins and minerals. Unfortunately, it is not practical to replace all of the nutrients lost during processing, especially the trace minerals and phytonutrients such as the carotenoids. Imitation foods present a special problem, as they are usually incomplete in more subtle ways. For example, imitation cheese and milkshakes are widely sold in this country. They usually contain the protein and calcium one would expect of the food they replace, but often do not contain the riboflavin which one would obtain from them. Fast food meals tend to be high in calories and fat, and low in certain vitamins and trace minerals. For example, the standard fast food meal provides over 50% of the calories the average adult needs for the entire day, while providing $< 5\%$ of the vitamin A and $< 30\%$ of biotin, folic acid, and pantothenic acid. Unfortunately, much of the controversy in recent years has centered on whether these trends are good or bad. This simply obscures the issue at hand. Clearly, it is possible to obtain a balanced diet that includes some processed, imitation, and fast foods if one compensates by selecting foods for the other meals that are low in caloric density and rich in nutrients. Without such compensation the balanced diet becomes a myth.

26.12 • ASSESSMENT OF NUTRITIONAL STATUS IN CLINICAL PRACTICE

Figure 26.28 Factors affecting individual nutritional status. Schematic representation of three important risk factors in determining nutritional status. A person in the periphery would have very low risk of any nutritional deficiency, whereas those in the green, orange, purple, or center areas would be much more likely to experience some symptoms of nutritional deficiencies.

It might seem that the process of evaluating the **nutritional status** of an individual patient would be an overwhelming task after surveying the major micronutrients and their biochemical roles. There are three factors that can contribute to nutritional deficiencies: poor diet, **malabsorption**, and increased nutrient need. Only when two or three components overlap in the same person (Figure 26.28) does the risk of symptomatic deficiency become significant. For example, infants and young children have increased needs for iron, calcium, and protein. Dietary surveys show that many of them consume diets inadequate in iron and some consume diets that are low in calcium. Protein is seldom a problem unless the children are being raised as strict vegetarians. Thus, the chief nutritional concerns for most children are iron and calcium. Teenagers tend to consume diets low in calcium, magnesium, vitamin A, vitamin B_6, and vitamin C. Of these, their needs are particularly high for calcium and magnesium during the teenage years, so these are the nutrients of greatest concern. Young women are likely to consume diets low in iron, calcium, magnesium, vitamin B_6, folic acid, and zinc, and all of these nutrients are needed in greater amounts during

pregnancy and lactation. Adult women often consume diets low in calcium, yet they may have a particularly high need for calcium to prevent rapid bone loss. Finally, the elderly have unique nutritional needs (see Clin. Corr. 26.7, p. 1083) and tend to have poor nutrient intake due to restricted income, loss of appetite, and loss of the ability to prepare a wide variety of foods. They are also more prone to suffer from malabsorption problems and to use multiple prescription drugs that increase nutrient needs (Table 26.3).

Illness and metabolic stress often cause increased demand or decreased utilization of certain nutrients. For example, diseases leading to fat malabsorption cause a particular problem with absorption of calcium and the fat-soluble vitamins. Other malabsorption diseases can result in deficiencies of many nutrients depending on the particular disease. Liver and kidney disease can prevent hydroxylation of vitamin D and storage or utilization of many other nutrients including vitamin A, vitamin B_{12}, and folic acid. Severe illness and trauma increase the need for calories, protein, and possibly vitamin C and certain B vitamins. Long-term use of many drugs in the treatment of chronic disease can affect the need for certain micronutrients. Some of these are listed in Table 26.3.

Who then is at a nutritional risk? Obviously, the answer depends on many factors. Nutritional counseling is an important part of treatment for infants, young children, and pregnant/lactating females. A brief analysis of a dietary history and further nutritional counseling are important when dealing with high-risk patients.

TABLE 26.3 • Drug–Nutrient Interactions

Drug	*Potential Nutrient Deficiencies*
Alcohol	Thiamin Folic acid Vitamin B_6
Anticonvulsants	Vitamin D Folic acid Vitamin K
Cholestyramine	Fat-soluble vitamins Iron
Corticosteroids	Vitamin D and calcium Zinc Potassium
Diuretics	Potassium Zinc
Isoniazid	Vitamin B_6
Oral contraceptives and estrogens	Vitamin B_6 Folic acid and B_{12}

26.13 • NUTRIGENOMICS—THE FUTURE OF NUTRITION

Rare gene defects that affect nutrient uptake and utilization (e.g., Wilson disease, Menkes disease, Vitamin D-resistant rickets, and phenylketonuria) have been known for years. However, more recently attention is being focused on common genetic polymorphisms that have more subtle effects on nutrient status and disease risk. The best characterized of these genetic polymorphisms at present are those affecting folate status in pregnant women and risk of giving birth to babies with neural tube defects (see Clin. Corr. 26.6, p. 1083) and those causing hemochromatosis (see Clin. Corr. 26.10. p. 1090).

The term ***nutrigenomics*** encompasses three distinct areas of nutrient–gene interactions. (1) **Nutritional genetics** describes how the response to nutrients in the diet is influenced by individual genetic differences. Genes involved in the metabolism or utilization of most nutrients are being systematically screened for commonly occurring polymorphisms. Most of these polymorphisms have no affect on enzyme activity and/or nutrient requirements. However, other examples of polymorphisms that affect nutrient status and disease risk have been identified and many more are likely to be discovered in the future. (2) **Nutritional epigenetics** describes nutrient induced changes in DNA methylation, histone post-translational modifications and other chromatin alterations. This is an important property of those nutrients (folate, vitamin B_{12}, choline, and methionine) that are involved in cellular methylation reactions, but may involve other nutrients as well. (3) **Nutritional transcriptomics** describes the effect of nutrients on gene expression. This is an important property of fat-soluble vitamins (vitamins A and D) that bind to nuclear receptors and directly affect gene expression, but it also appears to be a property of several of the antioxidant vitamins that affect redox signaling pathways which regulate gene expression.

Nutrigenomics has the potential to transform both clinical and public health nutritional practice. It can lead to genome-based nutrient and food guidelines for disease prevention, individualized nutritional recommendations for disease prevention and treatment, and better targeted public health nutrition interventions that maximize benefit and minimize risk. This is particularly important when we consider what types of nutritional interventions decrease the risk of multifactorial diseases like cardiovascular diseases, obesity, type 2 diabetes, and cancer. Most of the current large-scale intervention studies have focused on the effects of various nutrients on the risk of those diseases in the population as a whole. Those studies are likely to become obsolete in the future as we increasingly focus on nutrients that affect those diseases in genetically defined subpopulations (see the discussion of vitamin E supplementation and cardiovascular risk in Section 26.4, p. 1072).

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. The Estimated Average Requirement (EAR) of a nutrient is
- **A.** the same as the RDA of that nutrient.
- **B.** an amount that should meet the requirement of half of the healthy individuals of a particular group.
- **C.** based on the observed nutrient intake of a particular group.
- **D.** the highest level of nutrient deemed to pose no risk or adverse health effects on the particular population.
- **E.** two standard deviations higher than the RDA.

2. The effects of vitamin A may include all of the following except
- **A.** prevention of anemia.
- **B.** serving as an antioxidant.
- **C.** cell differentiation.
- **D.** the visual cycle.
- **E.** induction of certain cancers.

3. Ascorbic acid may be associated with all of the following except
- **A.** iron absorption.
- **B.** bone formation.
- **C.** acute liver disease when taken in high doses.
- **D.** wound healing
- **E.** participation in hydroxylation reactions.

4. Choline, recently reclassified as essential,
- **A.** cannot be synthesized *de novo.*
- **B.** affects DNA methylation so is critical during fetal development.
- **C.** deficiency has never been demonstrated in humans because it is abundant in the diet.
- **D.** is necessary to maintain the coenzyme A supply in mitochondria.
- **E.** supplementation raises serum homocysteine.

5. Copper is an essential element. All of the following are correct about copper except
- **A.** it is a component of several oxidase enzymes.
- **B.** it is involved in the conversion of stearic acid to oleic acid.
- **C.** copper deficiency may lead to anemia.
- **D.** cellular uptake and efflux of copper are catalyzed by different transporters.
- **E.** copper deficiency occurs in tandem with a zinc deficiency.

6. Alcohol impairs both absorption and storage of folate. Megaloblastic erythropoiesis occurs because cells are arrested in the S phase since DNA synthesis is inhibited. DNA synthesis is inhibited in folate deficiency because tetrahydrofolate is required
- **A.** in the synthesis of purine nucleotides and dTMP.
- **B.** in the conversion of homocysteine to methionine.
- **C.** for the utilization of Vitamin B_{12}.
- **D.** all of the above.
- **E.** none of the above.

Questions 7 and 8: Cystic fibrosis is a generalized dysfunction of the exocrine glands leading to viscid mucus, which plugs various ducts. Pulmonary infections are common and are usually the direct cause of death. Cystic fibrosis patients, however, also have severe malabsorption problems because pancreatic enzymes are deficient and there may be a partial obstruction of the common bile duct. Malabsorption of fat, fat-soluble vitamins, and calcium is the most common, but not only, problem. Patients have increased protein and energy needs because of chronic infections.

7. Serum calcium levels are usually normal in spite of suboptimal calcium absorption and Vitamin D deficiency. Serum calcium is being maintained
- **A.** by low parathyroid hormone (PTH) levels inhibiting calcium excretion.
- **B.** by an increase in calcitonin.
- **C.** by increased bone resorption stimulated by elevated PTH.
- **D.** because PTH stimulates calcium absorption from the stomach.
- **E.** by lack of 1,25-dihydroxy Vitamin D which prevents bone from taking calcium from blood.

8. Cystic fibrosis patients are frequently on antibiotics for infections. Antibiotics exacerbate the fat malabsorption problem for obtaining
- **A.** vitamin A.
- **B.** vitamin C.
- **C.** vitamin D.
- **D.** vitamin E.
- **E.** vitamin K.

Questions 9 and 10: Hemochromatosis is a genetic disease of iron overload in which iron deposits in liver, heart, and endocrine tissue even

though dietary intake of iron is normal. In most cases, the iron overload is secondary to a decrease in expression of hepcidin because of the mutation of the gene. This leads to an inability to regulate iron release to the circulation when iron is in excess.

9. Normally when iron is in excess, hepcidin
- **A.** increases the formation of ferritin.
- **B.** inactivates ferroportin.
- **C.** prevents the reduction of Fe^{+3} to Fe^{+2}.
- **D.** transports the iron across the cell membrane.
- **E.** catalyzes the oxidation of Fe^{+2} to Fe^{+3}.

10. In the intestinal absorption of iron,
- **A.** the presence of a reductant like ascorbate enhances the availability of iron.
- **B.** the regulation of uptake occurs between the lumen and the mucosal cells.
- **C.** the amount of apoferritin synthesized in the mucosal cell is directly related to the need for iron by the host.
- **D.** iron bound tightly to a ligand, such as phytate, is more readily absorbed than free iron.
- **E.** low pH in the stomach inhibits absorption by favoring Fe^{+2}.

Questions 11 and 12: Nutritional needs of the elderly are of interest because of ageing of the American population. Atrophic gastritis results in decreased acid production in the stomach. Absorption problems and decreased ability to convert some vitamins and minerals to their active forms contribute to nutritional deficiencies in the elderly. Chromium is not abundant in the diet and many elderly have difficulty in converting it to its active form, chromodulin.

11. The major symptom of chromium deficiency is impaired glucose tolerance. Chromodulin
- **A.** increases the number of insulin receptors.
- **B.** facilitates insulin binding to cell receptors.
- **C.** protects cell receptors by salvaging peroxides.
- **D.** facilitates the absorption of copper and zinc.
- **E.** increases the metabolism of homocysteine.

12. Atrophic gastritis can interfere with zinc absorption. Zinc normally plays a role in all of the following except
- **A.** growth in children.
- **B.** wound healing.
- **C.** taste acuity.
- **D.** prevention of goiter.
- **E.** immune function.

Problems

13. The neurological disorders seen in vitamin B_{12} deficiency are caused by progressive demyelination of nervous tissue. How does lack of B_{12} interfere with formation of the myelin sheath?

14. What is the chemical reaction in which vitamin K participates? How is this reaction involved in blood coagulation and bone formation?

Answers

1. B This is the first step in defining nutritional guidelines. A and E: The RDA is set at two standard deviations above the EAR. C: This is called the Adequate Intake (AI). D: This is the Total Upper Intake Level (UL).

2. E May have protective effects against some cancers. A. Retinol and/or retinoic acid is required for synthesis of transferrin. B. Various carotenoids are antioxidants. C. Retinol and retinoic acid may function like steroid hormones. D. Retinol cycles between the $\Delta 11$-*cis* and all-*trans* forms.

3. C Excess ascorbate is readily excreted. A: Ascorbic acid aids in iron absorption by reducing iron. B: Ascorbic acid is essential for collagen synthesis, which is critical in bone formation. D and E: Ascorbic acid is required for the hydroxylation of lysine and proline residues in protocollagen and, therefore, is required for wound healing.

4. B Choline can be a source of methyl groups (after conversion to betaine). A: It can be synthesized by methylation of phosphatidylethanolamine to phosphatidylcholine. C: Such conditions as liver cirrhosis could lead to a deficiency. D: This is carnitine. E: It lowers homocysteine.

5. E Zinc and copper compete for absorption so high zinc leads to low copper absorption. A: For example, cytochrome c oxidase and superoxide dismutase. B: Copper is part of C18, Δ^9 desaturase. C: Ceruloplasmin and hephaestin activity needed for iron absorption are copper containing. D: CTR1 is involved in uptake and ATP7A and ATP7B in efflux.

6. A *De novo* synthesis of purine nucleotides and dUMP to dTMP conversion require tetrahydrofolate. These components are required for DNA synthesis. B: Tetrahydrofolate is required in this process, but the process is not involved in DNA synthesis. C: Vitamin B_{12} is required for the release of tetrahydrofolate from N^5-methyl tetrahydrofolate, but this is not part of DNA synthesis.

7. C PTH promotes bone resorption and inhibits calcium excretion. A: PTH is elevated when vitamin D is low. B: Elevated calcitonin is a response to high serum calcium. D: Calcium is absorbed from the intestines, not the stomach. E: 1,25-dihydroxy vitamin D promotes bone resorption bone's does not necessarily affect bone's ability to take up calcium from blood.

8. E Some of our vitamin K is obtained from bacterial synthesis in the intestine, which is wiped out by antibiotics. A, C, and D: All of these require adequate fat absorption but come from foods not intestinal bacteria. B: Vitamin C is water soluble.

9. B This down-regulation of ferroportin decreases the transport of iron into the circulation. A: Ferritin sequesters iron in cells. C and E: Hepcidin is not an enzyme and is not involved in oxidation or reduction of iron. D: Hepcidin is not a transporter but binds to ferroportin and triggers its destruction.

10. A Ascorbate facilitates reduction to the ferrous state and, therefore, dissociation from ligands and absorption. B: Substantial iron enters the mucosal cell regardless of need, but the amount transferred to the capillary beds is controlled. C: Iron bound to apoferritin is trapped in mucosal cells and not transferred to the host. D: Iron must dissociate from ligands for absorption. This is why iron is spinach is not a good source of iron. E: Oxidation to Fe^{+3} is favored by higher pH.

11. B This would facilitate the uptake of glucose. A: Does not do this. C: This is the role of selenium. D: Metallothionein is the protein that influences copper and zinc absorption. E: Folate, B_6, and B_{12} are necessary for homocysteine catabolism.

12. D This is a role for iodine. A: RNA and DNA polymerases are zinc proteins. B: This is shown to be true. C: Zinc is part of a salivary polypeptide involved in development of taste buds. E: Zinc is required for cytokine production by monocytes and T-cells.

13. One of the reactions in which vitamin B_{12} participates is conversion of methylmalonyl CoA to succinyl CoA (a step in the catabolism of valine and isoleucine). Methylmalonyl CoA is a competitive inhibitor of malonyl CoA in fatty acid biosynthesis, necessary for the maintenance of the myelin sheath. Secondly, methylmalonyl CoA can be used in fatty acid synthesis leading to formation of branched-chain fatty acids, which might disrupt normal membrane structure.

14. Vitamin K is necessary for carboxylation of specific glutamic acid residues in certain proteins to form γ-carboxyglutamic acid residues. In blood coagulation, this step is required for the conversion of preprothrombin to prothrombin. In bone formation, this is required to form the calcium binding residues of the protein osteocalcin.

27.7 Metabolic Adaptation: Relationship between Carbohydrate Intake and Serum Triacylglycerols 1118

Key Concepts

- Energy balance is the relationship between food energy consumed and energy expended. Nitrogen balance is the relationship between intake of nitrogen and excretion of nitrogen.
- Essential amino acids must be present in the diet. Protein requirements are increased during growth, trauma, and illness.
- Protein-energy malnutrition can present in several forms depending on the age of the patient and the precipitating conditions, but the common feature is compromised immune function leading to decreased resistance to infection.
- Obesity is associated with insulin resistance and has significant health implications.
- The most common forms of carbohydrate intolerance are diabetes mellitus and lactase insufficiency.
- The amount and type of fats in the diet may have long-term health implications.
- The optimal diet composition varies from individual to individual.

27.1 • INTRODUCTION

The study of human nutrition can be divided into three areas: undernutrition, overnutrition, and ideal nutrition. The primary concern in this country is not with undernutrition because nutritional-deficiency diseases are now quite rare. However, overnutrition is a particularly serious problem in developed countries. The current estimate is that over 34% of the U.S. population is obese and another 32% is overweight, and obesity is associated with increased risk for a number of serious health consequences. Along with the concern about rising rates of obesity, there is increasing interest in the optimal macronutrient composition. Are there ideal ratios of carbohydrate, fat, and protein to reduce the risk of obesity and obesity-related diseases? Finally, there is the burgeoning area of nutrigenomics. What role does genetics play in obesity and the ideal diet composition for each of us as individuals? This is probably the most exciting area of nutrition today.

27.2 • ENERGY METABOLISM

Energy Content of Food Is Measured Primarily in Kilocalories

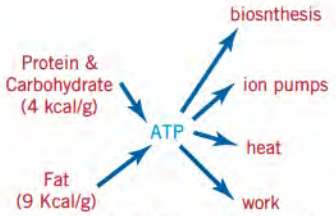

Figure 27.1 Metabolic fate of the foods we eat.

Much of the food we eat is converted to ATP and other high-energy compounds, which are utilized to drive biosynthetic pathways, generate nerve impulses, and power muscle contraction (Figure 27.1). The energy content of foods is generally described in terms of **calories**. Technically speaking, this refers to kilocalories of heat energy released by combustion of that food in the body. This is complicated by the fact that the international standard for energy measurements is the kilojoule (kJ). Since the public is likely to be counting calories rather than kilojoules in the foreseeable future, calories will be used in this chapter, with conversion to kilojoules where appropriate. Caloric values of protein, fat, carbohydrate, and alcohol are roughly 4, 9, 4, and 7 calories/g (16.7, 37.7, 16.7. and 29.3 kJ/g), respectively. Given these values and the amount and composition of the food, it is simple to calculate the caloric content (input) of the foods we eat. Calculating caloric content of foods is not a major problem in this country. Millions of Americans are able to do it with ease. The problem lies in balancing caloric input with caloric output. Where do these calories go?

Energy Expenditure Is Influenced by Four Factors

The four principal factors that affect an individual's energy expenditure are listed in Table 27.1. The effects of surface area are thought to be simply related to the rate of heat loss by the body; the greater the surface area, the greater the rate of heat loss. Although it may seem surprising, a lean individual actually has a greater surface area, and thus a greater energy requirement, than an obese individual of the same weight. Age may reflect two factors: growth and lean muscle mass. In infants and children, more energy expenditure is required for rapid growth, which is reflected in a higher basal metabolic rate (rate of energy utilization in resting state). In adults (even lean adults), muscle tissue is gradually replaced by fat and water during the aging process, resulting in a 2% decrease in **basal metabolic rate (BMR)** per decade of adult life. Women tend to have a lower BMR than men because of a smaller percentage of lean muscle mass and the effects of female hormones on metabolism. The effect of activity levels on energy requirements is obvious. However, most overemphasize the immediate, as opposed to the long-term, effects of exercise. For example, one would need to jog for over an hour to burn up the calories present in one piece of apple pie.

TABLE 27.1 • Factors that Influence Energy Expenditure

Surface area
Age
Sex
Activity level

Regular **exercise** increases basal metabolic rate, allowing calories to burn up more rapidly 24 h a day. A regular exercise program should be designed to increase lean muscle mass and should be repeated 3–5 days a week but need not be aerobic exercise to have an effect on basal metabolic rate. For an elderly or infirm individual, even daily walking may help to increase basal metabolic rate slightly.

Hormone levels are also important, since thyroxine, sex hormones, growth hormone, and, to a lesser extent, epinephrine and cortisol increase BMR. The effects of epinephrine and cortisol probably explain in part why severe stress and major trauma significantly

increase energy requirements. Finally, energy intake itself has an inverse relationship to expenditure in that during periods of starvation or semistarvation BMR can decrease up to 50%. This is of great survival value in cases of genuine starvation, but not much help to the person who wishes to lose weight on a calorie-restricted diet.

27.3 • PROTEIN METABOLISM

Dietary Protein Serves Many Roles Including Energy Production

Protein carries a certain mystique as a body-building food. Although it is an essential structural component of all cells, it is also important for maintaining essential secretions such as digestive enzymes and peptide or protein hormones. Protein is also needed for synthesis of plasma proteins, which are essential for maintaining osmotic balance, transporting substances through the blood, and maintaining immunity. However, the average North American adult consumes far more protein than needed to carry out these essential functions. Excess protein is treated as a source of energy, with glucogenic amino acids being converted to glucose and ketogenic amino acids to fatty acids and keto acids. Both kinds of **amino acids** are eventually converted to triacylglycerol in adipose tissue if fat and carbohydrate supplies are already adequate to meet energy requirements. Thus for most of us the only body building obtained from high-protein diets is in adipose tissue.

It has been popular to say that the body has no storage depot for protein, and thus adequate dietary protein must be supplied with every meal. However, this is not quite accurate. Although there is no separate class of storage protein, there is a certain percentage of body protein that undergoes a constant process of breakdown and resynthesis. In the fasting state, the breakdown of this protein is enhanced, and the resulting amino acids are utilized for glucose production, synthesis of nonprotein nitrogenous compounds, and the essential secretory and plasma proteins mentioned above. Even in the fed state, some of these amino acids are utilized for energy production and as biosynthetic precursors. Thus, the turnover of body protein is a normal process and an essential feature of what is called nitrogen balance.

Nitrogen Balance Relates Intake to Excretion of Nitrogen

Nitrogen balance (Figure 27.2) is the relationship between intake of nitrogen, primarily in the form of protein, and excretion of nitrogen, chiefly in the form of undigested protein in the feces and urea and ammonia in urine. A normal adult is in nitrogen equilibrium, with losses just balanced by intake. Negative nitrogen balance results from inadequate intake of protein, since amino acids utilized for energy and biosynthetic reactions are not replaced. It also occurs in injury when there is net destruction of tissue and in major trauma or illness when the body's adaptive response causes increased protein catabolism. Positive nitrogen balance occurs when there is a net increase in body protein, such as in growing children, pregnant women, or convalescing adults.

Essential Amino Acids Must Be Present in the Diet

Several other factors must be considered in addition to the amount of protein in the diet. One is the complement of **essential amino acids** ingested. Essential amino acids are amino acids that cannot be synthesized by the body (Table 27.2). If just one of these essential amino acids is missing from the diet, the body cannot synthesize new protein to replace that lost due to normal turnover, and a negative nitrogen balance results (Figure 27.2). Obviously, the complement of essential amino acids in dietary protein determines how well it can be used by the body.

Most **animal proteins** contain all essential amino acids in about the quantities needed by the human body. **Vegetable proteins**, on the other hand, often lack one or more essential amino acids and may, in some cases, be more difficult to digest. Even so, **vegetarian diets** can provide adequate protein provided enough extra protein is consumed to provide sufficient quantities of the essential amino acids and/or two or more different proteins are consumed together, which complement each other in amino acid content. For example, if corn

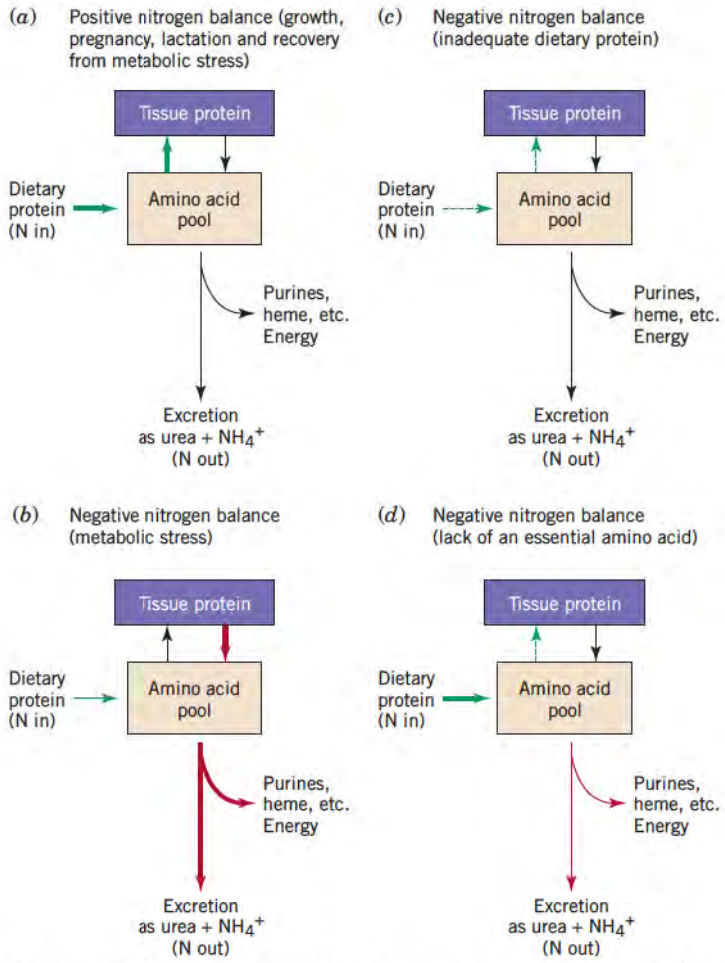

Figure 27.2 Factors affecting nitrogen balance. Schematic representations of the metabolic interrelationship involved in determining nitrogen balance. (*a*) Positive nitrogen balance (growth, pregnancy, lactation, and recovery from metabolic stress). (*b*) Negative nitrogen balance (metabolic stress). (*c*) Negative nitrogen balance (inadequate dietary protein). (*d*) Negative nitrogen balance (lack of an essential amino acid). Each figure represents the nitrogen balance resulting from a particular set of metabolic conditions. The dominant pathways in each situation are indicated by heavy red arrows.

(which is deficient in lysine) is combined with legumes (deficient in methionine but rich in lysine), the efficiency of utilization of the two vegetable proteins approaches that of animal protein. The adequacy of vegetarian diets with respect to protein and calories for children is discussed in Clin. Corr. 27.1; the need for high quality protein in the low protein diets used for treatment of renal disease is discussed in Clin. Corr. 27.2.

Protein Sparing Is Related to Dietary Content of Carbohydrate and Fat

Another factor that determines protein requirement is dietary intake of fat and carbohydrate. If they are present in insufficient quantities, some dietary protein must be used for energy generation, and it becomes unavailable for building and replacing tissue. Thus, as energy (calorie) content of the diet from carbohydrate and fat increases, the need for protein decreases. This is referred to as **protein sparing**. Carbohydrate is somewhat more efficient at protein sparing than fat presumably because it can be used as an energy source by almost all tissues, whereas fat cannot.

Normal Adult Protein Requirements

Assuming adequate calorie intake and a 75% efficiency of utilization, which is typical of mixed protein in the average American diet, the **recommended protein intake** is 0.8 g/kg

CLINICAL CORRELATION 27.1

Vegetarian Diets and Protein-Energy Requirements for Children

One of the most important problems of a purely vegetarian diet (as opposed to a lacto-ovo vegetarian diet) is the difficulty in obtaining sufficient calories and protein. Potential caloric deficit results because the caloric densities of fruits and vegetables are much less than the meats they replace (30–50 cal/100 g versus 150–300 cal/100 g; 7–12 kJ/100 mg versus 36–72 kJ/100 g). The protein problem is threefold. (1) Most plant products contain much less protein (1–2 g of protein/100-g serving versus 15–20-g/100-g serving). (2) Most plant protein is of low biological value. (3) Some plant proteins are not completely digested. Actually, well-designed vegetarian diets usually provide enough calories and protein for the average adult. In fact, the reduced caloric intake may well be of benefit because strict vegetarians tend to be lighter than their nonvegetarian counterparts.

However, whereas an adult male may require about 0.8 g/kg of protein and 40 cal/kg (9.6 kJ/kg) of body weight, a young child may require 2–3 times that amount. Similarly, a pregnant woman needs an additional 10 g of protein and 300 cal/day (72 kJ/day), and a lactating woman an extra 15 g of protein and 500 cal (120 kJ)/day. Thus both young children and pregnant and lactating women run a risk of protein-energy malnutrition. Children of vegetarian mothers generally have a lower birth weight than children of mothers consuming a mixed diet. Similarly, vegetarian children generally have a slower rate of growth through the first 5 years, but generally catch up by age of 10.

Sufficient calories and protein for these high-risk groups can be provided if the diet is adequately planned. Three principles should be followed to design a calorie–protein-sufficient vegetarian diet for young children.(1) Whenever possible, include eggs and milk; they are excellent sources of calories and high-quality protein. (2) Include liberal amounts of those vegetable foods with high-caloric density, including nuts, grains, dried beans, and dried fruits. (3) Include liberal amounts of high-protein vegetable foods that have complementary amino acid compositions. It used to be thought that these complementary proteins must be present in the same meal. Recent animal studies, however, suggest that a meal low in (but not devoid of) an essential amino acid may be supplemented by adding the limiting amino acid at a subsequent meal.

Health Care* 20:27, 2006.

CLINICAL CORRELATION 27.2

Dietary Protein Intake and Renal Disease

Chronic renal failure is characterized by accumulation of the end products of protein catabolism, mainly urea. Some degree of dietary protein restriction is usually necessary because these toxic end products are responsible for many of the symptoms associated with renal failure. The amount of protein restriction depends on the severity of the disease. It is easy to maintain patients in nitrogen balance for prolonged periods on diets containing as little as 40 g of protein/day if the diet is sufficient in calories. Diets containing less than 40 g/day pose problems. Protein turnover continues and a balance found between providing enough protein to avoid negative nitrogen balance, but little enough to avoid buildup of waste products.

The strategy employed in such diets is to (1) provide a physiologically adequate amount of protein, primarily of high biological value, and (2) provide the bulk of the daily caloric requirement as carbohydrates and fats. The goal is to provide just enough essential amino acids to maintain positive nitrogen balance. In turn, the body should be able to synthesize the nonessential amino acids from other nitrogen-containing metabolites. Enough carbohydrate and fat is provided so that essentially all dietary protein can be spared from energy metabolism. With this type of diet, it is possible to maintain a patient on 20 g of protein/day for considerable periods. Because of the difficulty in maintaining nitrogen equilibrium at such low-protein intakes, the patient's protein status should be monitored. This can be done by measuring serum albumin and transferrin.

Unfortunately, such diets are extremely monotonous and difficult to follow. A typical 20 g of protein diet consists of (1) one egg plus 3/4 cup milk or one additional egg or 1 oz of meat, (2) one-half lb of deglutenized (low-protein) wheat bread; all other breads and cereals must be avoided, and this includes almost all baked goods. (3) a limited amount of low-protein, low-potassium fruits and vegetables, and (4) sugars and fats to make up the rest of the needed calories; however, cakes, pies, and cookies should be avoided.

In contrast, hemodialysis causes a net protein catabolic state that can lead to decreased muscle mass and increase the risk of morbidity and mortality. Thus, patients with chronic renal failure who are on dialysis often have increased protein requirements. Recent studies have shown that either intravenous or dietary protein supplementation during dialysis can help restore normal protein homeostasis. Similarly, patients with acute renal failure caused by sepsis, shock, trauma, or burn injury often have increased protein requirements because of the catabolism associated with these conditions (see Clin. Corr. 27.3, p. 1106).

body wt/day. This amounts to about 58 g protein/day for a 72-kg (160-lb) man and about 44 g/day for a 55-kg (120-lb) woman. These recommendations need to be increased on a vegetarian diet if overall efficiency of utilization is less than 75%.

Protein Requirements Are Increased during Growth and Illness

Because dietary protein is essential for synthesis of new body tissue, as well as for maintenance and repair, the need for protein increases markedly during periods of rapid growth as occurs during pregnancy, infancy, childhood, and adolescence. Once growth requirements have been considered, age does not seem to have much effect on protein requirements. If anything, the protein requirement may decrease slightly with age. However, older people need and generally consume fewer calories, so high-quality protein should provide a larger percentage of their total calories. Some older people may have special protein requirements due to malabsorption problems.

Illness, major trauma, and surgery cause a major **catabolic response**. Energy and protein needs in these situations are very large, and the body responds by increasing production of glucocorticoids, epinephrine, and cytokines. Breakdown of body protein is greatly accelerated and a negative nitrogen balance results unless protein intake is increased (Figure 27.2). Although the increased protein requirement is of little significance in short-term illness, it can be vitally important in the recovery of hospitalized patients as discussed in the next section (Clin. Corr. 27.3).

CLINICAL CORRELATION 27.3

Providing Adequate Protein and Calories for Hospitalized Patients

The normal metabolic response to infection, trauma, and surgery is a complex and carefully balanced catabolic state. Glucocorticoids, interleukin-6 (IL-6), and other cytokines are released, greatly accelerating the rates of lipolysis, proteolysis, and gluconeogenesis. The net result is an increased supply of fatty acids and glucose to meet the increased energy demands of such major stress. The high serum glucose causes an increase in circulating insulin levels, which is more than counterbalanced by increased levels of cytokines and glucocorticoids. Skeletal muscle uses very little of the blood glucose, but relies on free fatty acids and its own catabolized protein as a primary source of energy. It continues to export amino acids, primarily alanine, for use elsewhere in the body, resulting in a very rapid depletion of body protein stores.

A highly catabolic hospitalized patient may require 35–45 kcal/kg/day (8.4–10.8 kJ/kg/day) and 2–3 g of protein/kg/day. A patient with severe burns may require even more. Several options are available to provide the postoperative patient with sufficient calories and protein to ensure optimal recovery. When the patient is unable to ingest enough food, it may be adequate to supplement the diet with high-calorie–high-protein preparations, which are usually mixtures of homogenized cornstarch, egg, milk protein, and flavorings. When the patient is unable to ingest solid food or to digest complex mixtures of foods adequately, elemental diets are usually administered via a nasogastric tube. Elemental diets consist of small peptides or amino acids, glucose and dextrins, some fat, vitamins, and electrolytes. These diets are sufficient to meet most of the short-term caloric and protein needs of a moderately catabolic patient.

When a patient is severely catabolic or unable to digest and absorb foods normally, parenteral (intravenous) nutrition is necessary. The least invasive method is to use a peripheral, slow-flow vein as for any other IV infusion. The main limitation of this method is hypertonicity. However, a solution of 5% glucose and 4.25% amino acids can be used safely. This solution will usually provide enough protein to maintain positive nitrogen balance, but will rarely provide enough calories for long-term maintenance of a severely catabolic patient.

The most aggressive nutritional therapy is total parenteral nutrition. Usually an indwelling catheter is inserted into a large fast-flow vessel such as the superior vena cava, so that the very hypertonic infusion fluid can be diluted rapidly. This allows solutions of up to 60% glucose and 4.25% amino acids to be used, providing sufficient protein and most of the calories for long-term maintenance. Intravenous infusions of lipid are often added to boost calories and provide essential fatty acids. Any of these methods can prevent or minimize the negative nitrogen balance associated with surgery and trauma. The choice of method depends on the patient's condition. As a general rule it is preferable to use the least invasive technique.

27.4 • PROTEIN-ENERGY MALNUTRITION

The most common form of malnutrition in the world is **protein-energy malnutrition** (PEM). In developing countries, inadequate intake of protein and energy is all too common, especially in infants and young children. While the symptoms vary widely from case to case, it is common to classify most cases as either **marasmus** or **kwashiorkor**. Marasmus is caused by inadequate intake of both protein and energy. Kwashiorkor is caused by inadequate intake of protein with adequate energy intake. Often the diets that lead to marasmus and kwashiorkor are similar, with kwashiorkor being precipitated by conditions of increased protein demand such as infection. Marasmic infants will have a thin, wasted appearance and will be small for their age. Children are permanently stunted in physical and mental development if PEM continues long enough. The patient with kwashiorkor often has a deceptively plump appearance due to edema. Other telltale symptoms associated with kwashiorkor are dry brittle hair, diarrhea, dermatitis of various forms, and retarded growth. The most devastating result of both conditions is reduced ability to fight off infection. These individuals have a reduced number of T lymphocytes (and thus diminished cell-mediated immune response) as well as defects in generation of phagocytic cells, and production of immunoglobulins, interferon, and other components of the immune system. Many die from secondary infections rather than from starvation.

The most common form of PEM seen in the United States occurs in the hospital setting. A typical course of events is as follows: The patient has not been eating well for several weeks or months prior to entering the hospital due to chronic or debilitating illness. He or she enters the hospital with major trauma, severe infection, or for major surgery, all of which cause a large negative nitrogen balance. This is often compounded by difficulties in feeding the patient or by the need for fasting in preparation for surgery or diagnostic tests. The net result is PEM as reflected by low levels of serum albumin and other serum proteins or by decreased cellular immunity. Hospitalized patients with demonstrable PEM have delayed wound healing, decreased resistance to infection, increased mortality, and increased length of hospitalization. Most major hospitals have programs that monitor the nutritional status of their patients and will intervene where necessary to maintain a positive nitrogen and energy balance (see Clin. Corr. 27.3).

27.5 • EXCESS PROTEIN-ENERGY INTAKE

Much has been said in recent years about the large amount of protein that the average American consumes. Certainly most consume far more than needed to maintain nitrogen balance. An average American currently consumes about 99 g of protein, of which 68% is from animal sources. However, a healthy adult can consume this amount of protein with no apparent harm. Concern has been raised about possible effects of high protein intake on calcium requirements. Some studies suggest that high protein intake increases urinary loss of calcium and may accelerate bone demineralization associated with aging. However, this issue is far from settled.

Obesity Has Dietary and Genetic Components

Perhaps the more serious and frequent nutritional problem in this country is excessive energy consumption. In fact, obesity has been described as an epidemic in the United States and much of the developed world. **Obesity** is defined in terms of body mass index (BMI. weight in kilograms divided by height in meters squared). Ideal weight is usually considered to be a BMI of 24.9 or less. People with a BMI of 25 to 29 are considered overweight; people with a BMI of 30 to 40 are considered obese; and people with BMIs over 40 are considered morbidly obese. An inexact way of thinking about it is that a 5-foot, 4-inch person is generally obese if she or he is 30 pounds or more overweight.

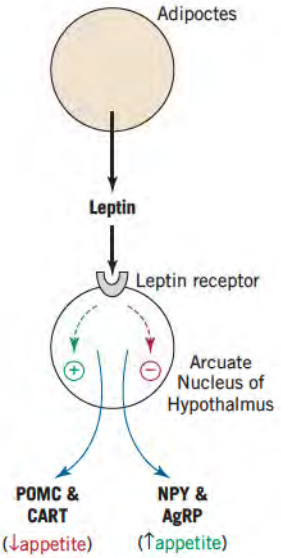

Figure 27.3 The leptin appetite suppression pathway. Schematic representation of the leptin appetite suppression pathway. Adipocytes produce leptin, which binds to its receptor in the arcuate nucleus of the hypothalamus and stimulates neurons that produce the appetite-suppressing hormones POMC (pro-opiomelanocortin) and CART (cocaine- and amphetamine-regulated transcript) and blocks neurons that produce the appetite-stimulating neuropeptides NPY (neuropeptide Y) and AgRP (agouti-related protein). Normally, the amount of leptin increases as the fat stores in adipocytes increase.

Obesity has a major genetic component, which is evident from its strong familial inheritance pattern and studies on monozygotic twins. Many experts think that the contribution of genetic factors to obesity is in the range of 30%–70%. However, to truly understand the role of genetics in obesity we need to think beyond classical Mendelian genetics. Most people tend to think of genetics in terms of rare genetic defects that lead directly to a disease such as phenylketonuria (p. 767) or cystic fibrosis (p. 494). In the case of obesity, it is more fruitful to think of genetics in terms of three levels of genetic influences: monogenic obesity, polygenic predisposition to obesity, and monogenic resistance to obesity.

Monogenic obesity refers to single genetic defects that are strongly linked to obesity irrespective of environmental and behavioral influences. These gene defects obey classical Mendelian inheritance and are exceedingly rare in the general population. For example, recent research has shown that fat cells (adipocytes) produce a hormone called **leptin** that suppresses appetite (Figure 27.3; see Clin. Corr. 17.8, p. 703). The leptin appetite suppression pathway was initially considered a very promising target for pharmacological intervention because a genetically obese strain of mice (ob/ob) was shown to be unable to produce leptin and administration of leptin to those mice resulted in weight loss. However, it turns out that most overweight individuals overproduce leptin, and defects in both the leptin gene and the leptin receptor gene are very rare in the human population.

In the case of polygenic predisposition to obesity, there are common polymorphisms in certain genes that increase the risk of obesity, but only in those individuals who consume more calories than they expend for extended periods of time. Some examples of these polymorphisms will be discussed in the section on nutrigenetics (see Section 27.10). In many cases the predisposition to obesity is relatively weak, so obesity only becomes likely in individuals who consume excess calories and have polymorphisms contributing to obesity in two or more genes. However, because there are many genes in this category and the polymorphisms that contribute to obesity are very common, polygenic predisposition to obesity is common. Finally, there are genetic polymorphisms that predispose to leanness even in individuals consuming excess calories over an extended period of time. Unfortunately, those polymorphisms are relatively rare in the general population.

In summary, even though genetics may exert a 30%–70% influence on obesity, most genetic traits that influence obesity do not cause it directly; they only predispose to obesity when calories consumed exceed calories expended for a prolonged period of time. Furthermore, genetic backgrounds that predispose to obesity when excess calories consumed are the most common genotypes in the general population. Genotypes that allow individuals to consume excess calories without gaining weight are relatively rare. In this light, it is easy to understand why diet and lifestyle play such a critical role in determining the incidence of obesity. The latest report of the National Center for Health Statistics shows 32.7% of Americans are overweight, 34% are obese. and 6% are morbidly obese. That means that over two-thirds of the U.S. population is now either overweight or obese. The prevalence of obesity has increased by 50% in adults and has more than doubled in children in the past 20 years. This clearly reflects recent lifestyle changes in this country because genetics does not change in a matter of a few years. The environmental and behavioral changes that have lead to this "epidemic" of obesity are clearly complex but include the increased availability of calorie-dense foods, an increase in portion size, and the more sedentary lifestyle of the U.S. population.

Obesity, Insulin Resistance, Metabolic Syndrome, and Type 2 Diabetes

Obesity is strongly associated with **type 2 diabetes**. Not only are 80% of people with type 2 diabetes overweight, but the incidence of type 2 diabetes has increased in parallel with the incidence of obesity over the last 20 years or more. However, not everyone who is obese has type 2 diabetes. In fact, there is a gradual, but fairly predictable, transition from simple obesity with no observable metabolic changes through **insulin resistance** with its many associated metabolic changes to type 2 diabetes. Why is this? Obesity is obviously associated with an increased number and/or size of adipose tissue cells. However, it is important to understand that adipocytes are endocrine-producing cells, not just repositories of fat stores.

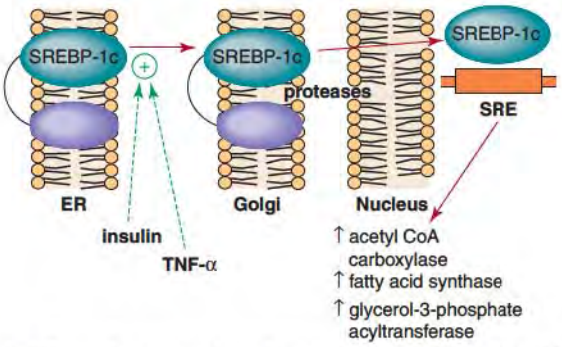

Figure 27.4 Effect of TNFα on the expression of enzymes involved in fatty acid and triglyceride synthesis in the liver. Adipokines such as TNFα mimic the effect of insulin on fatty acid and triglyceride synthesis in the liver by stimulating the movement of the transcription factor SREBP-1c (sterol regulatory element binding protein-1c) from the endoplasmic reticulum to the Golgi, where its membrane bound portion is cleaved by proteases. This allows SREBP-1c to diffuse into the nucleus where it binds to the sterol regulatory element (SRE) and increases the expression of acetyl CoA carboxylase, fatty acid synthase and glycerol-3-phosphate acy transferase.

When engorged with fat, adipocytes cells overproduce hormones such as leptin and **resistin** and **cytokines** such as **tumor necrosis factor alpha (TNFα)**. Although it is not clear at this point whether it is TNFα or other adipokines that exert their effects on muscle and liver metabolism, TNFα does exert a strong paracrine effect on adipose tissue. It stimulates hormone-sensitive lipase, which results in elevated levels of free fatty acids in the circulation, and inhibits lipoprotein lipase, which decreases the clearance rate of triacylglycerol-rich VLDL particles from the circulation.

The increased influx of the circulating free fatty acids into the liver increases the levels of fatty acyl CoA available for triacylglycerol synthesis and acetyl CoA available for fatty acid synthesis. At the same time TNFα activates the transcription factor SREBP-1c which, in turn, increases expression of key enzymes involved in fatty acid and triacylglycerol biosynthesis (Figure 27.4). The net result is increased production of triacylglycerol-rich VLDL particles by the liver. This, coupled with the decreased clearance of VLDL particles just described, leads to elevated levels of triglycerides (triacylglycerol-rich VLDL particles) in the circulation. TNFα also decreases lecithin: cholesterol acyltransferase (LCAT) expression and activity, ATP-binding cassette (ABCA1 and ABCG1) expression and apo A-I and apo A-IV expression, all of which are thought to contribute to a decline in HDL levels associated with obesity. Thus, obesity is often associated with a **dyslidemia** characterized by elevated triglycerides and decreased HDL levels. This dyslipidemia is highly associated with increased risk of cardiovascular disease.

The circulating free fatty acids associated with obesity also appear to be responsible for insulin resistance of the muscle and the liver. Fatty acids stimulate **PKC-θ** catalyzed serine phosphorylation of the insulin receptor 1 and 2 substrates, which in turn interferes with insulin stimulation of the PKB signaling pathway (Figure 27.5). In muscle, this interferes with the ability of insulin to stimulate translocation of the GLUT4 transporter to the membrane. In liver, it interferes with the ability of insulin to down-regulate gluconeogenesis. In addition, fatty acids are competitive inhibitors of glucose uptake by both the GLUT4 transporter in muscle and the GLUT2 transporter in liver. The decreased uptake of glucose by both muscle and liver and the increased production of glucose by the liver tend to lead to hyperglycemia.

In the early stages of obesity the pancreas compensates for the insulin resistance by overproducing insulin so that glucose homeostasis is maintained at normal or near normal levels. However, the pancreas cannot maintain this overproduction of insulin forever. The elevated levels of free fatty acids and/or cytokines lead to a gradual loss of the ability of the pancreas to overproduce insulin, a process called decompensation. Once the pancreas is no longer able to produce enough insulin to compensate for insulin resistance, hyperglycemia ensues. Since hyperglycemia is the defining criterion for diabetes, it is at this point that the patient is classified at having type 2 diabetes. **Type 2 diabetes** differs from type 1 diabetes

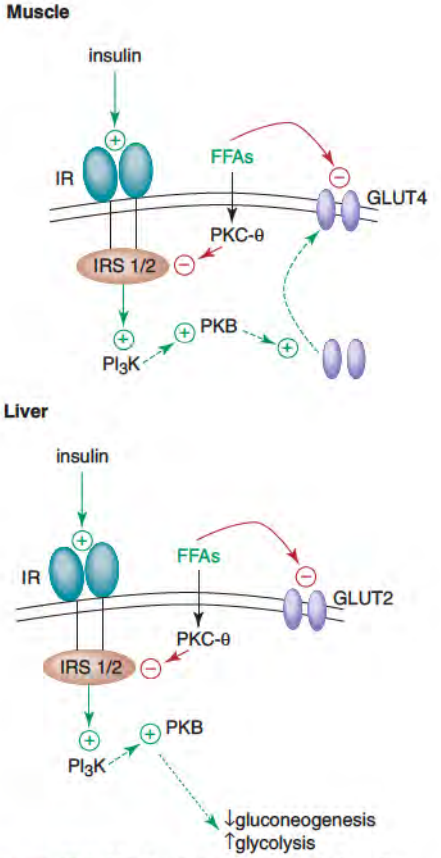

Figure 27.5 Mechanisms involved in insulin resistance in muscle and liver. Free fatty acids (FFA) stimulate PKC-θ (protein kinase C-θ), which serine phosphorylates and inactivates IRS1/2 (insulin receptor substrate 1 and 2). This interferes with the PI_3K (phosphoinositide-3 kinase)–PKB (protein kinase B) signaling pathway which normally causes transfer of the GLUT4 transporter to the cell surface in muscle and decreases gluconeogenesis and increases glycolysis in the liver. Free fatty acids also competitively inhibit transport of glucose by both the GLUT4 and GLUT2 transporters. + symbols denote positive regulation and – symbols denote negative regulation. The dotted lines denote responses to insulin that are not occurring because of insulin resistance.

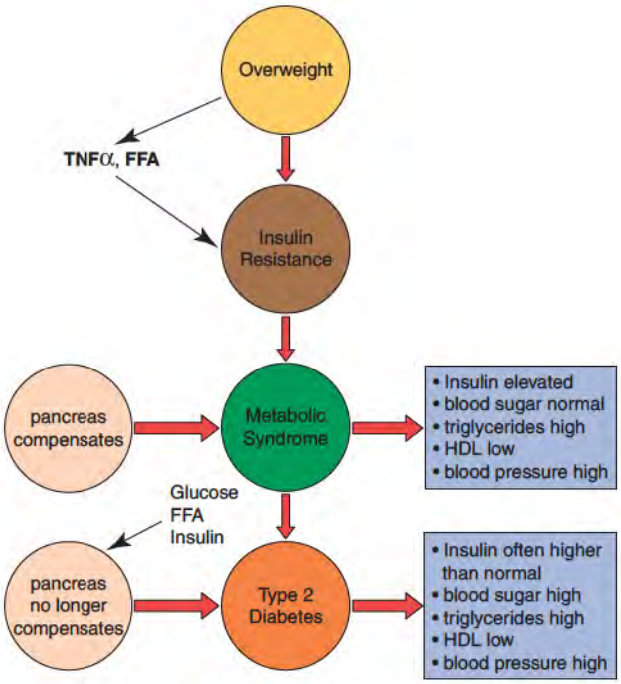

Figure 27.6 Schematic of the metabolic response to obesity over time.

in several fundamental aspects. Type 1 diabetes is caused by an inability of the pancreas to produce insulin, whereas type 2 diabetes is caused by an obesity-associated insulin resistance. In fact insulin levels in a type 2 diabetic are often elevated or near normal; they are just no longer sufficient to overcome the insulin resistance.

There is a relatively predictable sequence of metabolic changes associated with obesity (Figure 27.6). As described, one of the earliest changes is an overproduction and decreased clearance of VLDL particles, leading to a dyslipidemia characterized by elevated triacylglycerol-rich VLDL particles and decreased HDL levels. Insulin resistance is also a relatively early metabolic change associated with obesity, but the expected hyperglycemia often does not occur for many years because of the ability of the pancreas to compensate by overproducing insulin. However, the higher-than-normal levels of insulin required to maintain glucose homeostasis are not entirely benign. Insulin-signaling pathways lead to increased cell proliferation in many cells, and obesity appears to be associated with increased risk of several types of cancer. This hyperinsulinemia also appears to stimulate the sympathetic nervous system, leading to sodium and water retention and vasoconstriction, which increase blood pressure. Finally, if the obesity is maintained long enough, the ability of the pancreas to overproduce insulin is lost and type 2 diabetes ensues.

Thus, the insulin resistance associated with obesity increases the risk of developing type 2 diabetes, heart disease, hypertension, and several types of cancer. Since increased risk of some of those diseases may occur long before the patient becomes diabetic, there has been a movement to label the condition that exists between the onset of insulin resistance and the development of type 2 diabetes as **metabolic syndrome**. The World Health Organization defines metabolic syndrome as two or more of the following conditions: abdominal obesity, dyslipidemia (as defined by an elevation of triacylglycerol-rich VLDL and a decrease in HDL), hypertension, insulin resistance, modest increases in fasting blood sugar, a prothrombic state, or a pro-inflammatory state (usually defined by increase in C-reactive protein). However, because all of these conditions do not occur simultaneously in a given individual, the term *metabolic syndrome* is not universally accepted.

Obesity Has Significant Health Implications

Obesity is a primary risk factor in coronary heart disease, hypertension, and diabetes mellitus. Obesity is also associated with inflammatory diseases, some forms of cancer, bone and

joint disorders, and breathing disorders. This is nutritionally significant because all of these metabolic changes are reversible. Quite often reduction to ideal body weight is the single most important aim of nutritional therapy. When the individual is at ideal body weight, the composition of the diet becomes a less important consideration in maintaining normal serum lipid and glucose concentrations.

As mentioned, obesity can lead to increased retention of both sodium and water. As the fat stores are metabolized, they produce water (which is denser than fat), and the water may be largely retained. In fact, some individuals may observe short-term weight gain when they diet, even though the diet is working perfectly well in terms of breaking down their adipose tissue. This metabolic fact of life can be psychologically devastating to dieters, who expect quick results for all their sacrifice.

27.6 • CARBOHYDRATES

The chief metabolic role of **dietary carbohydrates** is for energy production. Any carbohydrate in excess of that needed for energy is converted to glycogen and triacylglycerol for storage. The body can adapt to a wide range of dietary carbohydrate levels (see Clin. Corr 27.7, p. 1118). Diets high in carbohydrate result in higher steady-state levels of glucokinase and some of the enzymes involved in the pentose phosphate pathway and triacylglycerol synthesis. Diets low in carbohydrate result in higher steady-state levels of some of the enzymes involved in gluconeogenesis, fatty acid oxidation, and amino acid catabolism. Glycogen stores are also affected by the carbohydrate content of the diet (Clin. Corr. 27.4).

The most common form of **carbohydrate intolerance** is diabetes mellitus, caused by either subnormal insulin production or insulin resistance. This causes intolerance to glucose and sugars that are readily converted to glucose. Dietary treatment of diabetes is discussed in

CLINICAL CORRELATION 27.4

Carbohydrate Loading and Athletic Endurance

The practice of carbohydrate loading dates to observations made in the early 1960s that endurance during vigorous exercise was limited primarily by muscle glycogen stores. Of course, glycogen is not the sole energy source for muscle. Free fatty acids increase in blood during vigorous exercise and are utilized by muscle along with its glycogen stores. Once glycogen has been exhausted, however, muscle cannot rely entirely on free fatty acids without tiring rapidly, probably because muscle becomes increasingly hypoxic during vigorous exercise. Although glycogen is utilized equally well aerobically or anaerobically, fatty acids can only be utilized aerobically. Under anaerobic conditions, fatty acids cannot provide ATP rapidly enough to serve as the sole energy source.

The practice of carbohydrate loading to increase glycogen stores was devised for track and other endurance athletes. The original carbohydrate loading regimen consisted of a 3–4-day period of heavy exercise while on a low-carbohydrate diet, followed by 1–2 days of light exercise while on a high-carbohydrate diet. The initial low-carbohydrate–high-energy demand period caused a depletion of muscle glycogen stores. The subsequent change to a high-carbohydrate diet resulted in the production of higher-than-normal levels of insulin and growth hormone and glycogen stores reached almost twice the normal amounts. This practice did increase endurance significantly. In one study, test subjects on a high-fat and high-protein diet had less than 1.6 g of glycogen per 100 g of muscle and could perform a standardized workload for only 60 min. When the same subjects then consumed a high-carbohydrate diet for 3 days, their glycogen stores increased to 4 g per 100 g of muscle and the same workload could be performed for up to 4 h.

Although the technique clearly worked, the athletes often felt lethargic and irritable during the low-carbohydrate phase of the regimen, and the high-fat diet ran counter to current health recommendations. Recent studies indicate that regular consumption of a high-complex carbohydrate low-fat diet during training increases glycogen stores without sudden dietary changes. Current recommendations are for endurance athletes to consume a high-carbohydrate diet (with emphasis on complex carbohydrates) during training. Then carbohydrate intake is increased further (to 70% of calories) and exercise tapered off during the 2–3 days just prior to an athletic event. This increases muscle glycogen stores to levels comparable to the previously described carbohydrate-loading regimen.

L., Carbohydrates and fat for training and recovery. *J. Sports Sci.* 22:15, 2004.

CLINICAL CORRELATION 27.5

High-Carbohydrate versus High-Fat Diet for Diabetics

For years the American Diabetes Association has recommended diets that were low in fat and high in complex carbohydrates and fiber for diabetics. The logic of such a recommendation seemed to be inescapable. Diabetics are prone to hyperlipidemia with attendant risk of heart disease, and low-fat diets seemed likely to reduce the risk of hyperlipidemia and heart disease. In addition, numerous clinical studies had suggested that the high-fiber content of these diets improved control of blood sugar. This recommendation has proved to be controversial and illustrates the difficulties in making dietary recommendations for population groups rather than individuals. There is significant variation in how individual diabetics respond to these diets. Some diabetic patients show poorer control (as evidenced by higher blood glucose levels, elevated VLDL and/or LDL levels, and reduced HDL levels) on the high-carbohydrate–high-fiber diets than on diets high in monounsaturated fatty acids. However, diets high in monounsaturated fatty acids tend to have higher caloric density and may be inappropriate for overweight individuals with type 2 diabetes. Thus, a single diet may not be equally appropriate for all diabetics. Even the glycemic index concept (see Table 27.2, p. 1103) may also turn out to be difficult to apply to the diabetic population as a whole, because of individual variation. In 2004, the American Diabetes Association abandoned the concept of a single diabetic diet. Instead their recommendations focus on achievement of glucose, lipid, and blood pressure goals, with weight reduction and dietary recommendations based on individual preferences and what works best to achieve metabolic control in the individual. However, that doesn't necessarily imply that any weight-reduction diet is satisfactory. In 2006 the Diabetes and Nutrition Study Group of the European Association for the Study of Diabetes made a very specific set of evidenced-based recommendations for the all diets used for the treatment and prevention of diabetes. Their grade A recommendations are that such diets should (1) reduce energy intake and increase energy expenditure among those who are overweight and to prevent weight regain once weight loss has been achieved, (2) reduce saturated fats and *trans*-unsaturated fatty acids to below 10% of total energy (below 8% if LDL-cholesterol levels are elevated), (3) restrict dietary cholesterol to less than 300 mg/day (especially if LDL-cholesterol is elevated), (4) include naturally occurring carbohydrate-rich foods that are high in dietary fiber and low in glycemic index (vegetables, legumes, fruits and whole grains) with a total dietary fiber intake of 40g/day, and (5) restrict salt to less than 6 g/day. Their position is that a wide range of carbohydrate, protein, and fat intakes are suitable for a diabetic as long as the foods chosen meet these criteria.

Clin. Corr. 27.5. **Lactase insufficiency** (p. 1050) is also a common disorder of carbohydrate metabolism affecting over 30 million people in the United States alone. It is most prevalent among blacks, Asians, and Hispanics. Without intestinal lactase, dietary lactose is not significantly hydrolyzed or absorbed. It remains in the intestine where it acts osmotically to draw water into the gut, and it is converted to lactic acid and CO_2 by intestinal bacteria. The result is bloating, flatulence, and diarrhea, all of which can be avoided simply by eliminating milk and milk products from the diet.

27.7 • FATS

Triacylglycerols, or fats, are directly utilized by many tissues as an energy source, and phospholipids are important constituents of membranes. Excess dietary fat can be stored only as triacylglycerol in adipose tissue. As with carbohydrate, the body adapts to a wide range of fat intakes. However, problems develop at the extremes (either high or low) of fat consumption. At the low end, **essential-fatty-acid** (**EFA**) deficiency may become a problem. The fatty acids linoleic and linolenic cannot be made by the body and thus are essential components of the diet. They are needed for maintaining the function and integrity of membrane structure, for fat metabolism and transport, and for synthesis of **prostaglandins** and related compounds. The most characteristic symptom of essential-fatty-acid deficiency is a scaly dermatitis. EFA deficiency is very rare in the United States, occurring primarily in low-birth-weight infants fed on artificial formulas lacking EFA and in hospitalized patients maintained on total parenteral nutrition for long periods. At the other extreme, there is concern that excess dietary

fat causes elevation of serum lipids and thus an increased risk of heart disease. Recent studies suggest that high fat intakes are associated with increased risk of colon, breast, and prostate cancer, but it is not clear whether the cancer risk is associated with fat intake *per se*, or with the excess calories and obesity associated with a high-fat diet. Animal studies suggest that polyunsaturated fatty acids of the ω-6 series may be more tumorigenic than other unsaturated fatty acids. The reason for this is not known, but it has been suggested that prostaglandins derived from the ω-6 fatty acids may stimulate tumor progression.

27.8 • FIBER

Dietary fiber comprises those components of food that cannot be broken down by human digestive enzymes. It is incorrect, however, to assume that fiber is indigestible since some fibers are, in fact, at least partially broken down by intestinal bacteria. Our current understanding of the metabolic roles of dietary fiber is based on three important observations: (1) there are several different types of dietary fiber. (2) they each have different chemical and physical properties, and (3) they each have different effects on human metabolism, which can be understood, in part, from their unique properties.

The major types of fiber and their properties are summarized in Table 27.3. **Cellulose** and most **hemicelluloses** increase stool bulk, decrease transit time, and are associated with the effects of fiber on regularity. They decrease intracolonic pressure and appear to play a beneficial role with respect to diverticular diseases. By diluting out potential carcinogens and speeding their transit through the colon, they may also play a role in reducing the risk of colon cancer. **Lignins** have bulk-enhancing properties and they adsorb organic substances such as cholesterol to lower plasma cholesterol concentration. Mucilaginous fibers, such as **pectin** and **gums**, tend to form viscous gels in the stomach and intestine and slow the rate of gastric emptying, thus slowing the rate of absorption of many nutrients. Their most important clinical role is to slow the rate at which carbohydrates are digested and absorbed. Thus, both the rise in blood sugar and the rise in insulin levels are significantly decreased if these fibers are ingested with carbohydrate-containing foods. Water-soluble fibers (pectins, gums, and some hemicelluloses, and storage polysaccharides) also help to lower serum cholesterol levels in most people. Whether this is due to their effect on insulin levels (insulin stimulates cholesterol synthesis and export) or to other metabolic effects (perhaps caused by end products of partial bacterial digestion) is not known. Vegetables, wheat, and most grain fibers are the best sources of the water-insoluble cellulose, hemicellulose, and lignin. Fruits, oats, and legumes are the best sources of the water-soluble fibers. Obviously, a balanced diet should include food sources of both soluble and insoluble fiber.

TABLE 27.3 • Major Types of Fiber and Their Properties

Type of Fiber	*Major Source in Diet*	*Chemical Properties*	*Physiological Effects*
Cellulose	Unrefined cereals Bran Whole wheat	Nondigestible Water-insoluble Absorbs water	Increases stool bulk Decreases intestinal transit time Decreases intracolonic pressure
Hemicellulose	Unrefined cereals Some fruits and vegetables Whole wheat	Partially digestible Usually water-insoluble Absorbs water	Increases stool bulk Decreases intestinal transit time Decreases intracolonic pressure
Lignin	Woody parts of vegetables	Nondigestible Water-insoluble Absorbs organic substances	Increases stool bulk Bind cholesterol Bind carcinogens
Pectin	Fruits	Digestible Water-soluble Mucilaginous	Decreases rate of gastric emptying Decreases rate of sugar uptake Decreases serum cholesterol
Gums	Dried beans Oats	Digestible Water-soluble Mucilaginous	Decreases rate of gastric emptying Decreases rate of sugar uptake Decreases serum cholesterol

27.9 • COMPOSITION OF MACRONUTRIENTS IN THE DIET

Since there are relatively few instances of macronutrient deficiencies in the American diet, much of the interest in recent years has focused on whether there is an ideal diet composition consistent with good health.

Composition of the Diet Affects Serum Cholesterol

With respect to heart disease, the current discussion centers around two key issues. (1) Can **serum cholesterol** and triacylglycerol concentration be controlled by diet? (2) Does lowering serum cholesterol and triacylglycerol levels protect against heart disease? The controversies around dietary control of cholesterol levels illustrate perfectly the trap one falls into by trying to look too closely at each individual component of the diet instead of at the diet as a whole. For example, at least four dietary components have an effect on serum cholesterol: cholesterol itself, **polyunsaturated fatty acids (PUFA)**, **saturated fatty acids (SFA)**, and fiber. It would seem that the more cholesterol one eats, the higher the serum cholesterol would be. However, cholesterol synthesis is tightly regulated, and decreases in dietary cholesterol have relatively little effect on serum cholesterol levels (p. 724). One can obtain a more significant reduction in cholesterol and triacylglycerol levels by increasing the **ratio of PUFA/SFA** in the diet. Finally, some plant fibers, especially the water-soluble fibers, appear to decrease cholesterol levels significantly.

While the effects of various lipids in the diet can be dramatic, the biochemistry of their action is still uncertain. Saturated fats inhibit receptor-mediated uptake of LDL, but the mechanism is complex. Palmitic acid (saturated, C_{16}) raises serum cholesterol levels whereas stearic acid (saturated, C_{18}) has no effect. Polyunsaturated fatty acids lower both LDL and HDL cholesterol levels, whereas oleic acid (monounsaturated, C_{18}) appears to lower LDL without affecting HDL levels. The ω-3 and ω-6 polyunsaturated fatty acids have slightly different effects on lipid profiles (Clin. Corr. 27.6). However, these

CLINICAL CORRELATION 27.6

Polyunsaturated Fatty Acids and Risk Factors for Heart Disease

Because reduction of elevated serum cholesterol levels can reduce risk of heart disease, there is considerable interest in the effects of diet on serum cholesterol levels and other risk factors for heart disease. One important dietary factor regulating serum cholesterol levels is the ratio of polyunsaturated fats (PUFAs) to saturated fats (SFAs) in the diet. Furthermore, recent research shows that different types of polyunsaturated fatty acids have different effects on lipid metabolism and on other risk factors for heart disease. Essential polyunsaturated fatty acids can be classified as either ω-6 or ω-3. Clinical studies have shown that the ω-6 PUFAs (chief dietary source is linoleic acid from plants and vegetable oils) primarily decrease serum cholesterol levels, with only modest effects on serum triacylglycerol levels. The ω-3 PUFAs (chief dietary source is eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) from certain ocean fish and fish oils) cause only modest decreases in serum cholesterol levels but significantly lower serum triacylglycerol levels. The mechanisms behind these effects on serum lipid levels are unknown.

In addition, the ω-3 PUFAs have other effects that may decrease the risk of heart disease; they decrease platelet aggregation, inflammation, and arrhythmia and increase endothelial relaxation. In the case of platelet aggregation, the mechanism is clear. Arachidonic acid (ω-6 family) is a precursor of thromboxane A_2 (TXA_2), which is a potent pro-aggregating agent, and prostaglandin I_2 (PGI_2), which is a weak anti-aggregating agent (p. 742). The ω-3 PUFAs are converted to thromboxane A_3 (TXA_3), which is only weakly pro-aggregating, and prostaglandin I_3 (PGI_3), which is strongly anti-aggregating. Thus, the balance between pro-aggregation and anti-aggregation is shifted toward a more anti-aggregating condition as the ω-3 PUFAs displace ω-6 PUFAs as precursors to the thromboxanes and prostaglandins. The ω-3 PUFAs also have been shown to reduce cardiac arrhythmia and promote plaque stabilization. Several clinical studies have shown that diets rich in ω-3 fatty acids significantly decrease the risk of sudden cardiac death in patients who have previously had a myocardial infarction. Because of these studies, both the American and European Heart Associations have incorporated recommendations for ω-3 PUFAs into their treatment and prevention guidelines for myocardial infarction.

Marchioli, R., Schweiger, C., Tavazzi, L., and Valagussa, F. Efficacy of n-3 polyunsaturated fatty acids after myocardial infarction: Results of the GISSI-Prevenzione Trial. Early protection against sudden death by n-3 polyunsaurated fatty acids after myocardial infarction: Time-course analysis of the results of the Gruppo Italiano per lo Studio della Sopravivenza nell'Infarcto Miocardico (GISSI)-Prevenzione. *Circulation* 105:1897, 2002; Kris-Etherton, T., Harris, W. H., and Appel, L. J. Omega-3 fatty acids and cardiovascular disease. New recommendations from the American Heart Association. Arterioscler. *Thromb. Vasc. Biol.* 23:151, 2003; and Biscione, F., Pignalberi, C., Totteri, A., Messina, F., and Altamura, G. Cardiovascular effects of omega-3 fatty acids. *Curr. Vascular Pharmacol.* 5:163, 2007.

complexities do not significantly affect dietary recommendations. Most foods high in saturated fats contain both palmitic and stearic acid, and are atherogenic. Since oleic acid lowers LDL levels, olive oil, and possibly peanut oil, may be as beneficial as polyunsaturated oils.

There is little disagreement with respect to these data. The question is: What can be done with the information? Much of the disagreement arises from the tendency to look at each dietary factor in isolation. For example, it is debatable whether it is worthwhile placing a patient on a highly restrictive 300-mg cholesterol diet (1 egg contains about 213 mg of cholesterol) if his serum cholesterol is lowered by only 5%–10%. Likewise, changing the PUFA/SFA ratio from 0.3 (the current value) to 1.0 would either require a radical change in the diet by elimination of foods containing saturated fat (largely meats and fats) or an addition of large amounts of rather unpalatable polyunsaturated fats to the diet. For many Americans, this would be unrealistic. Fiber is another good example. One could expect, at the most, a 5% decrease in serum cholesterol by adding a reasonable amount of fiber to the diet. Very few people would eat the 10 apples/day needed to lower serum cholesterol by 15%. Are we to conclude then that any dietary means of controlling serum cholesterol levels is useless? This would be the case only if each element of the diet is examined in isolation. For example, recent studies have shown that vegetarians, who have lower cholesterol intakes plus higher PUFA/SFA ratios and higher fiber intakes, may average 25%–30% lower cholesterol levels than their nonvegetarian counterparts. Perhaps, more to the point, diet modifications acceptable to the average American have been shown to cause a 10%–15% decrease in cholesterol levels in long-term studies, and a recent study called OmniHeart has shown that as long as saturated fat, cholesterol, fiber, sodium, calcium, magnesium, and potassium were at appropriate levels, a wide range of macronutrient composition was compatible with a heart-healthy diet.

Carbohydrates, Glycemic Index, and Glycemic Load

Much of the nutritional dispute in the area of carbohydrate intake centers around the effect of carbohydrate on blood glucose and triacylglycerol levels. The old paradigm that simple sugars raise blood sugar and triacylglycerol levels to a greater extent than complex carbohydrates is an oversimplification. The effect of the carbohydrates in a particular food is determined by the rate of digestion and absorption of the carbohydrate and by other components of the food. In particular soluble fiber, protein, and fat all blunt the effect of carbohydrates on blood glucose levels. Thus, the concept of **glycemic index** was developed to describe better the effects of carbohydrates on blood glucose. Glycemic index is determined empirically and is defined as the effect of 50 g of carbohydrate in a particular food on blood glucose levels compared to 50 g of glucose. In general, pastries, refined cereals, rice, and starchy vegetables have high glycemic indices, whereas nonstarchy vegetables, fruits, legumes, and nuts have low glycemic indices (Table 27.4). However, because the carbohydrate content of foods varies widely, even glycemic indices can be misleading. For example, carrots have a much higher glycemic index than ice cream (Table 27.4). Thus, the term ***glycemic load*** has recently been introduced. Glycemic load is the glycemic index times the amount of carbohydrate in a standard serving size of that food. As might be expected carrots have a much lower glycemic load than ice cream.

Nutritional Protein Requirements Are Achieved by Mixing Vegetable and Animal Proteins

Epidemiologic data and animal studies suggest that consumption of animal protein is associated with increased incidence of heart disease and various forms of cancer. One could assume that it is probably not the animal protein itself that is involved, but the associated fat and cholesterol. What sort of protein should we consume? Although the present diet may not be optimal, a strictly vegetarian diet may not be acceptable to many Americans. Perhaps a middle road is best. Clearly, there are no known health dangers associated with a mixed diet that is lower in animal protein than the current American standard.

TABLE 27.4 • Glycemic Index[a] of Selected Foods

Grain and cereal products	
Bread (white)	69 ± 5
Bread (whole wheat)	72 ± 6
Rice (white)	72 ± 9
Sponge cake	46 ± 6
Breakfast cereals	
All bran	51 ± 5
Cornflakes	80 ± 6
Oatmeal	49 ± 8
Shredded wheat	67 ± 10
Vegetables	
Sweet corn	59 ± 11
Frozen peas	51 ± 6
Dairy products	
Ice cream	36 ± 8
Milk (whole)	34 ± 6
Yoghurt	36 ± 4
Root vegetables	
Beets	64 ± 16
Carrots	92 ± 20
Potato (white)	70 ± 6
Potato (sweet)	48 ± 6
Dried legumes	
Beans (kidney)	29 ± 8
Beans (soy)	15 ± 5
Peas (blackeye)	33 ± 4
Fruits	
Apple (Golden Delicious)	39 ± 3
Banana	62 ± 9
Orange	40 ± 3
Sugars	
Fructose	20 ± 5
Glucose	100
Honey	87 ± 8
Sucrose	59 ± 10

Source: Data from Jenkins,D. A., et al. Glycemic index of foods: A physiological basis for carbohydrate exchange. *Am. J. Clin. Nutr.* 34:362, 1981.

[a]Glycemic index is defined as the area under the blood glucose response curve for each food expressed as a percentage of the area after taking the same amount of carbohydrate as glucose (mean: 5–10 individuals).

Fiber from Varied Sources Is Desirable

Because of current knowledge about effects of fiber on human metabolism, most suggestions for a prudent diet recommend an increase in dietary fiber. The current fiber content of the American diet is about 14–15 g/day. Most experts feel that an increase to at least 25–30 g would be safe and beneficial. Since different types of fibers have different physiological roles, the increase in fiber intake should come from a wide variety of sources, including fresh fruits, vegetables, and legumes as well as the more popular cereal fibers (which are primarily cellulose and hemicellulose).

Dietary Recommendations

Several private and government groups have made specific recommendations with respect to the **ideal dietary composition** for the American public. This movement was spearheaded by the Senate Select Committee on Human Nutrition, which first published its *Dietary Goals for the United States* in 1977. This Committee recommended that the American public reduce consumption of total calories, total fat, saturated fat, cholesterol, simple sugars, and salt to "ideal" goals more compatible with good health (Figure 27.7). In recent years the U.S. Department of Agriculture (USDA), the American Heart Association, the American Diabetes Association, the National Research Council, and the Surgeon General have published similar recommendations, and the USDA has used these recommendations to design revised recommendations for its **Food Guide Pyramid** (Figure 27.8). How valid is the scientific basis of the recommendations for a **prudent diet**? Is there evidence that it will improve the health of the general public? How much does individual variability affect these recommendations? These remain controversial questions.

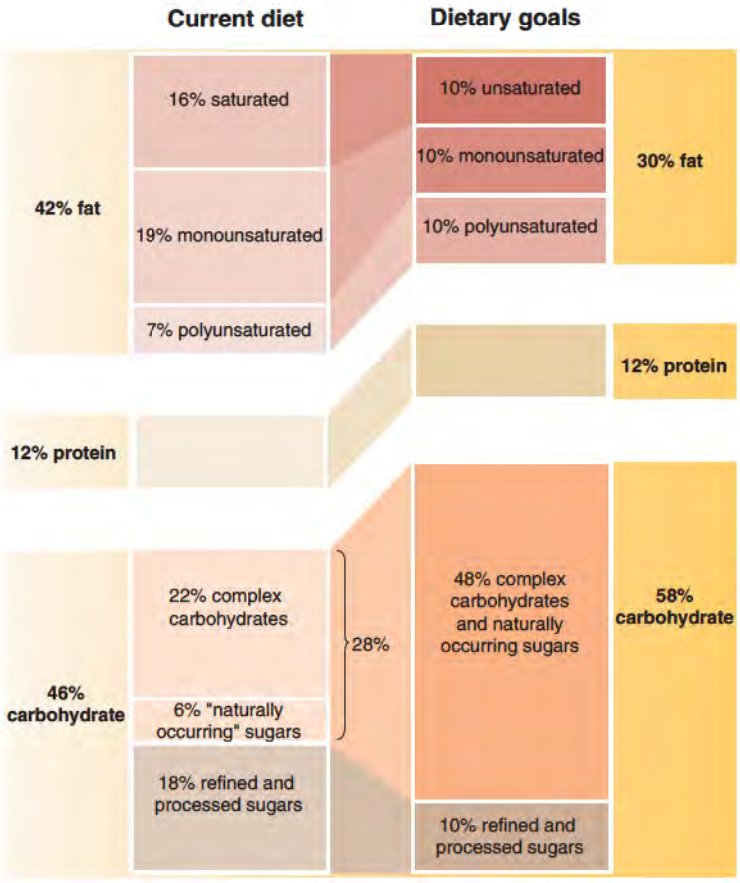

Figure 27.7 **U.S. dietary goals.** Graphical comparison of the composition of the current U.S. diet and the dietary goals for the U.S. population suggested by the Senate Select Committee on Human Nutrition. From *Dietary Goals for the United States,* 2d ed. Washington, DC: U.S. Government Printing Office, 1977.

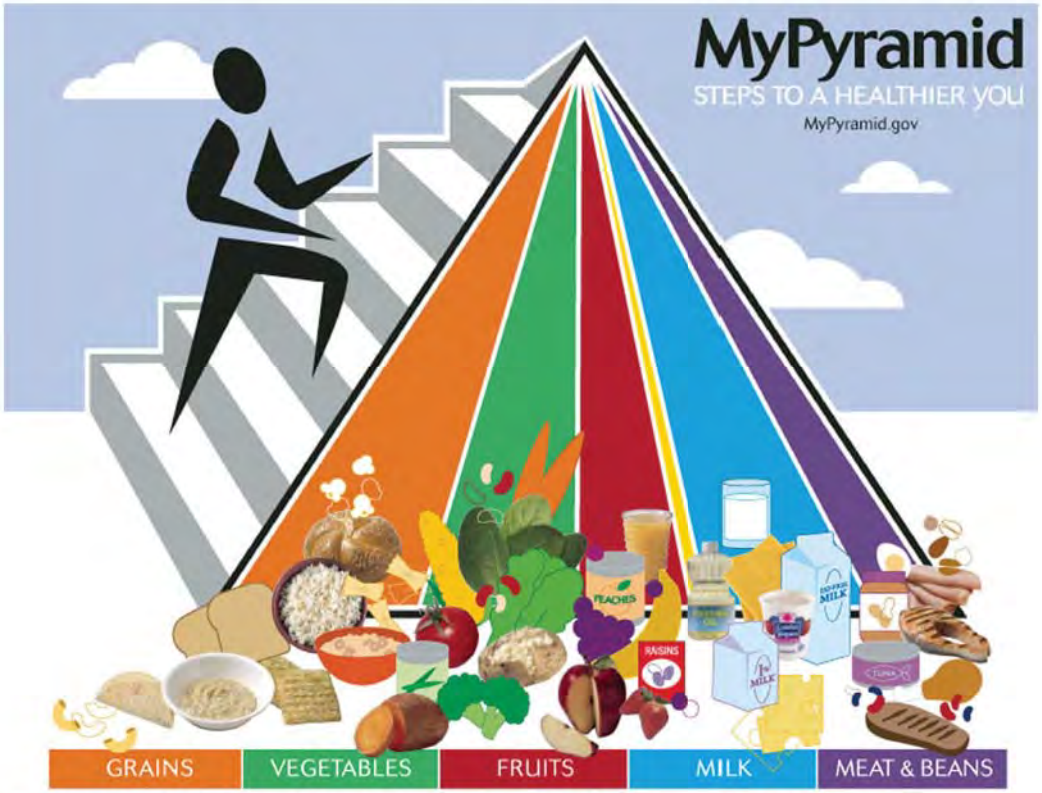

Figure 27.8 USDA food pyramid. Graphical representation of USDA recommendations for a balanced diet.www.mypyramid.gov.

The recent debate about diet composition and weight loss illustrates the complexity of these considerations. The debate was fueled by Dr. Atkins *Diet Revolution* and *New Diet Revolution* books claiming that weight loss was more effective with low-carbohydrate diets, and that fat, even saturated fat, did not adversely affect serum cholesterol levels. In fact, short-term studies seemed to confirm that weight loss was more rapid and control of blood sugar and improvement of lipid parameters were better on low-carbohydrate diets. There have now been a number of well-controlled clinical trials comparing low-fat (typically high carbohydrate, moderate-protein, and low-fat), low carbohydrate (typically low-carbohydrate, moderate-protein, and high-fat), high-protein (typically moderate-carbohydrate, high-protein, and moderate fat) and Mediterranean (typically moderate-carbohydrate, moderate-protein and moderate-fat with carbohydrates coming primarily from vegetables, protein coming primarily from poultry and fish, and fat coming primarily from olive oil) diets. Systematic analyses of these studies have concluded that weight loss is somewhat greater at 6 months on the low-fat and high-protein diets, but that there is very little difference in net weight loss on any of these diets at 1 year or more. Triglyceride levels (triacylglycerol-rich VLDL) and HDL levels appeared to improve slightly more on the low-carbohydrate diets, whereas total and LDL levels improved slightly more on the low-fat diets and blood sugar control was slightly better on the Mediterranean diet. However, all of the differences between the diets were very small, and there was a huge individual variation in response to the diets.

In evaluating the results of these trials, it is important to realize that the best of the studies were performed under controlled conditions using diets designed by trained dietitians. Thus, the high-carbohydrate diets generally incorporated a high percentage of low glycemic load carbohydrates and even the high-fat diets were low in saturated fats and cholesterol. This is important because the type of carbohydrates and fats in the diet appear to be just as important as their amounts. High-carbohydrate diets that are low in glycemic load appear to be just as effective in achieving weight loss and control of blood sugar as diets that are low in carbohydrate. Similarly, diets containing heart-healthy monounsaturated and ω-3 polyunsaturated fats are just as effective in achieving weight loss and lowering triglyceride levels and are better at lowering total and LDL cholesterol than diets containing saturated fats.

CLINICAL CORRELATION 27.7

Metabolic Adaptation: Relationship between Carbohydrate Intake and Serum Triacylglycerols

In evaluating the nutrition literature, it is important to be aware that most clinical trials are of rather short duration (2–6 weeks), whereas some metabolic adaptations may take considerably longer. Thus, even apparently well-designed clinical studies may lead to erroneous conclusions that will be repeated in the popular literature for years to come. For example, several studies conducted in the 1960s and 1970s tried to assess the effects of carbohydrate intake on serum triacylglycerol levels. Typically, young college-age males were given a diet in which up to 50% of their fat calories were replaced with sucrose or other simple sugars for a period of 2–3 weeks. In most cases serum triacylglycerol levels increased markedly (up to 50%). This led to the tentative conclusion that high intake of simple sugars, particularly sucrose, could increase the risk of heart disease, a notion that was popularized by nutritional best sellers such as *Sugar Blues* and *Sweet and Dangerous*. Unfortunately, while the original conclusions were promoted in the lay press, the experiments themselves were questioned. Subsequent studies showed that if these trials were continued for longer periods (3–6 months), the triacylglycerol levels usually normalized. The nature of this slow metabolic adaptation is unknown. It is also important to consider the type of carbohydrate in the diet. For many Americans, a high-carbohydrate diet means a diet that is high in simple sugars. Triacylglycerol levels in these individuals respond dramatically to diets that substitute foods containing either fat or complex carbohydrates and fiber for these foods contain simple sugars as a carbohydrate source.

Leahy, P., Croniger, C., and Hanson, R. W. Molecular and cellular adaptations to carbohydrate and fat intake. *Eur. J. Clin. Nutr.* 53, Suppl. 1:S6, 1999; and Parks, E. J., and Hellerstein, M. K. Carbohydrate-induced hypertriacylglycerolemia: Historical perspective and review of biological mechanisms. *Am. J. Clin. Nutr.* 71:412, 2000.

Finally, it is important to remember that dietary recommendations are for populations, not for individuals. The diet that works best for achieving weight control, blood sugar control, and healthy lipoprotein patterns is determined by an individual's genetic makeup (see Clin. Corr. 27.7, p. 1118, and Clin. Corr. 27.5, p. 1112).

27.10 • NUTRIGENETICS AND DIET COMPOSITION

In the past dietary recommendations have been made for the population as a whole without taking into account the influence of genetic background on whether or not the recommendations were advisable for any given individual. Moreover, it has often been difficult to make general dietary recommendations because of significant individual variation in the response to dietary interventions. However, as we learn more about the genetics underlying this individual variation, it may soon be possible to individualize dietary recommendations on the basis of the individual's genetic makeup. For example, it has been difficult in the past to draw firm conclusions about how the ratio of polyunsaturated fats and saturated fats (PUFA/SFA ratio) in the diet affects cardiovascular risk factors because of conflicting results from clinical trials conducted with different population groups. However, when differences in genetic background of these population groups are taken into account, the picture becomes much clearer.

For example, there is an A/G **SNP** (**single nucleotide polymorphism**) at the –75 position in the promoter region of the apoAI gene that affects the response of LDL-cholesterol to the relative amounts of polyunsaturated and saturated fats in the diet. An increase in the PUFA/SFA ratio results in a decrease in LDL-cholesterol in G/G homozygotes. However, the same increase in PUFA/SFA ratio results in an increase in LDL-cholesterol levels in G/A heterozygotes. Similarly, there is a SNP in the coding region of the PPARα gene that results in a L162V polymorphism that affects the response of serum triglycerides (triacylglycerol-rich VLDL) to the relative amounts of polyunsaturated and saturated fats in the diet. An increase in polyunsaturated fat intake leads to a decrease in triglyceride levels in V162 heterozygotes, but not in L162 homozygotes. Finally, there are two G/A SNPs in the promoter region of the TNFα gene that affect the response of HDL levels to the relative

amounts of polyunsaturated and saturated fats in the diet. An increase in polyunsaturated fat intake results in increased HDL levels in –238 G/A heterozygotes and decreased HDL levels in –238 G/G monozygotes. In contrast, an increase in polyunsaturated fat intake results in decreased HDL levels in –308 G/A heterozygotes and does not affect HDL levels in –308 G/G homozygotes.

Nutrigenics holds the promise of allowing a truly individualized approach to making dietary recommendations to reduce disease risk in the future. However, because obesity and the diseases associated with obesity are polygenic diseases, this will not be a simple task. The examples given illustrate the difficulties that lie ahead. The relationships between fatty acid intake and LDL-cholesterol, triglycerides, and HDL are determined by at least four distinct SNPs that we know about, and possibly many more that we don't yet know about. It is easy to imagine that in a single individual, an increase in dietary polyunsaturated fats could lead to a decrease in LDL cholesterol, an increase in triglycerides and a decrease in HDL. What would the individualized recommendation regarding polyunsaturated fat be for that individual?

lactase insufficiency
essential fatty acids
dietary fiber
glycemic index
glycemic load
monounsaturated fats
ω-6 polyunsaturated fats
ω-3 polyunsaturated fats
nutrigenetics

Questions • CAROL N. ANGSTADT

Multiple-Choice Questions

1. Protein energy malnutrition (PEM)
   - **A.** is always manifested by a thin, wasted appearance.
   - **B.** causes problems only when there is an inadequate consumption of calories.
   - **C.** causes problems only when there is an inadequate consumption of protein.
   - **D.** leads to a reduced ability to fight infection.
   - **E.** occurs only in infants.

2. Basal metabolic rate
   - **A.** is not influenced by energy intake.
   - **B.** increases in response to starvation.
   - **C.** may decrease up to 50 % during periods of starvation.
   - **D.** increases in direct proportion to daily energy expenditure.
   - **E.** is not responsive to changes in hormone levels.

3. Obesity
   - **A.** usually does not have adverse metabolic consequences.
   - **B.** causes metabolic changes that are usually irreversible.
   - **C.** frequently leads to elevated serum levels of fatty acids, cholesterol, and triglycerides.
   - **D.** is frequently associated with an increased sensitivity of insulin receptors.
   - **E.** is caused solely by high caloric consumption.

4. Dietary fat
   - **A.** is usually present, although there is no specific need for it.
   - **B.** if present in excess, can be stored as either glycogen or adipose tissue triacylglycerol.
   - **C.** should include linoleic and linolenic acids.
   - **D.** should increase on an endurance training program to increase the body's energy stores.
   - **E.** if present in excess, does not usually lead to health problems.

5. Which of the following statements about dietary fiber is/are correct?
   - **A.** Water-soluble fiber helps to lower serum cholesterol in most people.
   - **B.** Mucilaginous fiber slows the rate of digestion and absorption of carbohydrates.
   - **C.** Insoluble fiber increases stool bulk and decreases transit time.
   - **D.** All of the above.
   - **E.** None of the above.

6. Nutrigenetics indicates that
   - **A.** dietary recommendations for the population as a whole may not be advisable for a given individual.
   - **B.** a single nucleotide polymorphism (SNP) in a given gene may alter the response to a dietary change.
   - **C.** homozygotes for an SNP may have a different response to a dietary change than heterozygotes for that SNP.
   - **D.** SNPs may occur in the promoter region or in the coding region of a gene.
   - **E.** all of the above.

Questions 7 and 8: A young man suffered third-degree burns over much of his body and is hospitalized in a severe catabolic state. An individual in this state requires about 40 kcal kg per day and 2 g protein kg per day to be in positive caloric and nitrogen balance. This young man weighs 140 lb (64 kg). Total Parenteral Nutrition (TPN) is started with a solution containing 20 % glucose and 4.25 % amino acids (the form in which protein is supplied).

7. If 3000 g of solution is infused per day,
   - **A.** the patient would not be getting sufficient protein.
   - **B.** the calories supplied would be inadequate.
   - **C.** both protein and calories would be adequate to meet requirements.
   - **D.** this is too much protein being infused.

8. Sometimes a lipid solution is also infused in a patient on TPN. In the case of this young man, the purpose of the lipid solution would be to
   - **A.** supply additional calories to meet caloric needs.
   - **B.** supply essential fatty acids.
   - **C.** improve the palatability of the mixture.
   - **D.** provide fiber.
   - **E.** assure an adequate supply of cholesterol for membrane building.

Questions 9 and 10: For many years, the American Diabetic Association recommended a diet high in complex carbohydrates and fiber and low in fat for diabetics. It was later found that some individuals did not do as well on such a diet as on one high in monounsaturated fatty acids. Since 1994, the ADA has abandoned the concept of a single diabetic diet and now recommends a focus on achieving glucose, lipid, and blood pressure goals with weight reduction if necessary.

9. Which of the following statements is/are correct?
   - **A.** A high-carbohydrate–high-fiber diet often results in significant weight reduction because it has a lower caloric density than a diet high in fat.
   - **B.** A diet high in monounsaturated fatty acids would be most appropriate for an overweight diabetic.
   - **C.** The goal for lipids is to reduce all lipoprotein levels in the blood.
   - **D.** Obesity aggravates diabetes because it inhibits the production of insulin by the pancreas.
   - **E.** All of the above.

10. For diabetics,
    - **A.** the only carbohydrate that must be eliminated in the diet is sucrose.
    - **B.** fiber increases the rate at which carbohydrate is digested and absorbed.
    - **C.** not all carbohydrate foods raise blood glucose levels at the same rate because the glycemic index of all foods is not the same.
    - **D.** who are normally in good control, stress will have no effect on their blood sugar levels.
    - **E.** a vegetarian diet is the only appropriate choice.

Questions 11 and 12: Recent studies have confirmed that reducing elevated serum cholesterol levels can reduce the risk of heart disease. Obesity is another risk factor. Epidemiological studies suggest that consumption of animal protein is associated with an increased incidence of heart disease, although it is probably the fat and cholesterol in animal foods rather than the animal protein itself. Most Americans would probably not accept a strictly vegetarian diet.

11. All of the following have been shown to have some effect, although it may be small, on lowering serum cholesterol except
    A. restricting dietary cholesterol.
    B. increasing the ratio of polyunsaturated to saturated fatty acids.
    C. replacing oleic acid with palmitic acid.
    D. increasing the amount of soluble fiber.
    E. changing to a vegetarian diet.

12. A complete replacement of animal protein in the diet by vegetable protein
    A. would be expected to have no effect at all on the overall diet.
    B. would reduce the total amount of food consumed for the same number of calories.
    C. might reduce the total amount of iron and vitamin B_{12} available.
    D. would be satisfactory regardless of the nature of the vegetable protein used.
    E. could not satisfy protein requirements.

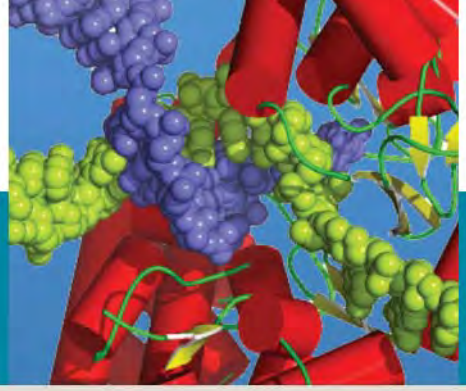
Problems

13. Calculate the number of grams each of carbohydrate, lipid, and protein a person on a 2300-kcal diet should consume to meet the guidelines established by the Senate Select Committee on Human Nutrition. Assuming the individual weighs 180 lb and the protein is from mixed animal/vegetable sources with a 75% efficiency of utilization, does the amount of protein you calculated meet the recommended amount of protein?

14. A 120-lb woman is consuming a diet with adequate total calories and 44 g of protein per day. The protein is exclusively from vegetable sources, primarily corn based. What would be her state of nitrogen balance?

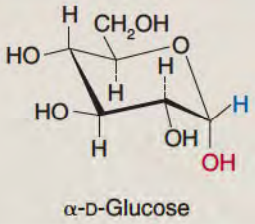
Answers

1. **D** They have reduced numbers of T lymphocytes and reduced production of immunoglobulins and other components of the immune system. A: This is true of marasmus but not kwashiorkor. B and C: Marasmus is a deficiency of both protein and calories whereas kwashiorkor is a deficiency of protein with adequate calories. E: Hospitalized adults can also suffer from PEM.
2. **C** This is part of the survival mechanism in starvation. A and B: BMR decreases when energy intake decreases. D: BMR as defined is independent of energy expenditure. Only when the exercise is repeated on a daily basis so that lean muscle mass is increased does BMR also increase. E: Many hormones increase BMR.
3. **C** Probably because of an increased number and/or size of adipose cells, which are less sensitive to insulin. A: Obesity has multiple effects. B: Most changes can be reversed if weight is lost. D: Sensitivity is decreased perhaps by interfering with autophosphorylation of the receptor. E: Inadequate exercise and a genetic component also play a role.
4. **C** A and C: Linoleic and linolenic acids are essential fatty acids and so must be present in the diet. B and D: Excess carbohydrate can be stored as fat but the reverse is not true. D: Carbohydrate loading has been shown to increase endurance. E: High-fat diets are associated with many health risks.
5. **D** These each illustrate the different properties and roles of the common kinds of fiber.
6. **E** They are all correct. A: The genetic makeup of the individual matters. B and C: For example, A/G SNP in the promoter of the apoA1 gene results in a decrease in LDL-cholesterol in response to increased PUFA/SFA in G/G homozygotes but an increase in G/A heterozygotes. D: The SNP is in the promoter of the apoA1 gene but in the coding region of the PPARα gene.
7. **C** This amount of solution would supply 128 g of protein and 2912 kcal (2400 from glucose and 512 from amino acids), both enough to meet the stated requirements.
8. **B** Patients on TPN need to have essential fatty acids supplied. A: The original solution supplies adequate calories, although additional calories should not hurt this young man. C: The patient is not tasting this mixture, so palatability is irrelevant. D: Fiber is supplied by complex carbohydrate sources. E: The body can make its own cholesterol.
9. **A** Since carbohydrate has less than half the caloric density of fat and fiber provides no calories, such diets have low caloric density. B: High fat would tend to increase weight. C: The goal is to reduce the LDL and VLDL but not HDL. D: The problem is that factors released by adipose cells invoke insulin resistance.
10. **C** Foods vary widely in their glycemic index. Bread and rice raise blood glucose levels more rapidly than does sucrose. A: See C. B: One of the benefits of fiber is that it decreases the rate of carbohydrate absorption. D: Stress raises blood glucose for everyone because of release of epinephrine and glucocorticoids. E: An appropriately designed vegetarian diet is perfectly acceptable but is certainly not the only choice.
11. **C** Oleic acid lowers cholesterol, but palmitic acid increases it. A, B, and D: These all have positive effects in lowering cholesterol. E: Vegetarians tend to have lower cholesterol (the diets actually incorporate A, B, and D).
12. **C** A and C: This would reduce the amount of fat, especially saturated fat, but could also reduce the amount of necessary nutrients that come primarily from animal sources. B: The protein content of vegetables is quite low, so much larger amounts of vegetables would have to be consumed. D and E: It is possible to satisfy requirements for all of the essential amino acids completely if vegetables with complementary amino acid patterns, in proper amounts, are consumed.
13. According to the SSCHN guidelines a 2300-kcal diet should consist of 333.5 g of carbohydrate (no more than 57.5 g as simple sugar); 69 g of protein and 76.7 g of fat (no more than 25.6 g of saturated fat). A 180-lb man weighs 81.8 kg times 0.8 g /kg = 65.5 g. of protein per day to meet requirements; 12 % of 2300 kcal supplies sufficient protein.
14. 44 g protein/120 lb is 0.8 g protein/kg/day. However, this is inadequate because pure vegetable protein is less than 75 % efficient in utilization. Also, heavy reliance on one protein (corn is deficient in lysine) would likely lead to a deficiency of one or more essential amino acids. Therefore, the woman in this problem is in negative nitrogen balance.



Appendix

Review of Organic Chemistry



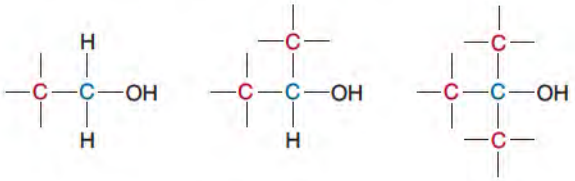
α-D-Glucose

Carol N. Angstadt

FUNCTIONAL GROUPS

Alcohols

The general formula of **alcohols** is R—OH, where R equals an alkyl or aryl group. They are classified as *primary, secondary,* or *tertiary,* according to whether the hydroxyl (OH)-bearing carbon is bonded to no carbon or one, two, or three other carbon atoms:

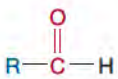


Primary Secondary Tertiary

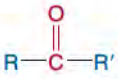
Aldehydes and Ketones

Aldehydes and **ketones** contain a carbonyl group:

Aldehydes are

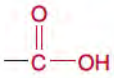


and a *ketone* has two groups (alkyl and/or aryl) at the carbonyl group

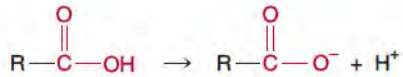


Acids and Acid Anhydrides

Carboxylic acids contain the functional group

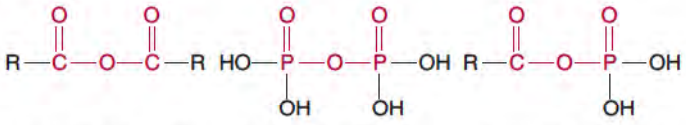


(—COOH). Dicarboxylic and tricarboxylic acids contain two or three carboxyl groups. A carboxylic acid dissociates in water to a negatively charged carboxylate ion:



Carboxylic acid Carboxylate ion

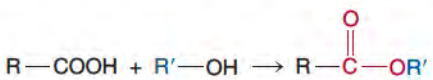
Names of carboxylic acids usually end in -ic and the carboxylate ion in -ate. **Acid anhydrides** are formed when two molecules of acid react with loss of a molecule of water. An acid anhydride may form between two organic acids, two inorganic acids, or an organic and an inorganic acid:



Organic anhydride Inorganic anhydride Organic–inorganic anhydride

Esters

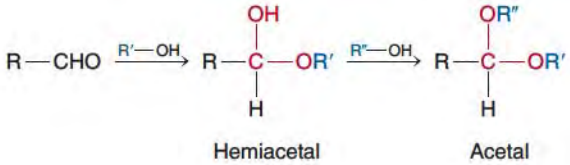
Esters form in the reaction between a carboxylic acid and an alcohol:



Esters may form between an inorganic acid and an organic alcohol, for example, glucose 6-phosphate.

Hemiacetals, Acetals, and Lactones

A reaction between an aldehyde and an alcohol gives a **hemiacetal**, which may react with another molecule of alcohol to form an **acetal**:



Hemiacetal Acetal

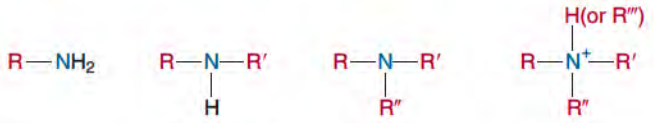
Lactones are cyclic esters formed when an acid and an alcohol group on the same molecule react and usually require that a five- or six-membered ring be formed.

Unsaturated Compounds

Unsaturated compounds are those containing one or more carbon—carbon multiple bonds, for example, a double bond: —C=C—.

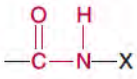
Amines and Amides

Amines, R—NH_2, are organic derivatives of NH_3 and are classified as *primary, secondary*, or *tertiary*, depending on the number of alkyl groups (R) bonded to the nitrogen. When a fourth substituent is bonded to the nitrogen, the species is positively charged and called a *quaternary ammonium ion*:



Primary amine | Secondary amine | Tertiary amine | Quaternary ammonium ion

Amides contain the functional group

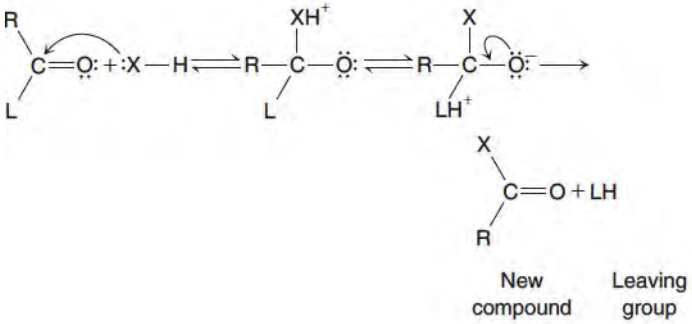


where X can be H (simple) or R (*N* substituted). The carbonyl group is from an acid, and the *N* is from an amine. If both functional groups are from amino acids, the amide bond is referred to as a **peptide bond**.

TYPES OF REACTIONS

Nucleophilic Substitutions at an Acyl Carbon

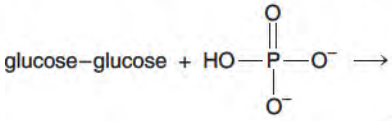
If the acyl carbon is on a carboxylic group, the leaving group is water. Nucleophilic substitution on carboxylic acids usually requires a catalyst or conversion to a more reactive intermediate; biologically this occurs via enzyme catalysis. X—H may be an alcohol (R—OH), ammonia, amine (R—NH_2), or another acyl compound. Types of nucleophilic substitutions include *esterification, peptide bond* formation, and *acid anhydride* formation.



Hydrolysis and Phosphorolysis Reactions

Hydrolysis is the cleavage of a bond by water:

Hydrolysis is often catalyzed by either acid or base. *Phosphorolysis* is the cleavage of a bond by inorganic phosphate:



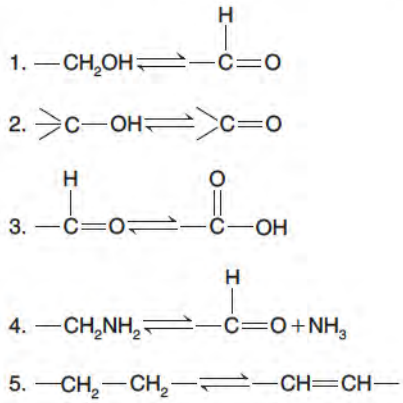
glucose 1-phosphate + glucose

Oxidation–Reduction Reactions

Oxidation is the loss of electrons; **reduction** is the gain of electrons. Examples of oxidation are as follows:

1. Fe^{2+} + acceptor → Fe^{3+} + acceptor · e^-
2. S(ubstrate) + O_2 + DH_2 → S—OH + H_2O + D
3. S—H_2 + acceptor → S + acceptor · H_2

Some of the group changes that occur on oxidation-reduction are:

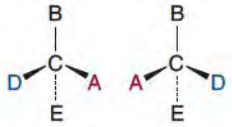


STEREOCHEMISTRY

Stereoisomers are compounds with the same molecular formulas and order of attachment of constituent atoms but with different arrangements of these atoms in space.

Enantiomers are stereoisomers in which one isomer is the mirror image of the other and requires the presence of a chiral atom.

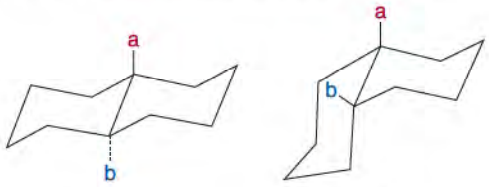
A chiral carbon (also called an asymmetric carbon) is one that is attached to four different groups:



Enantiomers will be distinguished from each other by the designations *R* and *S* or D and L. The maximum number of stereoisomers possible is 2^n, where n is the number of chiral carbon atoms. A molecule with more than one chiral center will be an achiral molecule if it has a point or plane of symmetry.

Diastereomers are stereoisomers that are not mirror images of each other and need not contain chiral atoms. **Epimers** are diastereomers that contain more than one chiral carbon and differ in configuration about *only one* asymmetric carbon.

Anomers are a special form of carbohydrate epimers in which the difference is specifically about the anomeric carbon (see p. 1126. Diastereomers can also occur with molecules in which there is restricted rotation about carbon—carbon bonds. Double bonds exhibit ***cis–trans* isomerism**. The double bond is in the *cis* configuration if the two end groups of the longest contiguous chain containing the double bond are on the same side and is *trans* if the two ends of the longest chain are on opposite sides. Fused ring systems, such as those found in steroids (see p. 1131), also exhibit *cis–trans* isomerism.



trans Rings *cis* Rings

TYPES OF FORCES INVOLVED IN MACROMOLECULAR STRUCTURES

A **hydrogen** bond is a dipole–dipole attraction between a hydrogen atom attached to an electronegative atom and a non-bonding electron pair on another electronegative atom:

$$:\ddot{X}—H\cdots\cdots:\ddot{X}—H$$
$$\delta^- \ \delta^+ \qquad \delta^- \ \delta^+$$

Hydrogen bonds of importance in macromolecular structures occur between two nitrogen atoms, two oxygen atoms, or an oxygen and a nitrogen atom.

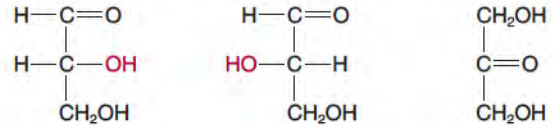
A **hydrophobic interaction** is the association of nonpolar groups in a polar medium. *Vander Waals* forces consist of dipole and induced dipole interactions between two nonpolar groups. A nonpolar residue dissolved in water induces a highly ordered, thermodynamically unfavorable, solvation shell. Interaction of nonpolar residues with each other, with the exclusion of water, increases the entropy of the system and is thermodynamically favorable.

Ionic (electrostatic) interactions between charged groups can be attractive if the charges are of opposite signs or repulsive if they are of the same sign. The strength of an electrostatic interaction in the interior of a protein molecule may be high. Most charged groups on the surface of a protein molecule interact with water rather than with each other. A **disulfide bond** (S—S) is a covalent bond formed by the oxidation of two sulfhydryl (SH) groups.

CARBOHYDRATES

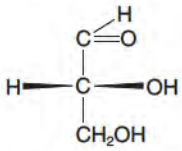
Carbohydrates are polyhydroxy aldehydes or ketones or their derivatives. **Monosaccharides** (simple sugars) are those carbohydrates that cannot be hydrolyzed into simpler compounds. The generic name of a monosaccharide includes the type of function, a Greek prefix indicating the number of carbon atoms, and the ending -ose; for example, *aldohexose* is a six-carbon aldehyde and *ketopentose* a five-carbon ketone. Monosaccharides may react with each other to form larger molecules. With fewer than eight monosaccharides, either a Greek prefix indicating the number or the general term **oligosaccharide** may be used. **Polysaccharide** refers to a polymer with more than eight monosaccharides. Oligo- and polysaccharides may be either homologous or mixed.

Most *monosaccharides* are asymmetric, an important consideration since enzymes usually work on only one isomeric form. The simplest carbohydrates are glyceraldehyde and dihydroxyacetone whose structures, shown as Fischer projections, are as follows:



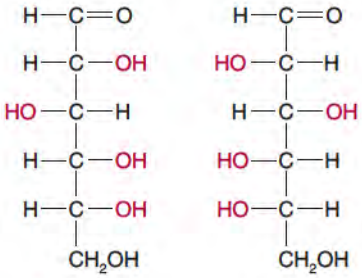
D-Glyceraldehyde L-Glyceraldehyde Dihydroxyacetone

D-Glyceraldehyde may also be written as follows:



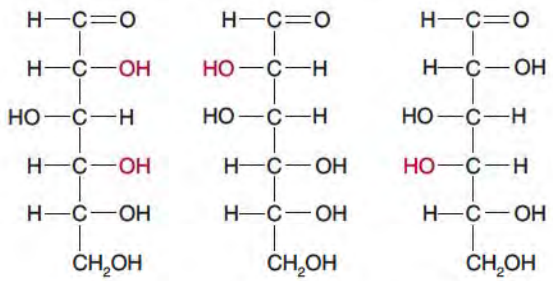
In the Cahn–Ingold–Prelog system, the designations are (*R*) (*rectus*; right) and (*S*) (*sinister*; left).

The configuration of monosaccharides is determined by the stereochemistry at the asymmetric carbon furthest from the carbonyl carbon (number 1 for an aldehyde; lowest possible number for a ketone). Based on the *position* of the OH on the highest number asymmetric carbon, a monosaccharide is D if the OH projects to the *right* and L if it projects to the *left*. The D and L monosaccharides with the same name are **enantiomers**, and the substituents on all asymmetric carbon atoms are reversed as in

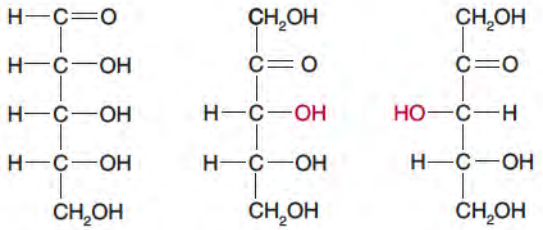


D-Glucose L-Glucose

Epimers (e.g., glucose and mannose) are stereoisomers that differ in the configuration about *only one* asymmetric carbon. The relationship of OH groups to *each other* determines the specific monosaccharide. Three aldohexoses and three pentoses of importance are

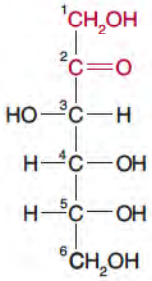


D-Glucose D-Mannose D-Galactose

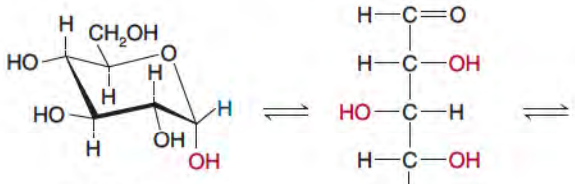


D-Ribose D-Ribulose D-Xylulose

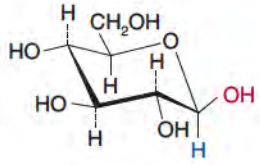
Fructose, a ketohexose, differs from glucose only on carbon atoms 1 and 2:



C_5 (pentose) and C_6 (hexose) monosaccharides form **cyclic hemiacetals** or **hemiketals** in solution. A new asymmetric carbon is generated so two isomeric forms are possible:

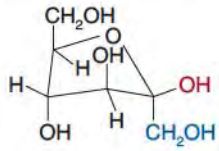


α-D-Glucose D-Glucose



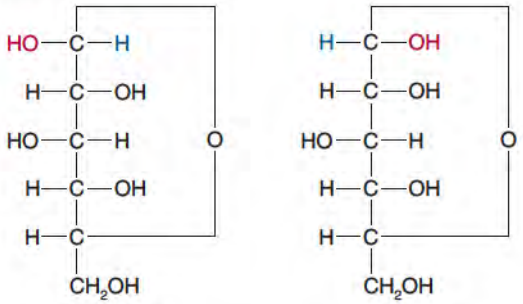
β-D-Glucose

Both five-membered (furanose) and six-membered (pyranose) ring structures are possible, although pyranose rings are more common. A furanose ring is written as follows:



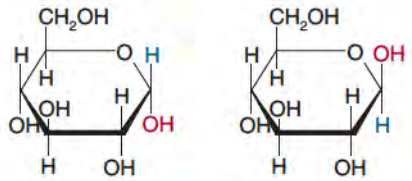
β-D-Fructose

The isomer is designated ***α*** if the OH group and the CH_2OH group on the two carbon atoms linked by the oxygen are *trans* to each other and ***β*** if they are *cis*. The hemiacetal or hemiketal forms may also be written as modified *Fischer projection formulas*: ***α*** if OH on the acetal or ketal carbon projects to the same side as the ring and ***β*** if on the opposite side:

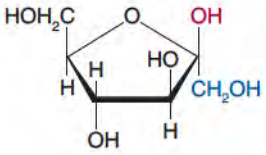


β-D-Glucose α-D-Glucose

Haworth formulas are used most commonly:



α-D-Glucose β-D-Glucose



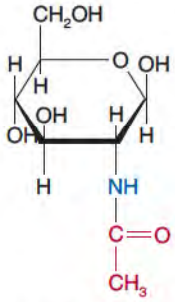
β-D-Fructose

The ring is perpendicular to the plane of the paper with the oxygen written to the back (upper) right, C1 to the right, and substituents above or below the plane of the ring. The OH at the acetal or ketal carbon is below in the ***α*** isomer and above in the ***β***. Anything written to the right in the Fischer projection is written down in the Haworth formula.

The ***α*** and ***β*** forms of the same monosaccharide are special forms of epimers called *anomers*, differing only in the configuration about the anomeric (acetal or ketal) carbon. Monosaccharides exist in solution primarily as a mixture of the hemiacetals (or hemiketals) but react chemically as aldehydes or ketones. **Mutarotation** is the equilibration of ***α*** and ***β*** forms through the free aldehyde or ketone. Substitution of the H of the anomeric OH prevents mutarotation and fixes the configuration in either the ***α*** or ***β*** form.

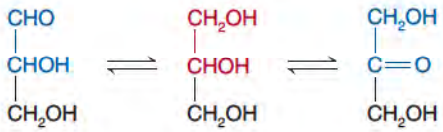
Monosaccharide Derivatives

A **deoxymonosaccharide** is one in which an OH has been replaced by H. In biological systems, this occurs at C2 unless otherwise indicated. An **amino monosaccharide** is one in which an OH has been replaced by NH_2, again at C2 unless otherwise specified. The amino group of an amino sugar may be *acetylated*:

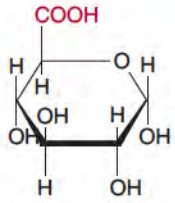


β-*N*-Acetylglucosamine

An aldehyde is reduced to a primary and a ketone to a secondary **monosaccharide alcohol (alditol)**. Alcohols are named with the base name of the sugar plus the ending *-itol* or with a trivial name (glucitol = sorbitol). Monosaccharides that differ around only two of the first three carbon atoms yield the same alditol. D-Glyceraldehyde and dihydroxyacetone give glycerol:

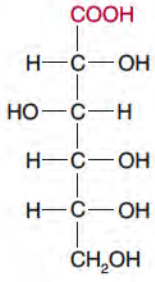


D-Glucose and D-fructose give D-sorbitol; D-fructose and D-mannose give D-mannitol. Oxidation of the terminal CH_2OH, but not of the CHO, yields a **-uronic acid**, a *monosaccharide acid*:

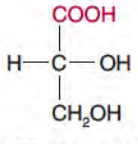


D-Glucuronic acid

Oxidation of the CHO, but not the CH_2OH, gives an **-onic acid**:

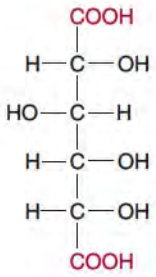


D-Gluconic acid



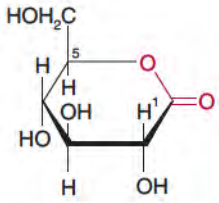
D-Glyceric acid

Oxidation of both the CHO and CH_2OH gives an **-aric acid**:

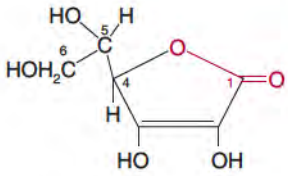


D-Glucaric acid

Ketones do not form acids. Both -onic and -uronic acids can react with an OH in the same molecule to form a **lactone** (see p. 1124):



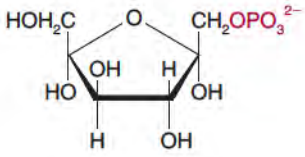
D-Glucono-5-lactone



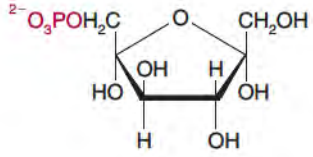
L-Ascorbic acid
(derivative of L-gulose)

Reactions of Monosaccharides

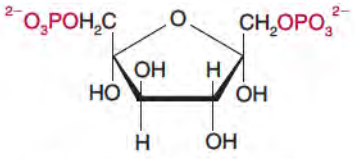
The most common *esters* of monosaccharides are phosphate esters at carbon atoms 1 and/or 6:



Fructose 1-Phosphate

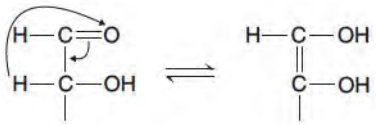


Fructose 6-Phosphate



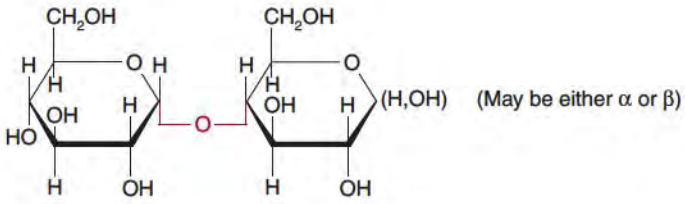
Fructose 1, 6 Bisphosphate

To be a **reducing sugar**, mutarotation must be possible. In alkali, enediols form that may migrate to 2,3 and 3,4 positions:



Enediols may be oxidized by O_2, Cu^{2+}, Ag^+, and Hg^{2+}. Reducing ability is more important in the laboratory than physiologically. A hemiacetal or hemiketal may react with the OH of another

monosaccharide to form a disaccharide (*acetal: glycoside*) (see below):

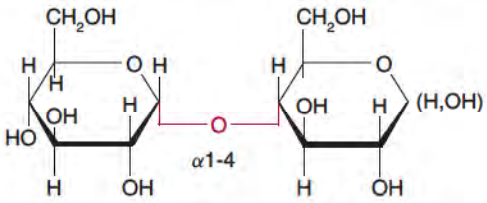


α-1,4-Glycosidic linkage

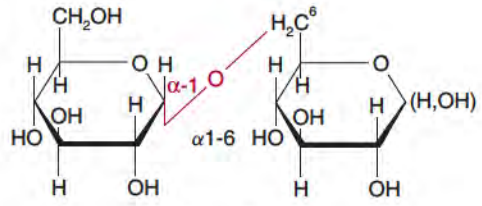
One monosaccharide still has a free anomeric carbon and can react further. Reaction of the anomeric OH may be with any OH on the other monosaccharide, including the anomeric one. The anomeric OH that has reacted is fixed as either ***α*** or ***β*** and cannot mutarotate or reduce. If the glycosidic bond is not between two anomeric carbon atoms, one of the units will still be free to mutarotate and reduce.

Oligo- and Polysaccharides

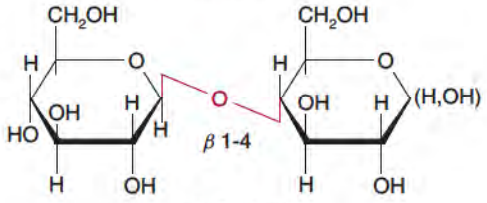
Disaccharides have two monosaccharides, either the same or different, in glycosidic linkage. If the glycosidic linkage is between the two anomeric carbon atoms, the disaccharide is nonreducing:



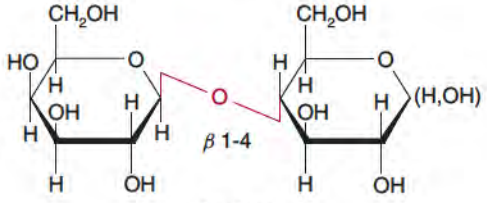
Maltose



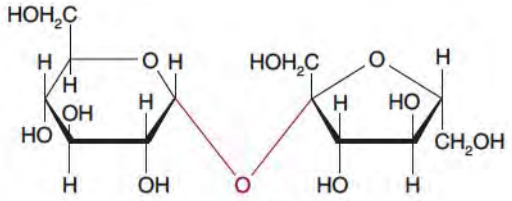
Isomaltose



Cellobiose



Lactose



α1, β2
Sucrose

Maltose = 4-*O*-(***α***-D-glucopyranosyl)D-glucopyranose; reducing

Isomaltose = 6-*O*-(***α***-D-glucopyranosyl)D-glucopyranose; reducing

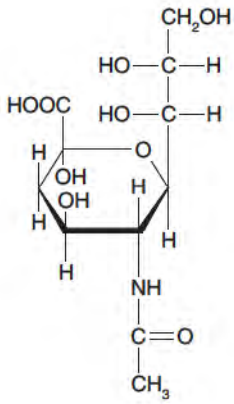
Cellobiose = 4-*O*-(***β***-D-glucopyranosyl)D-glucopyranose; reducing

Lactose = 4-*O*-(***β***-D-galactopyranosyl)D-glucopyranose; reducing

Sucrose = ***α***-D-glucopyranosyl-***β***-D-fructofuranoside; nonreducing

As many as thousands of monosaccharides, either the same or different, may be joined by glycosidic bonds to form *polysaccharides.* The anomeric carbon of one unit is usually joined to C4 or C6 of the next unit. The ends of a polysaccharide are not identical (reducing end = free anomeric carbon; nonreducing = anomeric carbon linked to next unit; branched polysaccharide = more than one nonreducing end). The most common carbohydrates are homopolymers of glucose; for example, starch, glycogen, and cellulose. Plant starch is a mixture of **amylose**, a linear polymer of maltose units, and **amylopectin**, branches of repeating maltose units (glucose–glucose in ***α***-1,4 linkages) joined via isomaltose linkages. **Glycogen**, the storage form of carbohydrate in animals, is similar to amylopectin, but the branches are shorter and occur more frequently. **Cellulose**, in plant cell walls, is a linear polymer of repeating cellobioses (glucose–glucose in ***β***-1,4 linkages). Heteropolysaccharides contain more than one kind of monosaccharide.

Mucopolysaccharides contain amino sugars, free and acetylated, uronic acids, sulfate esters, and sialic acids in addition to the simple monosaccharides. ***N*-Acetylneuraminic acid**, a sialic acid, is



LIPIDS

Lipids are a diverse group of chemicals related primarily because they are insoluble in water, soluble in nonpolar solvents, and found in animal and plant tissues.

Saponifiable lipids yield salts of fatty acids upon alkaline hydrolysis. *Acylglycerols* = glycerol + fatty acid(s); *phosphoacylglycerols* = glycerol + fatty acids + HPO_4^{2-} + alcohol; *sphingolipids* = sphingosine + fatty acid + polar group (phosphorylalcohol or carbohydrate); *waxes* = long-chain alcohol + fatty acid. *Nonsaponifiable lipids* (*terpenes, steroids, prostaglandins*, and related compounds) are not usually subject to hydrolysis. *Amphipathic* lipids have both a polar "head" group and a nonpolar "tail." Amphipathic molecules can stabilize emulsions and are responsible for the lipid bilayer structure of membranes.

Fatty acids are monocarboxylic acids with a short (<6 carbon atoms), medium (8–14 carbon atoms), or long (>14 carbon atoms) aliphatic chain. Biologically important ones are usually linear molecules with an even number of carbon atoms (16–20). Fatty acids are numbered using either arabic numbers (COOH is 1) or the Greek alphabet (COOH is not given a symbol; adjacent carbon atoms are α, β, γ, etc.). **Saturated fatty acids** have the general formula $CH_3(CH_2)_nCOOH$. (*Palmitic acid* = C_{16}; *stearic acid* = C_{18}.) They tend to be extended chains and solid at room temperature unless the chain is short. Both trivial and systematic (prefix indicating number of carbon atoms + *anoic acid*) names are used. $CH_3(CH_2)_{14}COOH$ = palmitic acid or hexadecanoic acid.

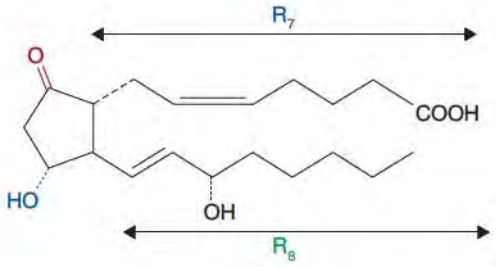
Unsaturated fatty acids have one or more double bonds. Most naturally occurring fatty acids have *cis* double bonds and are usually liquid at room temperature. Fatty acids with *trans* double bonds tend to have higher melting points. A double bond is indicated by Δ^n, where n is the number of the first carbon of the bond. *Palmitoleic* = Δ^9-hexadecenoic acid; *oleic* = Δ^9 -octadecenoic acid; *linoleic* = $\Delta^{9,12}$-octadecadienoic acid; *linolenic* = $\Delta^{9,12,15}$-octadecatrienoic acid; and *arachidonic* = $\Delta^{5,8,11,14}$-eicosatetraenoic acid. Since fatty acids are elongated *in vivo* from the carboxyl end, biochemists use alternate terminology to assign these fatty acids to families: omega (ω) minus x (or $n - x$), where x is the number of carbon atoms from the methyl end where a double bond is first encountered. *Palmitoleic* and *oleic* are $\omega - 9$ acids, *linoleic* and *arachidonic* are $\omega - 6$ acids, and *linolenic* is an $\omega - 3$ acid. Addition of carbon atoms does not change the family to which an unsaturated fatty acid belongs.

Since the pK values of fatty acids are about 4–5, in physiological solutions, they exist primarily in the ionized form, called salts or "soaps." Long-chain fatty acids are insoluble in water, but soaps form micelles. Fatty acids form esters with alcohols and thioesters with CoA.

Biochemically significant reactions of unsaturated fatty acids are:

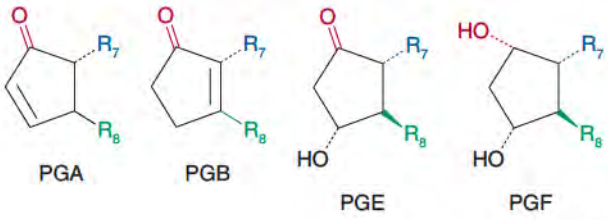
1. *Reduction* —CH=CH— + XH_2 → —CH_2CH_2— + X
2. *Addition of water* —CH=CH— + H_2O→ —CH(OH)—CH_2—
3. *Oxidation* R—CH=CH—R' → R—CHO + R'—CHO

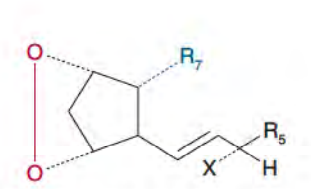
Prostaglandins, thromboxanes, and *leukotrienes* are derivatives of C_{20} polyunsaturated fatty acids, especially arachidonic acid. **Prostaglandins** have the general structure:

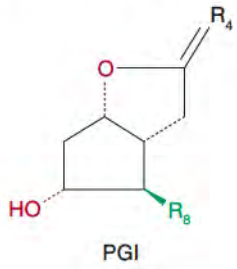


PGE_2

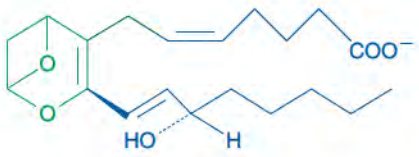
The series differ from each other in the substituents on the ring and whether C15 contains an OH or O · OH group. The subscript indicates the number of double bonds in the side chains. Substituents indicated by — (β) are above the plane of the ring; . . . (α) below:





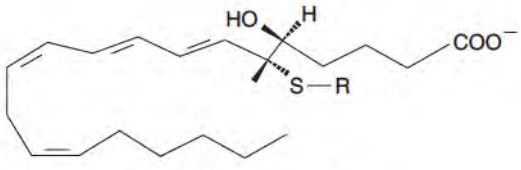


Thromboxanes have an oxygen incorporated to form a six-membered ring:



TXA_2

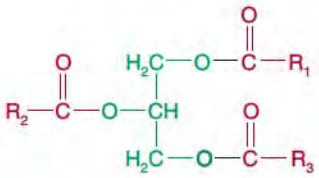
Leukotrienes are substituted derivatives of arachidonic acid in which no internal ring has formed; R is variable:



Leukotriene C, D, or E

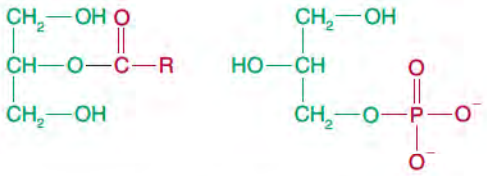
Acylglycerols are compounds in which one or more of the three OH groups of glycerol is esterified. In **triacylglycerols** (triglycerides) all three OH groups are esterified to fatty acids. At least two of the three

substituent groups are usually different. If R_1 is not equal to R_3, the molecule is asymmetric and of the L configuration:



The properties of the triacylglycerols are determined by those of the fatty acids they contain; *oils* are liquids at room temperature (preponderance of short-chain and/or *cis*-unsaturated fatty acids), and *fats*, solid (preponderance of long-chain, saturated, and/or *trans*-unsaturated).

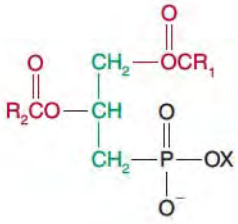
Triacylglycerols are hydrophobic and do not form stable micelles. They may be hydrolyzed to glycerol and three fatty acids by strong alkali or enzymes (lipases). *Mono-* [usually with the fatty acid in the **β**(2) position] and *diacylglycerols* also exist in small amounts as metabolic intermediates. Mono- and diacylglycerols are slightly more polar than triacylglycerols. *Phosphoacylglycerols* are derivatives of L-**α**-glycerolphosphate (L-glycerol 3-phosphate):



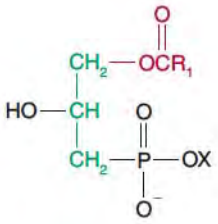
The parent compound, **phosphatidic acid** (two OH groups of L-**α**-glycerolphosphate esterified to fatty acids), has its phosphate esterified to an alcohol (XOH) to form several series of phosphoacylglycerols. These are amphipathic molecules, but the net charge at pH 7.4 depends on the nature of X—OH.

X—OH	*Phosphoacylglycerol*
	Phosphatidylcholines (lecithins)
	Phosphatidylethanolamines (cephalins)
	Phosphatidylserines
	Phosphatidylinositols phospate on 4, or 4 and 5

In **plasmalogens**, the OH on C1 is in *ether*, rather than ester, linkage to an alkyl group. If *one* fatty acid (usually **β**) has been hydrolyzed from a phosphoacylglycerol, the compound is a *lyso*-compound; for example, lysophosphatidylcholine (lysolecithin):

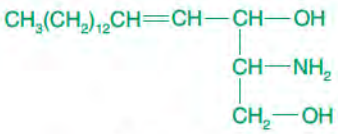


A phosphoacylglycerol

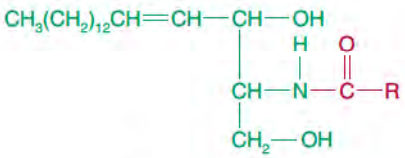


A lyso-compound

Sphingolipids are complex lipids based on the C_{18}, unsaturated alcohol, sphingosine. In *ceramides*, a long-chain fatty acid is in amide linkage to sphingosine:

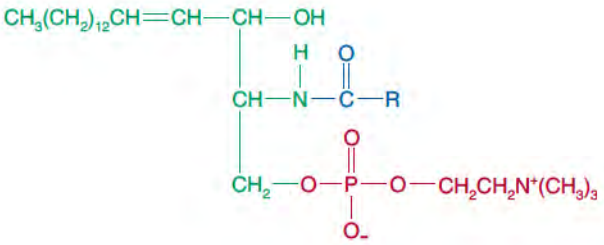


Sphingosine

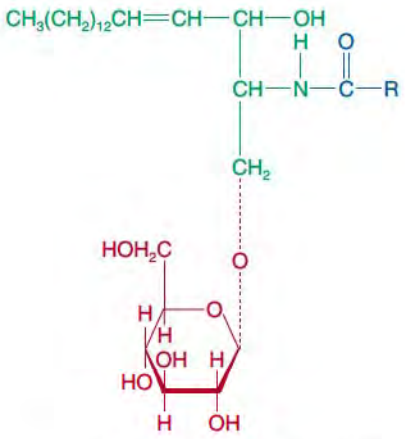


A ceramide

Sphingomyelins, the most common sphingolipids, are a family of compounds in which the primary OH group of a ceramide is esterified to phosphorylcholine (phosphoryl-ethanolamine):



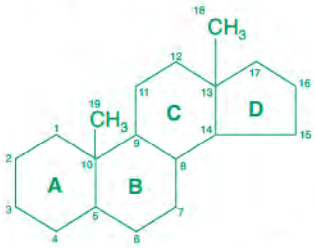
They are amphipathic molecules, existing as zwitterions at pH 7.4 and the only sphingolipids that contain phosphorus. *Glycosphingolipids* do not contain phosphorus but contain carbohydrate in glycosidic linkage to the primary alcohol of a ceramide. They are amphipathic and either neutral or acidic if the carbohydrate moiety contains an acidic group. **Cerebrosides** have a single glucose or galactose linked to a ceramide. *Sulfatides* are galactosylceramides esterified with sulfate at C3 of the galactose:

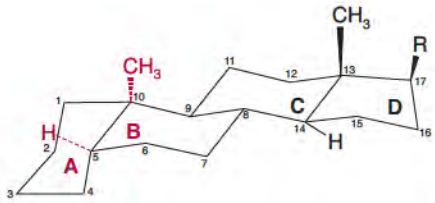


Glucosylceramide (glucocerebroside)

Globosides (*ceramide oligosaccharides*) are ceramides with two or more neutral monosaccharides, whereas in **gangliosides** the oligosaccharide contains one or more sialic acids.

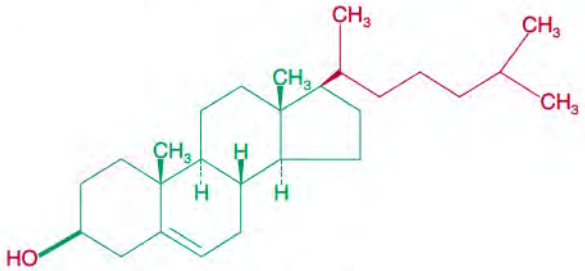
Steriods are derivatives of cyclopentanoperhydrophenanthrene. The steroid nucleus is a rather rigid, essentially planar structure with substituents above the plane of the rings designated ***β*** (solid line) and those below called ***α*** (dotted line):



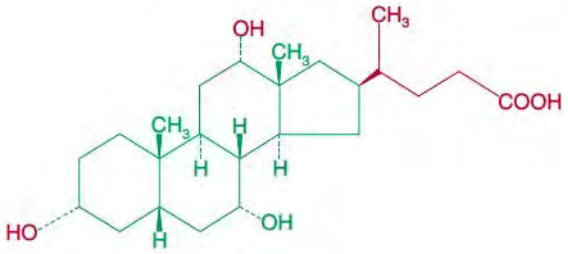


A and B rings—*cis*;
the others—*trans*

Most steroids in humans have methyl groups at positions 10 and 13 and frequently a side chain at position 17. *Sterols* contain one or more OH groups, free or esterified to a fatty acid. Most steroids are nonpolar. In a liposome or cell membrane, **cholesterol** orients with the OH toward any polar groups; cholesterol esters do not. **Bile acids** (e.g., cholic acid) have a polar side chain and so are amphipathic:

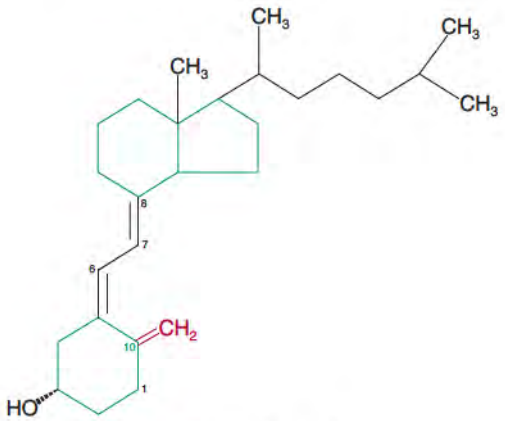


Cholesterol



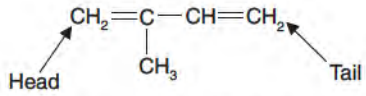
Cholic acid

Steroid hormones are oxygenated steroids of C_{18}, C_{19}, or C_{21} *Estrogens* have C_{18}, an aromatic ring A, and no methyl at C10. *Androgens* have C_{19} and no side chain at C17. *Glucocorticoids* and *mineralocorticoids* have C_{21} including a C_2, oxygenated side chain at C17. *Vitamin* D_3 (*cholecalciferol*) is not a sterol but is derived from 7-dehydrocholesterol in humans:

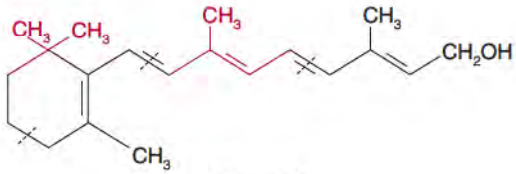


Cholecalciferol

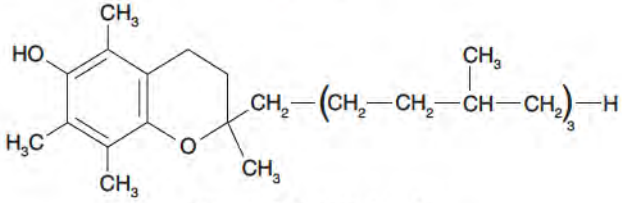
Terpenes are polymers of two or more isoprene units. **Isoprene** is



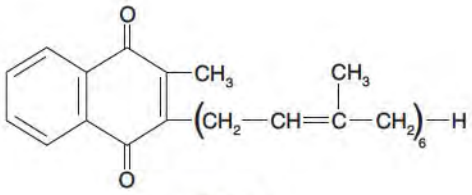
Terpenes may be linear or cyclic, with the isoprenes usually linked head to tail and most double bonds *trans* (but may be *cis* as in vitamin A). *Squalene*, the precursor of cholesterol, is a linear terpene of six isoprene units. Fat-soluble *vitamins* (A, D, E, and K) contain isoprene units:



Vitamin A



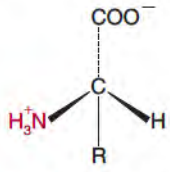
Vitamin E (α-tocopherol)



Vitamin K_2

AMINO ACIDS

Amino acids contain an *amino* (NH_2) and a *carboxylic acid* (COOH) group. Biologically important amino acids are usually **α**-amino acids with the formula



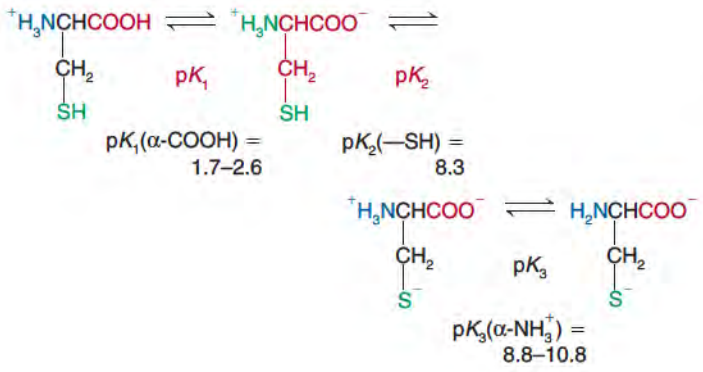
L-α-Amino acid

The amino group, has an unshared pair of electrons, is basic, with a pK_a of about 9.5, and exists primarily as $—NH_3^+$ at pH values near neutrality. The carboxylic acid group ($pK \sim 2.3$) exists primarily as a carboxylate ion. If R is anything but H, the molecule is asymmetric with most naturally occurring ones of the L configuration (same relative configuration as L-glyceraldehyde: see p. 1125).

The *polarity* of amino acids is influenced by their side chains (R groups) (see p. 78 for complete structures). *Nonpolar* amino acids include those with large, aliphatic, aromatic, or undissociated sulfur groups (aliphatic = Ala, Ile, Leu, Val; aromatic = Phe, Trp; sulfur = Cys, Met). *Intermediate* polarity amino acids include Gly, Pro, Ser, Thr, and Tyr (undissociated).

Amino acids with ionizable side chains are *polar*. The pK values of the side groups of arginine, lysine, glutamate, and aspartate are such that these are nearly always charged at physiological pH, whereas the side groups of histidine ($pK = 6.0$) and cysteine ($pK = 8.3$) exist as both charged and uncharged species at pH 7.4 (acidic = Glu, Asp, Cys; basic = Lys, Arg, His). Although undissociated cysteine is nonpolar, cysteine in dissociated form is polar. Asparagine and glutamine are polar even though their side chains are not charged (ionized).

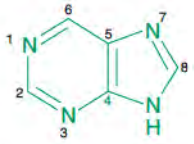
All amino acids are at least *dibasic acids* because of the presence of both the **α**-amino and **α**-carboxyl groups, the ionic state being a function of pH. The presence of another ionizable group will give a tribasic acid as shown for cysteine.



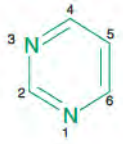
The **zwitterionic form** is the form in which the *net* charge is zero. The *isoelectric point* is the average of the two pK values involved in the formation of the zwitterionic form. In the above example this would be the average of $pK_1 + pK_2$.

PURINES AND PYRIMIDINES

Purines and pyrimidines, often called *bases*, are nitrogen-containing heterocyclic compounds with the structures



Purine

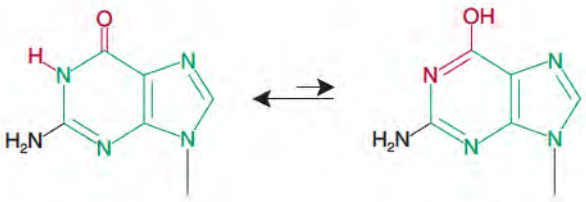


Pyrimidine

Major bases found in nucleic acids and as cellular nucleotides are the following:

Purines	*Pyrimidines*
Adenine: 6-amino	Cytosine: 2-oxy, 4-amino
Guanine: 2-amino, 6-oxy	Uracil: 2,4-dioxy Thymine: 2,4-dioxy, 5-methyl
Other important bases found primarily as intermediates of synthesis and/or degradation are	
Hypoxanthine: 6-oxy	Orotic acid: 2,4-dioxy, 6-carboxy
Xanthine: 2,6-dioxy	

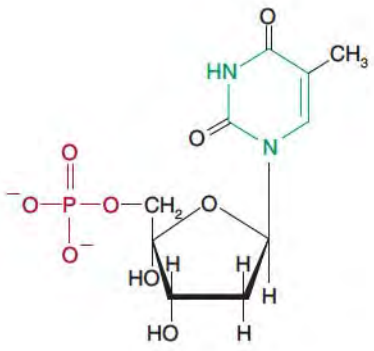
Oxygenated purines and pyrimidines exist as *tautomeric* structures with the keto form predominating and involved in hydrogen bonding between bases in nucleic acids:



Keto *Enol*

Nucleosides have either **β**-D-ribose or **β**-D-2-deoxyribose in an *N*-glycosidic linkage between C1 of the sugar and N9 (purine) or N1 (pyrimidine).

Nucleotides have one or more phosphate groups esterified to the sugar. Phosphates, if more than one is present, are usually attached to each other via phosphoanhydride bonds. Monophosphates may be designated as either the base monophosphate or as an *-ylic acid* (AMP: adenylic acid):



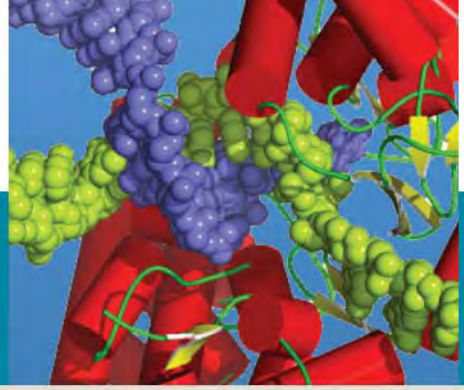
By conventional rules of *nomenclature*, the atoms of the base are numbered 1–9 in purines or 1–6 in pyrimidines and the carbon atoms of the sugar 1′–5′. A nucleoside with an unmodified name indicates that the sugar is ribose and the phosphate(s) is/are attached at C-5′ of the sugar. Deoxy forms are indicated by the prefix d (dAMP = deoxyadenylic acid). If the phosphate is esterified at any position other than 5′, it must be so designated [3′-AMP; 3′-5′-AMP (cyclic AMP = cAMP)]. The nucleosides and nucleotides (ribose form) are named as follows:

Base	*Nucleoside*	*Nucleotide*
Adenine	Adenosine	AMP, ADP, ATP
Guanine	Guanosine	GMP, GDP, GTP
Hypoxanthine	Inosine	IMP
Xanthine	Xanthosine	XMP
Cytosine	Cytidine	CMP, CDP, CTP
Uracil	Uridine	UMP, UDP, UTP
Thymine	dThymidine	dTMP, dTTP
Orotic acid	Orotidine	OMP

Minor (modified) bases and nucleosides also exist in nucleic acids. *Methylated* bases have a methyl group on an amino group (*N*-methyl guanine), a ring atom (1-methyl adenine), or on an OH group of the sugar (2′-*O*-methyl adenosine). *Dihydrouracil* has the 5–6 double bond saturated. In *pseudouridine*, the ribose is attached to C5 rather than to N1.

In **polynucleotides** (*nucleic acids*), the mononucleotides are joined by phosphodiester bonds between the 3′-OH of one sugar (ribose or deoxyribose) and the 5′-OH of the next (see p. 30 for the structure).

This page intentionally left blank



Glossary

Francis Vella

30-nm fiber: Fiber (30-nm diameter) of chromatin which has a solenoid structure consisting of six nucleosomes and their linker DNA and associated histone H1 per turn, stacked on top of each other.

5′ cap: 7-Methylguanosine linked to the 5′-terminal nucleotide of an mRNA via a 5′-5′-triphosphate bridge. It is formed during processing of pre-mRNA in the nucleus, inhibits degradation and enhances translation of the mRNA.

A site: Binding site on both ribosomal subunits that holds the tRNA that carries the amino acid to be added to the growing peptide chain during polypeptide synthesis. Also called aminoacyl site.

ABC transporter protein: Integral plasma membrane protein that consists of two domains (each of six transmembrane segments) and two loops (each containing an ATP-binding site) that uses the energy of ATP to transport a variety of hydrophobic natural products and synthetic drugs out of the cytoplasm. Also called ATP-binding cassette protein.

absorption spectrum: Pattern of absorption of incident light observed with a spectroscope or spectrometer.

absorption: Passage across intestinal cell membranes of the products of digestion.

abzyme: Catalytic antibody, natural or one that is raised against an antigen that has a transition state structure for a reaction. Also called catalytic antibody.

acceptor stem: In tRNA, the part in which the 5′- and 3′-ends are base paired. The 3′-end terminates in an unpaired CCA sequence with the A being the site of attachment of a cognate aminoacyl residue.

acid anhydride: See anhydride.

acid-base catalysis: Catalysis of a reaction that is aided by transfer of a proton from an acid or abstraction of a proton by a base.

acidosis: Abnormal physiological state in which an increase in proton concentration lowers the pH of plasma below 7.35.

acrosome: Organelle at the tip of a spermatozoon that is rich in enzymes for digestion of the protective coat of an oocyte at fertilization.

actin: Globular protein that forms the microfilaments of cytoskeleton and the thin filaments of skeletal and cardiac muscle. Its interaction with the heads of thick filaments produces muscle contraction.

activation energy: Energy required for a specific chemical reaction to occur.

active site: Region usually in a cleft on an enzyme surface that binds the appropriate substrate and catalyzes its conversion to product.

active transport: Passage of solutes across a cell membrane that is effected with energy expenditure from ATP.

activin: Glycoprotein hormone secreted by the gonads, that stimulates secretion of follicle-stimulating hormone. It consists of two B_A or B_B chains in inhibins A and B respectively, or of a B_A and a B_B chain, joined by a disulfide bond.

acyl carrier protein (ACP): In prokaryotes, the protein with an attached phosphopantetheine moiety that is the central component of fatty acid synthase complex. In eukaryotes, it is present as a domain of the multicatalytic fatty acid synthase protein.

adaptin: Major multimeric protein of clathrin-coated vesicles that binds on the cytoplasmic portion of various integral membrane proteins to mediate formation of the clathrin coat. Also called adaptor protein.

adenylate cyclase system: Pathway of signal transduction in which a hormone binding to its cognate serpentine receptor activates a trimeric G protein to stimulate or inhibit adenylate cyclase, thereby affecting production of cyclic AMP as a second messenger.

adenylate cyclase: Enzyme that is an integral protein of the plasma membrane. Its active site on the inner membrane surface converts ATP to cyclic AMP. Also called adenylyl cyclase.

adenylyl cyclase: See adenylate cyclase.

adherens junction: Part of a plasma membrane that contains cadherins, is involved in cell–cell adhesion and is linked on the inner surface to actin microfilaments via catenins and other proteins.

adipose tissue: Loose connective tissue dominated by adipocytes whose major component is neutral fat (i.e., triacylglycerol). Two varieties are recognized, white and brown.

A-DNA: Double-helical DNA that has 11 base pairs per right-handed turn, a diameter of ~26 Å, and forms in pure dehydrated DNA. It is also the common form of double-stranded RNA and of RNA–DNA heteroduplexes.

adrenal gland: One of two small endocrine glands each situated above a kidney. It consists of an outer cortex that secretes steroid hormones, and a central medulla that secretes catecholamines, particularly adrenaline. Also called suprarenal gland.

adrenaline: *N*-methyl noradrenaline, the major hormone derived from tyrosine in the adrenal medulla and some neurons. It is secreted in response to stress and increases glycogenolysis (in muscle and liver), gluconeogenesis (in liver), glycolysis (in muscle), and lipolysis (in adipocytes). Also called epinephrine.

adrenocortical hormone: Any glucocorticoid, mineralocorticoid or sex hormone secreted by the adrenal cortex.

adrenocorticotropic hormone (ACTH): Polypeptide hormone secreted by the anterior pituitary in response to corticotrophin-releasing hormone of the hypothalamus. It stimulates production and secretion of glucocorticoids by the zona fasciculata. Also called corticotropin, cortin.

aerobic metabolism: Complete breakdown of glucose and fatty acids in muscle in the presence of adequate amounts of oxygen into carbon dioxide and water via acetyl CoA. The oxygen-requiring part releases large amounts of energy as ATP and occurs within mitochondria.

aerobic: Occurring only in the presence of oxygen.

agglutination: Aggregation of erythrocytes produced by interaction between antigens on their surface and specific antibodies in plasma.

agglutinin: Antibody in plasma that reacts with antigens on the surface of erythrocytes when donor and recipient differ in their blood group.

agglutinogen: Antigen on the surface of erythrocytes whose presence and structure are genetically determined.

aggrecan: Proteoglycan rich in chondroitin sulfate and keratan sulfate attached to a large protein that is present in cartilage.

agonist: Hormone, neurotransmitter drug, or other compound that binds to a specific receptor and elicits a functional response.

alanine cycle: See glucose-alanine cycle.

aldimine: Compound formed by condensation of a primary amine with an aldehyde. Also called Schiff base.

aldosterone: Mineralocorticoid produced by zona glomerulosa and secreted in response to angiotensin II. It enhances reabsorption of Na^+ and water by renal tubules. Excessive secretion produces aldosteronism.

alkalosis: Abnormal physiological state in which a deficiency of protons or an excess of bicarbonate ions raises the pH of plasma above 7.45.

alkaptonuria: Autosomal recessive condition in which homogentisate, produced during catabolism of phenylalanine and tyrosine, accumulates because of a deficiency of homogentisate oxidase activity.

allosteric effector: See allosteric modulator.

allosteric site: Site on a regulatory enzyme that is remote from the active site and, when bound to an appropriate effector or modulator, increases or decreases the affinity of the enzyme for its substrate.

α + β-protein: Protein in which α-helical and β-strand regions are present in a nonrandom fashion.

α/β-barrel: Protein structure in which alternating α helices and β strands form a barrel of parallel β-strands, surrounded by a barrel of α-helices.

α/β protein: Protein in which α-helical and β-strands are interspersed or alternate with each other.

A-helix: Common form of secondary structure of polypeptides; spiral conformation that results from maximal hydrogen bonding between components of peptide bonds of adjacent turns of the spiral, each turn being 3.6 residues long.

all-α protein: Protein that consists solely or mostly of α-helical segments.

all-β protein: Protein that consists solely or mostly of β-strands.

allostery: Property of an enzyme or other protein whereby noncovalent binding of a ligand at one site induces a conformational change that affects binding of a ligand at another site.

alternative RNA splicing: Deletion of certain exons or incorporation of alternative exons during splicing of pre-mRNA, thus forming more than one mRNA and generating more than one protein from a primary transcript. Also called differential RNA splicing.

amino terminus: See N-terminus.

aminoacyl site: Site on a ribosome that binds aminoacyl-tRNA during polypeptide synthesis. Also called A site.

aminoacyl-tRNA: tRNA carrying an amino acid to be added to the growing peptide chain during polypeptide synthesis.

aminotransferase: Enzyme that catalyzes transfer of an amino group from an α-amino to an α-keto acid, yielding a new α-keto acid and a new α-amino acid and using pyridoxal phosphate as coenzyme. Also called transaminase.

amphipathic: Having both a hydrophilic region and a hydrophobic region.

amphoteric: Capable of serving as an acid (by donating protons) or as a base (by accepting protons).

amyloid: Insoluble protein highly resistant to proteolysis that is present in the brain in a variety of neurological diseases. It consists of aggregates of fibrils composed of subunits rich in β-sheet structure. The β-amyloid present in plaques in Alzheimer disease consists of a polypeptide (39 to 43 amino acid residues) derived from β-amyloid precursor protein.

anabolism: Phase of intermediary metabolism in which energy-utilizing metabolic reactions are used for synthesis of macromolecules and other biomolecules from simpler precursors.

anaerobic metabolism: Breakdown of glucose with production of lactate that occurs in vigorous exercise when muscle lacks adequate oxygen.

anaphase: Stage in mitosis in which the paired chromatids separate and move to the opposite ends of the spindle apparatus.

anaplerotic reaction: Reaction that replenishes the supply of intermediates in a metabolic pathway or cycle.

androgen: Steroid hormone secreted mainly by interstitial cells of the testis, and in small amounts by the adrenal cortex in both genders. It stimulates development and maintenance of the reproductive system and secondary sex characteristics in males. Oversecretion leads to virilization in either gender.

angiogenesis: Formation of new blood vessels or their development and growth from existing ones.

angiotensin I: N-terminal decapeptide released by renin acting on the plasma protein angiotensinogen.

angiotensin II: N-terminal octapeptide released in the lung capillaries by angiotensin-converting enzyme acting on angiotensin I. It produces arteriolar constriction and a rise in blood pressure and promotes thirst and release of antidiuretic hormone and aldosterone.

angiotensin-converting enzyme (ACE): Transmembrane glycoprotein present in the lung capillaries and plasma. It is a zinc-

containing peptidase that cleaves off the C-terminal dipeptide of angiotensin I to produce angiotensin II.

angiotensinogen: Plasma glycoprotein secreted by the liver, the precursor of angiotensin I.

angstrom (Å): Å unit of length, 10^{-10} m.

anhydride: Product of condensation, with loss of water, of two molecules of an acid. Also called acid anhydride.

ankyrin: Large globular protein that is associated with the channel for antiport of Cl^- and HCO_3^- in the membrane, and with spectrin of the cytoskeleton, of erythrocytes.

anomer: Either of the stereoisomers formed by cyclization of an aldose or a ketose, differing only in the configuration around the carbonyl carbon.

anoxia: State of tissue deprivation of oxygen.

ANP: See atrial natriuretic peptide.

antagonist: Agent that binds to a receptor and inhibits binding of the specific agonist for the receptor.

anterior pituitary hormone: Hormone secreted by the anterior pituitary gland, that is, one of the glycoproteins luteinizing hormone, follicle-stimulating hormone, and thyroid-stimulating hormone, the simple proteins growth hormone and prolactin, and the polypeptide adrenocorticotrophic hormone.

anterograde transport: Transport toward the periphery of an axon.

antibody-based immunity: Type of immunity mediated by circulating antibodies secreted by B cells in response to an antigen. Also called humoral immunity.

anticodon arm: In tRNA, the stem-and-loop portion that contains the anticodon region.

anticodon: Three bases on a tRNA molecule that interact with a complementary codon on an mRNA molecule.

antidiuretic hormone (ADH): Nonapeptide hormone produced in the hypothalamus but secreted by the posterior pituitary. It causes reabsorption of water by causing recruitment of an aquaporin into the apical membranes of renal tubules and collecting ducts, and raises blood pressure. Deficient secretion causes diabetes insipidus. Also called vasopressin.

antigen: Substance or cluster of chemical groups capable of inducing production of specific antibodies by B cells.

antigenic determinant: Portion of an antigen that is responsible for eliciting production of an antibody and that interacts with the antibody.

antigen-presenting cell (APC): Cell that is essential for initiating a normal immune response by processing antigens and displaying them on its surface bound to MHC proteins.

antiparallel: Relative orientation of two β-strands (N to C and C to N, respectively) within the same or on two polypeptides, or within two strands of DNA (5′ to 3′, and 3′ to 5′, respectively).

antiport: Cotransport of two different solutes in opposite directions across a membrane.

antisense RNA: RNA, synthetic or transcribed from the noncoding strand of genetic DNA by genetic engineering, that is complementary to and inhibits the RNA transcript of that gene.

AP endonuclease: See apurinic/apyrimidinic endonuclease.

AP site: See apurinic site, apyrimidinic site.

APC protein: Tumor suppressor protein that promotes degradation of β-catenin. It is absent or nonfunctional in adenomatous polyposis coli.

apoenzyme: Catalytically inactive protein component of an enzyme freed from any required cofactor, coenzyme or prosthetic group.

apolipoprotein (apoLp): Protein component of a plasma lipoprotein freed from any associated lipids.

apoprotein: Protein component of a conjugated protein freed from any non-amino acid moiety.

apoptosis: Form of cell death in which the cell shrinks and condenses, its cytoskeleton collapses, the nuclear membrane disintegrates, and the DNA becomes fragmented. The cell membrane becomes altered and evokes rapid phagocytosis without loss of cell contents into the surrounding medium or induction of an inflammatory response. The process is genetically programmed and depends on activation of a caspase cascade. Also called programmed cell death.

apurinic site (AP site): Site on a strand of DNA from which a purine base is missing.

apurinic/apyrimidinic endonuclease (AP endonuclease): Endonuclease that removes a segment of DNA that contains an apurinic or an apyrimidinic site during base excision repair.

apyrimidinic site (AP site): Site on a strand of DNA from which a pyrimidine base is missing.

aquaporin: Integral membrane homotetrameric protein that forms a hydrophilic channel for rapid movement of water down a concentration gradient. Each subunit contains six transmembrane segments.

arrestin: Protein that binds to the phosphorylated intracellular segment of a serpentine receptor and prevents its interaction with a trimeric G protein.

asymmetric carbon atom: See chiral carbon atom.

ATM protein: Large protein kinase that is mutated in ataxia telangiectasia and is required to activate p53 in response to double-strand DNA breaks induced by ionizing radiation or oxidative damage.

ATP synthase: See F-type ATPase.

ATP-binding cassette protein: See ABC transporter protein.

atrial natriuretic peptide (ANP): Peptide hormone secreted by cardiocytes of the atrium when stretched by increased venous return. It promotes reduction of blood pressure and of venous return, and renal water loss. Its receptor contains guanylate cyclase activity in its intracellular segment. Also called atriopeptin.

atriopeptin: See atrial natriuretic peptide.

attenuator: Sequence within the leader region of nascent mRNA that is involved in regulating expression of certain genes for enzymes of amino acid synthesis in prokaryotes by terminating transcription in the presence of an adequate supply of the particular amino acid.

autoantibody: Antibody that interacts with antigens on the surface of a person's own cells and tissues.

autocatalysis: Process in which the product of a reaction is the catalyst for the same reaction (e.g., activation of pepsinogen by pepsin).

autocrine hormone: Biomolecule that acts on the cell that secretes it or on neighboring cells of the same type.

autoimmune disease: Disorder (such as myasthenia gravis) in which the immune system behaves abnormally by responding to antigens that are normal components of an individual's cells or tissues.

autolysis: Self-digestion of a proteolytic enzyme or the breakdown of a cell or tissue by its own degradative enzymes.

autophosphorylation: Phosphorylation of a protein kinase by another molecule of the same enzyme.

axonal transport: Movement of organelles and other particles along microtubules in the axon of a nerve cell, being anterograde (away from the cell body) and effected by kinesin or retrograde (toward the cell body) and effected by dynein.

B cell: Type of lymphocyte derived from the bone marrow that is capable of maturing and differentiating into a plasma cell that produces antibodies or into a B cell which retains a memory for a previous immune response to an antigen.

backbone: Chain of atoms (N-C_α-C) formed by the amino acid residues in a polypeptide or of atoms ($C_{4'}$-$C_{3'}$-O-P-O-$C_{5'}$) formed by the repeating sugar phosphate units in a nucleic acid.

basal lamina: Thin layer of extracellular matrix beneath epithelial sheets or tubes or surrounding individual muscle, adipose tissue, or Schwann cells that separates them from the underlying connective tissue.

basal metabolic rate (BMR): Number of kilocalories that a normal, resting, fasting individual requires to maintain that state during a period of time.

base pairing: Formation of a maximum number of hydrogen bonds between a pair of complementary bases (a purine and a pyrimidine) on two strands of a nucleic acid or within one strand folded back on itself.

base-excision repair: Correction of an abnormal base in a strand of DNA by removal of that base by a DNA glycosylase, removal of the remaining deoxyribosephosphate unit and possibly neighboring nucleotides by an AP endonuclease, and filling in of the gap by DNA polymerase and DNA ligase.

basement membrane: Layer of filaments and fibers that attach an epithelium to the connective tissue beneath it.

basic leucine zipper (bZIP): Protein motif in which a DNA-binding basic α-helix is the N-terminal extension of a leucine zipper. It is commonly present in transcription factors.

basophil: White blood cell with an affinity for basic stains. It contains granules of vasoactive amines and is important in the local response to infection.

B-DNA: Double-helical DNA that has 10.5 base pairs per right-handed turn and a diameter of 20 Å and is the most stable conformation under physiological conditions.

Bence Jones protein: Free light chain of an immunoglobulin produced in excess in myelomatosis. It is detectable in plasma and/or urine.

benign: Tumor that is noninvasive and usually grows slowly.

β–α–β loop: Protein structural motif consisting of two parallel β-strands separated by an α-helix.

β-amyloid precursor protein (β-APP): Single-pass integral glycoprotein of plasma membrane. The isoform that contains 695 residues is expressed in neurons; those which contain 751 and 770 are expressed mainly in non-neuronal tissues. Cleavage of β-APP 695 within the transmembrane segment by α-secretase releases β-amyloid, accumulation of which forms amyloid plaques that injure nerve cells and are associated with Alzheimer disease.

β-amyloid: See amyloid.

β-barrel: Supersecondary structure of proteins that consists of an antiparallel β-sheet rolled into a cylinder.

β- bend: See reverse turn.

β-conformation: See β-strand.

β-hairpin: Protein motif in which two antiparallel β-strands are connected by a turn or short loop.

***B* oxidation:** Metabolism of fatty acids by oxidation of the β-carbon (or C3) with release of acetyl CoA. This process occurs in the mitochondria of eukaryotes.

β-pleated sheet: See β-sheet.

$\beta\beta$-sheet: Common protein motif in which β-strands in different regions of a polypeptide or on two polypeptides, run beside each other in parallel or antiparallel direction and are held together by hydrogen bonds between the nitrogen and oxygen atoms of their peptide bonds. Also called β-pleated sheet.

β-strand: Common secondary structure in which a segment of a polypeptide assumes an extended zigzag arrangement. Also called β-conformation.

bilayer: Double layer of amphipathic lipid molecules arranged with their polar ends oriented toward the solvent surface and their nonpolar regions associated in the center.

bile pigment: Either of the linear tetrapyrroles, bilirubin and biliverdin, that are produced by catabolism of heme. They are excreted in bile as the bisglucuronides.

bile salt: Na or K salt of a glycine or taurine conjugate of a bile acid (e.g., cholic acid) derived from cholesterol. It is responsible for emulsification of dietary lipids and their digestion by pancreatic lipase.

bile: Alkaline secretion produced by the liver and contains bile pigments, bile salts, cholesterol and phospholipids, which become concentrated during storage in the gall bladder. It is released into the duodenum and is essential for emulsification and digestion of dietary lipid.

binding site: Region, usually a crease or pocket, on a protein surface in which a ligand binds.

biocytin: ϵ-*N*-biotin lysine, present as a prosthetic group in the holoprotein of biotin-dependent carboxylases.

bioenergetics: Analysis of energy production and utilization during metabolism.

biomolecule: Organic compound normally present in, or formed by, living organisms.

biopolymer: Biological macromolecule formed by covalent linking of similar or identical small units, end to end, to form a long chain. Examples are polysaccharides, polypeptides, and polynucleotides.

biotransformation: Chemical reactions responsible for conversion of drugs and other xenobiotics into metabolites that are more water soluble for excretion. Consists of Phase I and/or Phase II reactions.

blood clot: Network of fibrin fibers and trapped blood cells that is formed when blood is shed or a blood vessel is damaged. When it forms within a blood vessel, it is called a thrombus.

body mass index (BMI): Measure of adiposity obtained from the weight in kilograms divided by the square of the height in meters. An index up to 25 is considered normal.

Bohr effect: Decreased affinity of hemoglobin for oxygen when the carbon dioxide and H^+ levels in blood are increased.

bond energy: Energy that is required to break or that is released in making a chemical bond. Also called bond strength.

bond strength: See bond energy.

botulinum toxin: Mixture of neurotoxic zinc metalloproteases formed by Clostridium botulinum, the causative agent of botulism (severe food poisoning). It is a potent inhibitor of acetylcholine release from cholinergic neurons.

bound ribosome: Ribosome that is attached to the outer surface of the endoplasmic reticulum and that synthesizes proteins destined for the endoplasmic reticulum lumen, Golgi complex, lysosomes, secretory vesicles or plasma membrane.

branched-chain ketonuria: See maple syrup urine disease.

BRCA: Either of two genes (BRCA 1 or BRCA 2) that when mutated, greatly increase the risk of development of breast cancer. Both genes encode large proteins that are involved in DNA binding and protein–protein interactions.

brown fat: Specialized form of adipose tissue rich in mitochondria in which fuel oxidation is used for thermogenesis rather than for ATP synthesis. It is the site of nonshivering thermogenesis.

brush border: Dense covering of microvilli that are formed by the plasma membrane on the apical surface of cells of the intestinal mucosa and renal tubules.

buffer: Mixture of nearly equal amounts of a weak acid and its salt that stabilizes the pH of a solution by releasing or removing hydrogen ions.

cadherin: Single-pass intrinsic glycoprotein of adherens junctions of the plasma membrane. It mediates Ca^{2+}-dependent cell–cell adhesion. Several types (E - in epithelia, N - in nerve and muscle, P - in placenta, and epidermis, and VE - in vascular endothelium) exist.

calbindin: Calcium-binding protein of absorptive cells of the small intestine whose synthesis is dependent on vitamin D.

calcitonin: Polypeptide hormone that contains 32 residues, is secreted by parafollicular or C cells of the thyroid gland in response to an increase in circulating Ca^{2+} concentration and increases the rate of bone calcification and of Ca^{2+} loss from the kidney.

calcitriol: 1,25-dihydroxycholecalciferol, the active form of vitamin D_3.

calmodulin (CaM): Dumbbell-shaped protein present in cytosol that contains 148 residues and four Ca^{2+}-binding sites. It activates a variety of Ca^{2+}-calmodulin-dependent protein kinases (CaM kinases).

calorie (cal): Amount of energy required to raise the temperature of a gram of water from 14.5 to 15.5°C, being equal to 4.184 J. In nutrition the energy released by combustion of a food in the body is measured in kilocalories (1000 cal).

CaM kinase: Ca^{2+}-calmodulin-dependent protein kinase.

cap-binding complex (CBC): Complex of proteins, including initiation factor 4F, that binds the 5′cap of mRNA.

capsid: Protein shell composed of subunits (called capsomeres) that encloses a viral genome.

capsomere: Protein subunit of a capsid.

carbaminohemoglobin: Hemoglobin with carbon dioxide molecules bound to its N-terminal amino groups.

carbohydrate loading: Practice common among athletes of exercising intensively for a period (to deplete muscle glycogen) followed by consumption of a high-carbohydrate diet (to promote larger-than-normal glycogen stores).

carboxyl terminus: End of a polypeptide chain that contains an α carboxyl group that is free or, less frequently, aminated. Also called C-terminus.

carcinoma: Most common form of cancer in humans, arising from epithelial cells.

cardiac muscle: Specialized form of striated muscle that is characteristic of the heart. It is rich in mitochondria that are in contact with fibrils that branch and interdigitate. The membranes at the ends that abut each other are extensively folded to form intercalated disks, whereas those along the sides fuse over considerable distances and form gap junctions that permit the muscle to function like a syncytium. Also called myocardium.

cardiomyopathy: Progressive disease characterized by damage to cardiac muscle tissue.

carnitine shuttle: Transport of fatty acyl CoA across the inner mitochondrial membrane by formation of a fatty acyl-carnitine that is exchanged for free carnitine in its passage through an acylcarnitine/carnitine transporter.

carnitine: 4-*N*-trimethyl-3-hydroxybutyrate, derived metabolically from ϵ-amino methylated lysine residues of certain proteins. It is present especially in muscle and liver, and participates in transfer of fatty acyl CoA across the inner mitochondrial membrane.

carotene: Yellow-orange unsaturated tetraterpene hydrocarbon present in carrots and green and orange leafy vegetables. It is the precursor of retinol (vitamin A), retinaldehyde, and retinoic acid in the body.

cartilage: Flexible type of connective tissue that lacks blood vessels and nerves, and consists of chondrocytes and a matrix composed of collagen fibrils and the proteoglycan aggrecan that is rich in chondroitin sulfate that they secrete. It is present mostly at the ends of long bones in the articulating surfaces of joints, and in the intervertebral disk. During development it is the precursor of the long bones.

cascade: Process that consists of sequential activation of an increasing number of components of a signaling system so as to amplify that signal.

caspase cascade: Amplifying proteolytic cascade in the cytosol in which a procaspase is activated by an initiator of apoptosis and then activates another procaspase and so on until apoptosis is produced.

caspase: Cytosolic proteolytic enzyme that contains a cysteine residue in its active site, cleaves its substrates on the carboxyl-terminal side of an aspartate residue, is activated from a procaspase, and is involved in apoptosis.

catabolism: Phase of intermediary metabolism in which nutrient molecules are degraded with release of energy.

catalytic antibody: See abzyme.

catalytic triad: Histidine residue hydrogen-bonded with a serine and aspartate residues in the active site of chymotrypsin and of other serine proteases.

catechol: Aromatic ortho-diol, the characteristic chemical group present in catecholamines.

catecholamine: Catechol derivative of tyrosine such as dopamine, noradrenaline, and adrenaline that are major elements in the body's response to stress.

catenin: Either of two proteins (α or β) that mediate linking of cadherin in adherens junctions to the actin microfilaments of cytoskeleton.

cathepsin: Proteolytic enzyme found in lysosomes.

CCAAT box: Consensus sequence CCAAT present in promoter elements in transcription promoters of many eukaryotic genes.

CDC gene: See cell-division-cycle gene.

cell adhesion molecule (CAM): Integral protein of the plasma membrane that mediates binding of cell to cell or to extracellular matrix in a Ca^{2+}-dependent (e.g., a cadherin) or Ca^{2+}-independent (e.g., neural CAM) fashion.

cell coat: See glycocalyx.

cell junction: Specialized region of a plasma membrane at which cell to cell or extracellular matrix adhesion occurs.

cell-division-cycle gene (cdc gene): Gene that controls one or more steps in the cell cycle.

cell-mediated immunity: Type of immunity mediated by T cells in lymphoid tissue and in the circulation that functions in defense against microorganisms (including viruses within cells) and foreign tissue transplants.

centriole: Intracellular organelle that consists of nine groups of short microtubules with three in each group, that organizes the microtubules of the spindle apparatus during cell division.

centromere: Region where daughter chromatids remain connected after a chromosome has replicated, and where fibers of the spindle apparatus become attached.

centrosome: Region of the cytoplasm that contains a pair of centrioles oriented at right angles to each other.

ceramide: Metabolic precursor of the sphingolipids consisting of a fatty acid in amide linkage with the C2 amino group of sphingosine.

cerebroside: Glycosphingolipid that contains a glucose or galactose moiety linked to C1 of ceramide.

cerebrospinal fluid (CSF): Fluid that bathes the internal and external surfaces of the central nervous system. It is secreted and reabsorbed via aquaporins in membranes of cells of the choroid plexus.

channeling: Direct transfer of the product of an enzyme reaction to the active site of another enzyme for which it is the substrate.

chaotropic agent: Ion or small organic molecule that increases the solubility of nonpolar substances in water. It is useful for dissolving membranes, solubilizing particular proteins, and denaturing proteins and nucleic acids.

chaperone: Protein that helps other proteins avoid misfolding and production of inactive or aggregated species. Also called heat shock protein, molecular chaperone.

charge repulsion: Mutual repulsion of chemical groups with like charge.

chemiosmosis: Mechanism by which certain membranes in cells use the energy of electron transfer to pump protons across the membrane and to harness the energy stored in the H^+ gradient to drive cellular work, including ATP synthesis.

chief cell: Cell in the gastric mucosa that secretes pepsinogen. Also called peptic cell.

chiral atom: Carbon atom with four different substituents that can exist in two configurations making it optically active. Also called asymmetric carbon atom, chiral center.

chloride shift: Exchange of plasma Cl^- for HCO_3^- produced by dissociation of carbonic acid within erythrocytes.

cholecystokinin (CCK): Polypeptide hormone that contains 39 residues, is secreted by the duodenal mucosa, and causes contraction and emptying of the gall bladder and secretion of enzymes by the pancreas. Also called pancreozymin.

cholelithiasis: Presence or formation of biliary calculi or gall stones.

choline: *N*-trimethylethanolamine, a vitamin component of acetylcholine, phosphatidylcholine, plasmalogens, and platelet-activating factor.

chondroitin sulfate: Predominant glycosaminoglycan of cartilage. It consists of the repeating unit glucuronic acid β1-3*N*-acetylgalactosamine, and forms part of the proteoglycan aggrecan.

chorionic gonadotropin (CG): Protein hormone homologous with growth hormone and prolactin. It is secreted by the placenta, has most of the actions of growth hormone, and maintains the corpus luteum during the first third of human pregnancy. Also called chorionic somatomammotropin, placental lactogen.

chorionic somatomammotropin: See chorionic gonadotropin.

chorionic villus sampling: Technique of obtaining a sample of the fetal portion of the placenta for determining the presence of genetic abnormalities in the fetus while it is still in the womb.

chromaffin cell: Cell found in clusters in the adrenal medulla and elsewhere, that contains granules for biosynthesis, storage and, secretion of the catecholamines.

chromatid: Complete copy of the double-stranded DNA of a chromosome with its associated nucleoproteins.

chromatin: Complex of DNA, histones, and other proteins in the nucleus of a eukaryotic cell.

chromosome condensation: Process by which, prior to the M phase of the cell cycle, chromatin becomes packed into chromosomes.

chromosome decondensation: Process by which chromosomes present in the M phase of the cell cycle become less compact and form chromatin when that phase is passed.

chromosome walking: Technique for identifying and sequencing long parts of a DNA strand such as a chromosome by breaking these into smaller fragments and cloning them. A cloned fragment that has already been identified is used as a probe to select clones that contain adjacent sequences which are then used to select clones

adjacent to them. In this way a walk is made along a chromosome from the starting fragment.

chromosome: DNA strand that contains a portion of the genome along with associated proteins. In humans there are 23 pairs of chromosomes.

chronotropic: Denoting the rate and strength of rhythmic movements such as the heart beat.

chylomicron: Particle present in plasma during the absorption of dietary lipid. It consists of triacylglycerols, phospholipids, cholesterol esters, fat-soluble vitamins, and apolipoprotein B48. It is synthesized and secreted by cells of the intestinal mucosa and enters venous blood via the lymphatic duct.

chyme: Acidic, semifluid mixture of ingested food and digestive secretions that enters the small intestine from the stomach during the early phases of digestion.

cirrhosis: Disorder of the liver in which degeneration of the hepatocytes is accompanied by their replacement by fibrous connective tissue.

cis-acting regulatory element: Sequence of DNA that regulates expression of a gene on the same chromosome, e.g. a promoter or an enhancer.

cis–Golgi network: Interconnected cisternae and tubules of the Golgi complex that are closest to the endoplasmic reticulum and receive protein- and lipid-containing vesicles from that reticulum. It is the site of phosphorylation of oligosaccharides on proteins destined for lysosomes.

cisterna: Flattened membrane-bound compartment of the Golgi complex and endoplasmic reticulum.

clathrin: Protein composed of three large and three small polypeptides arranged into a three-legged structure (triskelion) that can assemble into a basket-like framework on the inner surface of a portion of the membrane to form a structure which can be released into the cytoplasm as a coated vesicle.

clathrin-coated vesicle: Type of vesicle that mediates transport from the plasma membrane or Golgi complex. Its outer surface is covered by a framework of clathrin triskelions bound to transmembrane proteins via adaptins.

cloning vector: Agent such as a plasmid or modified virus that is used to transfer DNA in genetic engineering.

cloning: Construction of a recombinant DNA molecule, its insertion into a vector and then into a cell, and the production of multiple copies by expression in the progeny of that cell.

coactivator: Protein that binds to a DNA-bound protein or protein complex thereby activating transcription of an adjacent gene. Also an ion or biomolecule that with one or more participates in activating an allosteric enzyme.

coated vesicle: Small membrane-enclosed particle with a meshwork of clathrin or other proteins on its outer surface. It may be formed at the plasma membrane, endoplasmic reticulum, or components of the Golgi complex.

coding strand: Strand of genetic DNA that has the same sequence as RNA transcribed from that region; it is complementary to the template strand from which RNA is transcribed.

codon: Triplet of purine and/or pyrimidine bases in an mRNA molecule that specifies the insertion of a particular amino acid residue during polypeptide synthesis.

coenzyme A (CoA): Nucleotide coenzyme that contains pantetheine as a constituent. Its terminal sulfhydryl group functions as an acyl carrier in many reactions.

coenzyme B12: 5′-deoxyadenosylcobalamine, derived by binding of a 5′-deoxyadenosyl group to the cobalt atoms of cobalamine (vitamin B_{12}), and the coenzyme in conversion of methylmalonyl CoA to succinyl CoA; also methylcobalamine, derived by binding of a methyl group to the cobalt of cobalamine, the coenzyme in conversion of homocysteine to methionine.

coenzyme Q (Q): Ubiquinone, the benzoquinone isoprenoid that functions as a lipophilic electron carrier from complexes I and II to complex III and cytochrome c in the mitochondrial electron transport system.

coenzyme: Complex nonprotein organic cofactor required for activity of some enzymes. Most vitamins are precursors of coenzymes.

cofactor: Ion or molecule that on binding to the catalytic site of an apoenzyme renders it active.

cognate: Two biomolecules that normally interact (e.g., a receptor and its proper ligand).

coiled-coil: Structure present in some fibrous proteins (e.g., keratins, tropomyosin, myosin) formed by two polypeptides that contain α-helical regions that consist of repeats of seven residues (abcdefg) in which "a" and "d" are hydrophobic or in which "g" is a leucine residue (leucine zipper proteins).

compartmentation: Subdivision of the enzymes of a eukaryotic cell into functionally distinct, membrane-enclosed spaces or organelles.

complement: System of plasma proteins secreted by the liver that interact on exposure to activated antibodies or to the surface of certain pathogens, to promote cell lysis, phagocytosis and an inflammatory response.

complementary DNA (cDNA): DNA produced by retroviral reverse transcriptase from an RNA template.

complex oligosaccharide: Oligosaccharide of an N-linked glycoprotein that, by trimming and further modification in the Golgi complex, retains three of the mannose residues introduced in the endoplasmic reticulum. One or more trisaccharide units terminating in a sialic acid residue are added to the end of the oligosaccharide.

complex protein: See conjugated protein.

condensation reaction: Covalent linking of two molecules through loss (usually) of water.

configuration: Arrangement in space of atoms in an organic molecule that results from the presence of one or more chiral centers or of one or more double bonds. It can only be changed by breaking or reforming of covalent bonds.

conformation: Arrangement in space of an organic molecule whose substituent groups can assume different positions around single bonds.

conjugated protein: Protein that contains one or more tightly associated non-amino acid moieties. Examples include metalloprotein, phosphoprotein, hemoprotein, glycoprotein, lipoprotein, nucleoprotein, and flavoprotein. Also called complex protein.

conjugation: Addition, usually in the liver, of a moiety of glucuronic acid, acetate, sulfate, glycine, glutamine, or glutathione, to increase the polarity and excretability of nonpolar metabolites or foreign compounds introduced into the body. Also called Phase II reaction.

connectin: See titin.

connective tissue: Supporting tissue found between other tissues. It contains fibroblasts, chondrocytes, osteoblasts, osteoclasts, adipocytes, or smooth muscle cells and the extracellular material that they produce.

connexin: Integral protein that spans the plasma membrane four times. A cluster of six connexins constitute a connexon.

connexon: Channel in the plasma membrane that consists of six connexin units. When affixed to a connexon on an adjacent cell, a gap junction is formed that permits transit of material between both cells.

consensus sequence: Sequence of nucleotides or of amino acid residues that occurs most frequently within a related region of two or more nucleic acids or polypeptides respectively.

conservative substitution: Replacement in a polypeptide of a residue by another of similar characteristics (e.g., serine by threonine).

constitutive protein: Protein present in relatively constant amounts in the cells that produce it.

cooperative binding: Change in affinity (increase or positive cooperativity, decrease or negative cooperativity) for binding of a ligand at one site by prior binding of a molecule of the same (homotropic effect) or of a different (heterotropic effect) ligand at another site of a multimeric protein.

cooperativity: Interaction by which a conformational change induced in one subunit is transmitted to all others in a multimeric protein.

corepressor: Protein that binds to a DNA-bound protein or protein complex thereby blocking transcription of a gene.

Cori cycle: See glucose–lactate cycle.

corpus luteum: Mass of yellow follicle cells that develops in the ovary after ovulation. It secretes progesterone.

corticoliberin: See corticotropin-releasing hormone.

corticosteroid: Steroid hormone synthesized from cholesterol and secreted by the adrenal cortex. It may be a glucocorticoid, a mineralocorticoid or a sex hormone.

corticotropin: See adrenocorticotropic hormone.

corticotropin-releasing hormone (CRH): Polypeptide hormone that contains 41 residues that is secreted from the hypothalamus and causes release of adrenocorticotropic hormone (ACTH) by the anterior pituitary. Also called corticoliberin.

cortin: See adrenocorticotropic hormone.

cotransport: See symport.

coupled reaction: Linkage of an exergonic with an endergonic reaction that transfers energy from one to the other.

covalent catalysis: Catalysis that occurs when part or all of a substrate molecule forms a covalent bond with a component of the enzyme's active site before transfer to a second substrate.

cristae: Infoldings of the inner mitochondrial membrane.

cross-talk: Interaction of pathways for hormonal signal transduction, for example, through effects on a common component, common second messenger, or similar patterns of phosphorylation of target proteins.

C-terminal residue: Residue in a polypeptide that contains an α-carboxyl group that is free or occasionally aminated.

C-terminus: End containing the C-terminal residue in a polypeptide.

cyanosis: Bluish discoloration of skin that results from presence of deoxygenated blood in capillaries near the body surface.

cyclin: Protein whose concentration fluctuates during the cell cycle and that activates a cyclin-dependent protein kinase thereby regulating progression through the cycle.

cyclin-dependent kinase (cdk): Protein kinase whose activity is modulated by the concentration of a cyclin.

cysteamine: Decarboxylated cysteine, a component (with pantothenic acid) of pantetheine in coenzyme A.

cytochrome: Heme protein involved in an electron transport system in the endoplasmic reticulum or inner mitochondrial membrane.

cytokine receptor: Plasma membrane receptor for a cytokine that is stably associated with a cytosolic tyrosine protein kinase and functions by modulation of specific gene activity.

cytokine: Small protein secreted by cells of the immune system that mediates local cell–cell communication.

cytoskeleton: Network of microtubules, microfilaments and intermediate filaments present in the cytoplasm.

D arm: In tRNA the stem and loop portion that contains two or three dihydrouracil bases.

dalton (Da): Unit of atomic mass, one twelfth the mass of a ^{12}C atom.

***de novo* pathway:** Pathway for synthesis of a biomolecule (e.g., a nucleotide) from preformed precursors.

deletion: Loss of a fragment of a chromosome through breakage or unequal crossing over, or through mutational loss of one or more contiguous nucleotides from a gene.

denaturation: Loss of higher-order structure in a protein or nucleic acid as a result of change in pH, salt concentration or temperature.

depolarization: Change in transmembrane electrical potential from a negative value toward a more positive value.

detoxification: Removal of a harmful substance. Often refers to hydroxylation reactions catalyzed by cytochrome P450 enzymes of the hepatic smooth endoplasmic reticulum that render lipophilic drugs or other substances more water soluble for excretion.

diabetes insipidus: Condition of excessive thirst and water intake and urinary excretion of a dilute urine, produced by decreased secretion of, or resistance to, antidiuretic hormone (vasopressin).

differential RNA splicing: See alternative RNA splicing.

differentiation: During development, the gradual appearance of specific cellular characteristics caused by differential gene activation and repression.

dinucleotide fold: See nucleotide-binding fold.

diploid: Having two sets of chromosomes, one set coming from each parent, as in somatic cells.

dipolar ion: See zwitterion.

disulfide bond: Covalent bond formed between sulfhydryl groups of two cysteine residues within the same polypeptide (intrachain) or between two polypeptides (interchain).

DNA fingerprinting: Technique of breaking a piece of DNA containing a variable number of repeat sequences with a restriction enzyme, and the resulting fragments being separated by electrophoresis on

a suitable support. The pattern of bands is characteristic of the DNA donor. (Also called genetic profiling).

DNA glycosylase: Enzyme that hydrolyses the N-glycosidic bond between a base and the DNA backbone as the first step in base-excision repair.

DNA helicase: Enzyme that utilizes the chemical energy of ATP to catalyse strand separation in DNA before replication.

DNA library: Collection of bacterial or phage clones that contain cDNA that represents the mRNA of an organism, specific cell type, or tissue.

DNA ligase: Enzyme that seals a nick (creates a phosphodiester bond between adjacent sugars) in the backbone of DNA.

DNA melting: Unwinding and separation of the two strands of DNA on heating, the melting temperature being determined by the base composition of the DNA.

DNA methylation: Enzymatic transfer of the methyl group of S-adenosylmethionine to adenine or cytosine in DNA that keeps genes in an inactive state.

DNA microarray: Compact arrangement of numerous short DNA sequences, derived by chemical synthesis or from PCR fragments immobilized on a solid that can be easily probed by hybridization with other nucleic acids that have been fluorescently labeled.

DNA probe: Natural or synthetic labelled oligonucleotide that is used to detect a gene of interest by hybridization to a complementary sequence.

dolichol: Long-chain polymer of isoprene present in endoplasmic membranes that, in the diphosphate form, is used to carry activated sugars in the biosynthesis of glycoproteins and some polysaccharides.

domain: Segment of a polypeptide or polynucleotide chain that may fold and function independently from the rest of the molecule.

dominant: Gene (or allele) that affects the phenotype when it is received from only one parent (i.e., in the heterozygous form). It also describes a character or trait due to such a gene.

down-regulation: Decrease in transcription of a DNA genetic sequence in response to an external variable.

dynamin: Cytosolic protein with GTPase activity that binds to the neck of a clathrin-coated pit and participates in separating it from the membrane as an intracellular vesicle.

dynein: Motor protein unrelated to the kinesins, composed of two or three heavy chains that contain a motor domain and a variable number of light chains. Cytoplasmic dyneins contain two heavy chains, are probably present in all eukaryotic cells, and are important in vesicle trafficking. Axonemal dyneins contain two or three heavy chains and are responsible for the sliding movement that drives the beating of cilia and flagella.

dynorphin: Polypeptide that has the same N-terminal pentapeptide as Leu-enkephalin. It is a powerful analgesic and is present in hypothalamus and brain stem and in the duodenum.

dystrophin: Cytoskeletal protein of cardiac and skeletal muscle that consists of a fibrous antiparallel homodimer of a large polypeptide whose central region consists of 24 repeats of a sequence characteristic of β-spectrin. It links the plasmalemma to actin filaments. It is absent in Duchenne muscular dystrophy and reduced or altered in structure in Becker muscular dystrophy.

E site: See exit site.

effector enzyme: Membrane-associated enzyme that responds to an extracellular signal transmitted via a membrane receptor by producing an intracellular messenger.

electrogenic transport: Transport across a plasma membrane of ionic solutes by a process that produces a change in the membrane potential.

emulsification: Physical breaking up of ingested lipids in the intestinal tract, by mixing with bile salts and other emulsifying agents, to form smaller particles that are accessible to lipolytic digestive enzymes.

endergonic: Requiring energy input to occur; a nonspontaneous process.

endocytosis: Entry of extracellular material by invagination of the cell plasma membrane to form vesicles called endosomes

endoplasmic reticulum (ER): Extensive network of membrane channels in the cell cytoplasm that is studded with (rough ER) or lacks (smooth ER) ribosomes and functions in protein synthesis and lipid metabolism and in intracellular transport, storage, packaging, or secretion.

endorphin: Neuromodulator and analgesic peptide that includes in its structure the pentapeptide of Leu-enkephalin or Met-enkephalin, is produced mostly in the central nervous system and gastrointestinal tract, and binds to an opiate receptor. Also called opioid peptide.

endosome: Small intracellular vesicle formed by endocytosis that transfers its contents to a lysosome for degradation.

enterohepatic circulation: Secretion of bile salts by the liver followed by their absorption by the intestinal mucosa for return to the liver via the portal vein.

enthalpy (H): In thermodynamics the heat content of a system.

entropy (S): In thermodynamics the degree of disorder or randomness in a system.

enzyme cascade: Series of proenzymes or weakly active enzymes, in which activation of the first causes that of the second and so on. Activation may be by proteolytic cleavage (e.g., in blood clotting) or by phosphorylation (e.g., in the insulin receptor pathway) and results in amplification of the original activation signal.

enzyme-linked receptor: Integral protein receptor of the plasma membrane that has an intracellular catalytic domain (e.g., a protein kinase or protein phosphatase, guanylate cyclase) or becomes associated with a cytosolic enzyme, and is activated on ligand binding.

enzymopathy: Disorder produced by lack of an enzyme activity.

epigenetic: Describing a change in a characteristic of a cell or organism that is not the result of a change in the nucleotide sequence of the DNA.

epinephrine: See adrenaline.

epitope: Region on the surface of an antigen that elicits secretion of a specific antibody and also binds to it. Also called antigenic determinant.

ER retention signal: Sequence Lys-Asp-Glu-Leu (KDEL) at the C-terminal end of proteins that are retained and function within the endoplasmic reticulum.

ER signal sequence: N-terminal hydrophobic sequence that directs polypeptides destined for lysosomes, the endoplasmic reticulum, Golgi complex, secretory vesicles, or plasma membrane to enter the endoplasmic reticulum where it is cleaved off by a signal peptidase soon after its entry.

ER-resident protein: Protein that functions within the endoplasmic reticulum being retained there via the sequence Lys-Asp-Glu-Leu (KDEL) at the C-terminal end.

erythropoietin: Glycoprotein hormone secreted mostly by kidneys on exposure to low oxygen concentration that stimulates erythropoiesis.

essential fatty acid: Polyunsaturated fatty acid that is required but cannot be synthesized by an animal.

euchromatin: Decondensed form of chromatin that is available for transcription.

eukaryote: Organism that consists of one or more cells that each contain a nucleus and other membrane-bounded organelles.

excinuclease: Complex enzyme system that excises the abnormal segment of the affected DNA strand during nucleotide excision repair. Also called excision-repair endonuclease.

Excision-repair endonuclease: See excinuclease.

exergonic: Accompanied by release of energy; a spontaneous process.

exit site: Site, mainly on the large subunit of a ribosome, from which the uncharged tRNA is released after an elongation step in protein synthesis. Also called E site.

exocytosis: Release or secretion of material contained within an intracellular vesicle by fusion of its membrane with the plasma membrane.

exon: Segment of coding DNA of a eukaryotic gene that is represented in mRNA and the amino acid sequence of its translated protein, or in mature tRNA or rRNA. Also called expressed sequence.

expressed sequence: See exon.

expression vector: Plasmid or virus into which a foreign DNA gene sequence and its regulatory elements have been introduced and which can produce that gene product in a host cell.

extracellular matrix (ECM): Secreted intercellular component of connective tissue, consisting mostly of glycoproteins and proteoglycans.

extreme obesity: See morbid obesity.

extrinsic protein: See peripheral protein.

facilitated diffusion: Rapid permeation of solutes, based on their concentration gradient across a cell membrane, by interaction with specific membrane transport proteins. Also called passive transport.

familial hypercholesterolemia: Presence of abnormally high concentrations of cholesterol in LDL in plasma, the result of a lack of functional LDL receptors, that is transmitted as an autosomal dominant trait.

feedback inhibition: Slowing down or stoppage, in a metabolic pathway, of an early reaction by the product of a later reaction

feedforward activation: Activation, in a metabolic pathway, of a later reaction by a product of an earlier reaction.

FeS center: An iron–sulfur cluster.

fibril-associated collagen: Collagen, such as type IX and type XII, that forms short triple-helical and nonhelical domains and binds to the side of collagen type I or type II fibrils, respectively.

fibrillar collagen: Collagen, such as type I, II, III, V, or XI, that forms fibrils and occurs in connective tissue.

fibrillin: Large glycoprotein component of the microfibrils present in the extracellular matrix of many tissues, that is secreted by fibroblasts and forms a scaffold for deposition of elastin. Hereditary abnormalities in structure of the protein are associated with Marfan syndrome.

fibroblast growth factor (FGF): Family of proteins classed as acidic (from brain or retina) or basic (from brain, retina, or cartilage). They are mitogenic and angiogenic, act as growth factors in tissue culture, and exert their effects through receptors that are tyrosine kinases. Mutation in one form of FGF receptor is responsible for achondroplasia (the commonest form of dwarfism).

fibroblast: Type of cell common in loose connective tissue, that secretes collagen and other macromolecules of the extracellular matrix and readily migrates to and proliferates in wounded tissue.

first law of thermodynamics: Law that requires that in all processes the total energy of the universe remains constant.

flagellum: Extension of the cell membrane of a spermatozoon that forms an organ of locomotion driven by dyneins. It consists of two single microtubules surrounded by a ring of nine doublet microtubules.

flippase: Protein that facilitates translocation of a membrane lipid from one membrane monolayer to the other.

flux: Flow of material through a metabolic pathway or of a solute across a membrane.

frameshift: Change in the coding frame of codons during protein synthesis as a result of insertion or deletion of one or more nucleotides into the DNA sequence of an exon.

free energy of activation: Energy required to raise a substrate from the ground state to the transition state at which it will react. Also called activation energy.

free ribosome: Ribosome in the cytoplasm that is unattached to any membrane and is used for synthesis of proteins destined for the cytosol, mitochondria, peroxisomes, or nucleus.

F-type ATPase: H^+-transporting F_0F_1–ATP synthase of the inner mitochondrial membrane that catalyses synthesis of ATP during transport of electrons from metabolic substrates to oxygen. Also called ATP synthase or complex V.

futile cycle: Two opposing sets of enzyme-catalyzed reactions that result in release of energy as heat by the net hydrolysis of ATP.

G protein: GTP-binding protein with inherent GTPase activity. It is active with bound GTP but not with GDP, may be monomeric (e.g., ras) or heterotrimeric (containing α-, β-, and γ-subunits), and plays an important role in intracellular signaling pathways.

G protein-linked receptor: Serpentine receptor of the plasma membrane that on binding of a ligand activates a trimeric G protein.

G_0 phase: Nondividing state of a cell that has exited the cell cycle at the restriction point during the G_1 phase.

G_1 phase: Phase in the cell cycle that consists of the growth portion in interphase before DNA replication begins.

gated ion channel: Ion channel that opens and closes to allow alteration of the cell membrane potential. It may be voltage-gated, mechanically gated, or ligand-gated (extracellularly or intracellularly).

gene amplification: Selective synthesis of extra copies of a gene or genes. This is normal for some organisms and occurs for some oncogenes in certain cancers.

gene cloning: Formation by a bacterium that carries a foreign gene, introduced into it via a recombinant vector, of a clone of cells that contain the replicated gene.

gene knockout: Deletion or inactivation of a gene in an experimental animal by genetic-engineering methods.

gene: Segment of chromosomal DNA that encodes a functional polypeptide or RNA molecule, including exons, introns, and regulatory sequences.

genomic DNA library: Collection of bacterial or phage clones that contain overlapping parts of the genome of an organism.

genomics: Study of DNA sequences and properties of genomes.

genotype: Genetic constitution or complement of an individual.

germ-line cell: Cell of the lineage that forms the gametes (sperm or ova).

gestational diabetes: Condition in which previously normal woman exhibits an abnormally high level of blood sugar during a pregnancy

glial cell: See neuroglia cell.

glicentin: Polypeptide derived from preproglucagon in special cells of the lower intestinal tract. It consists of glucagon extended by additional residues at either end and by glicentin-related polypeptide at the N-terminal end. Its activity is similar to that of glucagon.

globin: Apoprotein of myoglobin or of hemoglobin.

globular protein: Protein whose tertiary structure makes it compact and spheroidal.

gluconeogenesis: Metabolic pathway for synthesis of glucose from noncarbohydrate precursors in the liver.

glucose tolerance: Ability of the body to utilize glucose as ascertained by the nature of the blood glucose curve following administration of a test amount of glucose. It is decreased most commonly in diabetes mellitus and in conditions associated with liver damage.

glucose–alanine cycle: Interorgan metabolic conversion of alanine released from skeletal muscles during prolonged fasting or starvation, into glucose that is produced and secreted into the blood stream by the liver. Also called alanine cycle or Randle cycle.

glucose–lactate cycle: Interorgan conversion of lactate released from skeletal muscle after exertion, into glucose produced and secreted into the blood stream by the liver. Also called lactate cycle or Cori cycle.

glyceroneogenesis: An abbreviated version of gluconeogenesis in which the glycerol 3-phosphate that is required for triglyceride synthesis is generated from noncarbohydrate precursors such as lactate and amino acids.

glycocalyx: Fuzzy coat on the external surface of cells, consisting of the carbohydrate component of glycoproteins and glycolipids of the cell membrane and of secreted glycoproteins and proteoglycans that adhere to that surface. Also called cell coat.

glycoform: Glycoprotein that differs only in the location and/or structure of the carbohydrate component from another.

glycolipid: Lipid that contains a monosaccharide (e.g., in glucosyl cerebroside) or an oligosaccharide (e.g., in a ganglioside) component.

glycolysis: Metabolic pathway by which a molecule of glucose is catalyzed to two of pyruvate with net production of two ATP and two of NADH.

glycoprotein: Conjugated protein that contains covalently bound carbohydrate.

glycosuria: Presence of abnormally high concentration of glucose (most commonly) or of other sugars (e.g., galactose, fructose, or pentose) in urine.

Golgi complex: Series of stacked membranous cisternae (cis, medial, and trans) in the cytoplasm of eukaryotic cells in which proteins transferred from the endoplasmic reticulum are modified and sorted, and also the site of synthesis of glycosaminoglycans of the extracellular matrix.

Golgi stack: Pile, usually of three cisternae, between the cis- and the trans-Golgi networks, the site of processing of N-linked oligosaccharides and of *O*-glycosylation, and also production of proteoglycans.

gonadotrope: Cell in the anterior pituitary gland that produces the gonadotropins, that is, the glycoproteins luteinizing hormone and follicle-stimulating hormone.

granulocyte: Leukocyte that contains granules visible under light microscopy and may be basophilic, eosinophilic, or neutrophilic on appropriate staining.

growth factor: Protein that promotes synthesis of proteins and other cell constituents and produces an increased cell mass but not cell number. It is frequently used to include mitogens and survival factors.

guide RNA: Small RNA that is involved in editing of pre-mRNA and of pre-rRNA (when it is call snoRNA).

H chain: See heavy chain.

half-life ($t_{1/2}$): Time required for decay or disappearance of one-half of an amount of a given component in a system. Also called half-time.

half-time: See half-life.

haploid: Having one set of chromosomes as in germ cells.

hb S: Hemoglobin that contains the mutant β globin that causes erythrocyte sickling.

heat shock protein: See chaperone protein.

heavy chain: Larger of the two types of polypeptide in a protein. Also called H chain.

helix cap: Structure formed when the side chain of residues such as asparagine or glutamine that flank an α-helix fold back to form hydrogen bonds with peptide bond components of the first or of the last turn of the helix.

helper T cell: Type of lymphocyte that by its secretion and other activities helps trigger and coordinate cell-mediated and antibody-mediated immunity.

hemoglobinopathy: Hereditary condition that manifests itself as a structural variant of a hemoglobin (e.g. sickle cell anemia), a thalassemia, or persistence of fetal hemoglobin.

heptad repeat: Seven-residue sequence (abcdefg) that is repeated in tandem in a polypeptide, in which "d" and "g" are hydrophobic or in which "g" is leucine (as in a leucine zipper). Such heptads allow the polypeptides to dimerize as coiled-coils.

heterochromatin: Condensed form of chromatin that is not transcribed and forms a dense region, visible with a light microscope, in resting cells.

heterogeneous nuclear ribonucleoprotein (hnRNP): Complex of hnRNA present in the nucleus of eukaryotic cells.

heterogeneous nuclear RNA (hnRNA): RNA in the nucleus that is usually the primary transcript of genes for polypeptides and contains one or more intron sequences. Also called pre-mRNA.

heteropolysaccharide: Polysaccharide that consists of more than one type of monosaccharide (e.g., a glycosaminoglycan).

heterozygous: Having two different alleles at corresponding sites on a chromosome pair.

high-mannose oligosaccharide: Oligosaccharide of an N-linked glycoprotein that retains all or most of the nine mannose residues transferred onto it in the endoplasmic reticulum and undergoes little or no further modification in the Golgi complex.

histone core: Protein core of a nucleosome, consisting of two copies of each of histones H2A, H2B, H3, and H4.

HLA protein: Human leucocyte antigen or major histocompatibility complex protein.

homeobox: Conserved DNA sequence (~100 bp long) that encodes a protein domain (homeodomain) that regulates differentiation during development of the organism.

homeodomain: Protein domain (~60 residues long) that forms a helix–loop–helix structural motif and is encoded by a homeobox.

homeostasis: Maintenance of a relatively constant internal environment within the body.

homeotic gene: Gene involved in controlling the overall body plan by controlling the fate of groups of cells during development of the organism.

homologous chromosome: One of a pair of chromosomes in somatic cells that are similar in length, position of centromere, and location of alleles for the same traits and are derived from the father and the mother respectively. In germ cells, only one member of a pair is carried by each gamete.

homologous: Macromolecules that share similarity because of a common evolutionary origin, and more specifically in the primary structure of polypeptides or nucleic acids.

homopolysaccharide: Polysaccharide that consists of one type of monosaccharide (e.g., starch or glycogen).

homozygous: Having the same alleles at the corresponding sites on a chromosome pair.

hormone response element: DNA sequence to which a nuclear receptor for a hormone of the steroid family binds to and alters transcription of an adjacent DNA genetic sequence that is regulated by that hormone.

humoral immunity: See antibody-based immunity.

hyaluronidase: Enzyme that hydrolyses the glycosidic bonds of hyaluronic acid, is the spreading factor secreted by some bacteria, and is present at the acrosomal cap of spermatozoa.

hybridoma: Cell line obtained by fusing antibody-secreting lymphocytes with lymphoma cells, and used for production of monoclonal antibodies.

hydrogen bond: Weak electrostatic bond in which a hydrogen atom in covalent linkage with an electronegative atom is partially shared with another electronegative atom.

hydrolase: Enzyme that catalyses a hydrolytic cleavage reaction.

hydrophilic: Capable of associating freely with water molecules.

hyperammonemia: Presence of abnormally high concentrations of ammonia in blood usually associated with neurological and other abnormalities. It results from underutilization of ammonia in urea synthesis as a result of liver disease, of inborn errors of urea synthesis, or of organic acidemias.

hyperchromic shift: Increase in absorption of ultraviolet light by a DNA solution as the DNA melts on raising the temperature.

hyperglycemia: Elevated plasma glucose concentration relative to that during fasting. It occurs physiologically within 2–3 h after a meal, but when higher than normal, it is usually symptomatic of diabetes mellitus.

hyperplasia: Abnormal enlargement of an organ or tissue from increase in number of cells.

hypertrophy: Abnormal enlargement of an organ or tissue from increase in the size of its cells.

hypervariable region: Any of the three short loop segments in the variable region of the light or heavy chains of immunoglobulins that are poorly conserved and form part of the antigen-binding site. Also, a region in a polypeptide that shows great variability in sequence in different species.

hypervariable residue: Residue in a hypervariable region.

hypoglycin: Toxic non-proteogenic α-amino acid present in the unripe ackee fruit. Its deaminated and decarboxylated derivative is a potent inhibitor of β-oxidation of short-chain fatty acids and produces Jamaican vomiting sickness.

hypopituitarism: Condition of partial or total loss of function of the pituitary gland that leads to decreased secretion of one or more of the hormones produced there.

IF protein: See intermediate filament protein.

Ig domain: See immunoglobulin domain.

Ig superfamily: Family of proteins that contain one or more domains like those which characterize the immunoglobulins. It includes Ca^{2+}-dependent cell adhesion molecules, T and B cell receptors, MHC proteins, and transmembrane IgM.

immunoglobulin domain: Domain (~100 residues) that forms a sandwich consisting of a three- and a four- stranded antiparallel β sheet and is characteristic of the variable and constant regions of L and H chains of immunoglobulins. Also called immunoglobulin fold or Ig-domain.

immunoglobulin fold: See immunoglobulin domain.

induced fit: Change in conformation induced in an enzyme by binding to its substrate, also the change in conformation induced in any macromolecule by ligand binding.

inducer: Compound that promotes the activity of a specific gene; also a stimulus that provokes a physiological response.

inducible protein: Protein that is produced in amounts that depend on conditions in the environment.

inflammation: Nonspecific local defense mechanism that is characterized by swelling, warmth, redness and, pain in a part of the body.

inhibin: Glycoprotein hormone secreted by the gonads that inhibits its secretion of follicle-stimulating hormone. It consists of a glycosylated α chain linked to a β_A chain (inhibin A) or to a β_B chain (inhibin B) by a disulfide bond.

inhibitory G protein (Gi): Heterotrimeric G protein that inhibits adenylate cyclase or regulates ion channels.

inhibitory neurotransmitter: Neurotransmitter (e.g., GABA, glycine) that opens transmitter-gated channels for Cl^- or K^+ in the target cell plasma membrane and makes formation of an action potential more difficult.

initiation codon: Nucleotide triplet AUG that codes for methionine as the first amino acid residue during polypeptide synthesis in eukaryotes and for *N*-formylmethionine in prokaryotes, mitochondria and chloroplasts.

innate immunity: Antigen-nonspecific mechanisms involved in the early phase of the response to a pathogen. It is not increased by repeated presence of the pathogen and includes phagocytic cells, the complement proteins and secretion of cytokines.

insertion mutation: Mutation that results from addition of one or more extra nucleotides into coding DNA.

integral protein: Protein that traverses a cell membrane one or more times and can only be released by disruption of the membrane. Also called transmembrane protein and intrinsic protein.

integrin: Heterodimeric intrinsic protein of plasma membrane that links a cell to proteins of the extracellular matrix (e.g., collagen and laminin) or to other cells including white blood cells and platelets.

intercalating agent: Dye or other compound that contains an aromatic ring or other planar structure that can fit between two successive bases of DNA and may cause insertion or deletion mutations.

interchain: Interaction or linkage between parts of two strands of a biopolymer.

interconvertible enzyme: Enzyme whose activity is modulated by a reversible posttranslational modification (e.g.. phosphorylation).

interferon (IFN): Protein released by cells infected by a virus or in response to other inducing agents. IFNα is secreted by leukocytes, IFNβ by fibroblasts, and IFNγ by macrophages and B cells. IFNs have nonspecific antiviral and anticancer activity.

intermediate filament (IF): Rope-like fiber (10 nm diameter) of the cytoskeleton that consists of one of a variety of IF proteins depending on cell type. The IFs of the nuclear lamina are composed of lamin proteins.

intermediate filament protein: Protein component of intermediate filaments of the cytoskeleton or nuclear lamina.

interphase: Major portion of the cell cycle in which the chromosomes are uncoiled and form chromatin between one M phase and the next.

intervening sequence: See intron.

intrachain: Interaction or linkage between parts within a strand of a biopolymer.

intrinsic factor: Glycoprotein secreted by parietal cells of the gastric mucosa that binds and facilitates absorption of cobalamin (vitamin B_{12}). Its deficiency, as from gastric atrophy, results in pernicious anemia.

intrinsic protein: See integral protein.

intron: Segment of noncoding DNA in a eukaryotic gene that is transcribed but is then excised from the primary transcript. Also called intervening sequence.

invariant residue: Amino acid residue that occurs in the same position in a homologous polypeptide derived from a different species.

ion channel: Integral membrane protein that provides regulated passage for a specific ion or ions across a membrane.

ionophore: Compound (often an antibiotic) that increases ion flux across a plasma membrane by forming an ion channel or functioning as a mobile ion carrier in the membrane.

isoaccepting tRNA: tRNA species that accepts the same amino acid as another tRNA species but has a different anticodon.

isoenzyme: Protein that can catalyze the same reaction as one or more different proteins from the same species. Also called isozyme.

isomerase: Enzyme that catalyses transfer of a group within a molecule to yield an isomeric form.

isopeptide bond: Amide bond formed between an amino group of an amino acid and the carboxyl group of another where either or both occupy a position other than α (C-2).

isoprenoid: Lipid (e.g.. a steroid or lipid-soluble vitamin) that is structurally derived from isoprene units.

isoschizomer: Restriction endonuclease that cleaves at the same nucleotide sequence as another such enzyme.

isozyme: See isoenzyme.

jaundice: Yellowing of skin and conjunctiva due to elevated plasma and tissue bilirubin concentration caused by overproduction or under excretion of this bile pigment.

junk DNA: Regions of DNA in a genome for which no function has yet been discovered.

KDEL: C-terminal tetrapeptide (Lys-Asp-Glu-Leu) signal for retention of proteins resident in the endoplasmic reticulum.

keratin: Fibrous protein that is a coiled-coil consisting of a type I (acidic) and a type II (neutral or basic) polypeptide cross-linked by disulfide bonds. They form a family of intermediate filament proteins synthesized by keratinocytes in epithelial tissues. Over 20 types occur in human epithelia, and at least 10 are specialized for hair and nails.

ketimine: Product of the condensation of a primary amine with a ketone. Also called Schiff base.

Keto acid: Organic acid such as pyruvic acid or oxaloacetic acid that contains a keto group adjoining the carboxylic group (an α-keto acid) or elsewhere.

ketogenesis: Production of acetoacetate and its derivatives, β-hydroxybutyrate and acetone, within the mitochondrial matrix in liver from the acetyl CoA, derived mainly from the increased catabolism of fatty acids that occurs during prolonged fasting.

ketone bodies: Acetoacetate and its derivatives, β-hydroxybutyrate and acetone, which are made by ketogenesis in the liver and become an important fuel for non-hepatic tissues during prolonged fasting.

killer T cell: Type of lymphocyte involved in cell-mediated immunity that secretes pore-forming proteins (perforans) that kill the target cells.

kilobase pair (kb): Unit of length of DNA, 1000 base pairs.

kinesin: Cytosolic motor protein that associates with an organelle and uses the energy of ATP to propel it along a microtubule.

kinetochore: Complex protein structure that links each sister chromatid to the spindle microtubules during metaphase.

knockin: Functional DNA genetic sequence introduced into germ cells of an organism by genetic-engineering technology.

knockout: Deleted or inactivated DNA genetic sequence produced in germ cells of an organism by genetic-engineering technology.

L chain: See light chain.

lactase deficiency: See lactose intolerance.

lactate cycle: See glucose–lactate cycle.

lacteal: Lymph vessel that extends into the core of a villus in the small intestinal mucosa into which chylomicrons are passed during absorption of ingested lipid.

lactic acidosis: Condition in which blood pH is lowered by an excess of lactic acid. It results from severe exercise, shock, hypoxia, cardiovascular insufficiency, intoxication by certain drugs, or as part of several inborn errors of metabolism.

lactose intolerance: Condition characterized by acid diarrhea and flatulence produced by the inability to digest lactose and resulting from intestinal lactase deficiency. Also called lactase deficiency.

lagging strand: DNA strand that is synthesized discontinuously and away from the replication fork during replication.

lamin: Protein component of intermediate filaments of the nuclear lamina. It may be isoprenylated for attachment to the inner surface of the nuclear membrane.

laminin: Flexible major component of basal lamina that consists of three long polypeptides (α, β, and γ) held together by disulfide bonds in the shape of a cross. It binds to the surface of cells and to other constituents of the basal lamina. Mutations in some forms of laminin are associated with epidermolysis bullosa.

leader sequence: Sequence of nucleotides, which may be coding or noncoding, that is present upstream of the initiation codon in mRNA and may have regulatory or targeting function. Also signal sequence of proteins synthesized on bound ribosomes.

leading strand: DNA strand that is synthesized continuously in the direction of the replicating fork during replication.

lectin: Highly specific carbohydrate-binding protein of plasma membranes, lumen of trans-Golgi network, or blood plasma.

leucine zipper protein: Protein that dimerizes by coiled-coil formation via interaction between leucine zippers that may be immediately preceded by a region rich in basic residues that form an α helix or a helix–loop–helix fold.

leucine zipper: Structural motif present in many DNA-binding proteins that dimerize via coiled-coil formation by interaction between the side chains of leucine residues in tandem heptad repeats within α-helical regions.

leukotriene: Eicosanoid produced by leukocytes, macrophages, and platelets from arachidonic acid, that contains four double bonds of which three are conjugated, and may be linked to glutathione, cysteinylglycine, or cysteine through their sulfur atom. Leukotrienes activate and attract leukocytes, increase capillary permeability, and are involved in inflammatory or immediate hypersensitivity reactions.

ligand: Small molecule that binds specifically and noncovalently to a larger one.

ligase: Enzyme that catalyzes bond formation between two substrates which is coupled with hydrolysis of ATP or another energy-rich compound. Also called synthetase.

light chain: Smaller of two types of polypeptide in a protein. Also called L chain.

lipid-anchored protein: See lipid-linked protein.

lipid-linked protein: Peripheral protein attached to a membrane by a fatty acyl (myristoyl or palmitoyl), isoprenoid (farnesyl or geranylgeranyl), or glycosylphosphatidylinositol group. Also called lipid- anchored protein.

lipogenesis: The *de novo* synthesis of fatty acids from sugars (mainly glucose and fructose), amino acids, and ethanol.

lipoic acid (lipoate): 6,8-Dithiooctanoic acid, that may exist in oxidized or reduced form and is joined in amide linkage to the side chain of a lysine residue in the dehydrogenase complexes specific for pyruvate, α-ketoglutarate or branched-chain α-keto acids.

lipolysis: The hydrolysis of triglycerides that generates glycerol and fatty acids.

lipophilic: Hydrophobic, soluble in lipid.

lipoprotein: Multimolecular complex of protein, phospholipid, and cholesterol that encloses a core composed of triacylglycerols, cholesterol esters, or other lipids.

liposome: Artificial vesicle that consists of one or more closed concentric phospholipid bilayers that enclose some of the suspending aqueous medium in the central compartment.

lipoxin: Eicosanoid produced in leukocytes from arachidonic acid that contains four conjugated double bonds and functions in an autocrine or paracrine manner.

locus: Particular site on a chromosome where a gene for a particular trait is located.

lyase: Enzyme that catalyzes elimination of a group from a molecule with formation of a double bond.

lymphocyte: Spherical leukocyte with a large nucleus and sparse cytoplasm, the predominant cell in lymphoid tissue. It is either a B cell and responsible for antibody-based immunity or a T cell and responsible for cellular immunity.

lymphokine: Cytokine secreted by activated lymphocytes.

lysosome: Cytoplasmic membrane-bounded organelle rich in hydrolytic enzymes for degrading and recycling unneeded cell components.

lysozyme: Enzyme of egg white and human body fluids that, by hydrolyzing polysaccharides in the cell wall of some bacteria, has antibiotic properties.

M phase: Portion of the cell cycle in which the nucleus and cytoplasm divide to form two daughter cells.

M protein: Abnormal protein present in plasma in myelomatosis. Also called myeloma protein or paraprotein.

macromolecule: Large polymeric molecule characteristic of living matter, formed by joining together of small subunits. Polysaccharides, polypeptides, and nucleic acids are macromolecules.

macrophage: Mononuclear actively phagocytic cell that migrates into tissues and ingests particulate material such as microorganisms and dead cells. It is rich in lysozyme and lysosomes and an oxidative system that is microbicidal when activated.

major histocompatibility complex (MHC) protein: Integral membrane glycoprotein of antigen-presenting cells that carries on its extracellular region a peptide derived by intracellular digestion of a protein antigen during synthesis of the MHC protein. Also called human leukocyte antigen (HLA).

malignant: Quality of a tumor or cell that grows rapidly and is invasive.

mast cell: Cell of connective tissue that on stimulation initiates an inflammatory response by releasing histamine, serotonin, heparin and other constituents.

matrix: Aqueous fluid of the cytoplasm, nucleus, or other cell compartment.

M-cyclin: Cyclin that regulates progression of the cell cycle from G_2 phase to M phase.

MDR protein: See multidrug resistance protein.

mechanism-based inhibitor: See suicide inhibitor.

melatonin: *N*-acetyl-5-methoxytryptamine, synthesized in the pineal gland in amounts that vary in a daily cycle and is involved in regulation of several functions that also exhibit a daily cycle.

membrane potential: Difference in charge across the plasma membrane of a cell (positive outside, negative inside) caused by unequal distribution of ions between the extracellular fluid and the cytoplasm.

memory B cell: Long-lived non-proliferating lymphocyte that retains a memory of a previous immune response to an antigen.

metabolic syndrome: See syndrome X.

metabolic turnover: Continuous breakdown and synthesis of biomolecules within living cells.

metabolite: Substance that participates as an intermediate in metabolism.

metal ion catalysis: Catalysis that occurs when an enzyme-bound metal ion participates in labilizing a substrate.

metaphase: Stage in cell division when the nuclear membrane disintegrates, chromosomes line up at the equatorial plan, and microtubules growing from their centromeres attach to those of the mitotic spindle.

micelle: Spherical particle made up of amphipathic compounds such as bile acids, fatty acids, and monoacylglycerols, that form a hydrophilic surface and a hydrophobic interior that contains virtually no water.

microarray: Glass slide or other support on which is mounted a large collection of known, short DNA sequences that is used to monitor the expression of many genes simultaneously.

microfilament: Fibrous (5 to 9 nm in diameter) component of the cytoskeleton and of the contractile part of skeletal and cardiac muscle. It consists of actin and functions in cell structure and in movement. Also called actin filament.

microsome: Small membranous vesicle produced by fragmentation, mostly of the endoplasmic reticulum, on homogenization of eukaryotic cells.

microtubule: Long, hollow cylindrical structure (25 nm diameter) of the cytoskeleton. It is composed of tubulin and is present in cilia, flagella, centrioles, and spindle fibers.

microvillus: Small finger-like extension of the exposed cell membrane of an epithelial cell in the intestinal mucosa or renal tubules that enhances absorption. A dense covering of microvilli constitutes a brush border.

mineralocorticoid: Steroid hormone (e.g. aldosterone) secreted from the adrenal cortex that affects mineral metabolism by enhancing renal absorption of Na^+ and excretion of K^+ and H^+.

mismatch repair: Enzymatic repair of a DNA strand that contains a base that cannot pair properly with that of the complementary strand.

missense mutation: Mutation in which substitution of a nucleotide that is part of a coding triplet changes the codon to one for another amino acid.

mitochondrial DNA (mtDNA): Each mitochondrion contains several copies of closed-circular double-stranded DNA molecule. In humans each mtDNA molecule contains about 16,600 base pairs and codes for 13 polypeptides of the electron transport chain, 2 for mitochondrial rRNA, and 22 for mitochondrial tRNA species.

mitochondrial signal sequence: Usually an N- terminal sequence of residues that can form an amphipathic helix that directs polypeptides synthesized on free ribosomes for entry across the mitochondrial membranes and is removed by a signal peptidase soon after its entry.

mitogen: Protein (e.g., platelet-derived growth factor) that stimulates cell division primarily by acting at the restriction point of the cell cycle.

modular protein: Polypeptide that contains two or more modules with specific binding properties that are also found in other polypeptides alone or in various combinations.

modulator: Molecule that binds the allosteric site of an enzyme and increases or decreases its activity. Also called allosteric effector.

module: Autonomously folding unit or domain of a polypeptide that usually functions as a specific binding site.

molar solution: Aqueous solution that contains one mole of solute in a total volume of 1000 mL.

mole: Amount of a substance that is its molecular weight in grams.

molecular chaperone: See chaperone.

monoclonal antibody: Antibody produced under laboratory conditions by cloned hybridoma cells which are therefore genetically identical and produce antibody against the same antigenic epitope.

monokine: Cytokine released by monocytes.

monotopic protein: Integral membrane protein that spans the membrane once. Also called single-pass protein.

motif: Supersecondary structure or fold (e.g., β-α-β, zinc finger) that is present in different polypeptides. Also a set of amino acid residues present in different polypeptides or of nucleotides in nucleic acids, that is associated with a particular function (e.g., KDEL in ER-resident proteins, TATA in some promotor sequences).

motor domain: Globular head that has ATPase activity in motor proteins such as myosin.

motor protein: Cytosolic dimeric protein that consists of two globular heads with ATPase activity and a coiled-coil body, that propels itself along a filament or microtubule.

mucus: Viscous secretion composed of water and glycoproteins called mucins that are produced by cells of the mucosa of respiratory, gastrointestinal, and urogenital tracts, and lubricates and forms a protective barrier as a sticky trap for foreign particles and microorganisms.

multicatalytic polypeptide: Polypeptide that contains two or more catalytic sites (e.g., mammalian fatty acid synthase).

multidrug resistance protein (MDR protein): ABC transporter protein that transports hydrophobic natural products or synthetic drugs out of the cytoplasm across the plasma membrane.

multienzyme complex: Cluster of catalytic proteins (enzymes) that are isolated together and catalyze several related metabolic reactions (e.g., pyruvate dehydrogenase complex).

multipass protein: Integral protein that spans a membrane two or more times. Also called polytopic protein.

muscarinic receptor: Serpentine receptor of plasma membrane that binds acetylcholine or the alkaloid muscarine and activates a trimeric G protein to modulate adenylate cyclase, K^+ channels or phospholipase C, thereby transmitting a nerve impulse.

mutagen: Physical or chemical agent that induces a change in DNA that converts one allele into another. Mutagens are frequently carcinogenic.

myelin: Specialized cell membrane that ensheathes an axon to form a myelinated nerve fiber in peripheral nerves (where it is produced by Schwann cells) and in the central nervous system (where it is produced by oligodendrocytes). It is rich in glycolipid and specific proteins.

myelomatosis: Condition in which a cancerous B cell proliferates to produce one or more tumors that secrete a single type of immunoglobulin or of its constituent polypeptides. The abnormal protein (M protein or paraprotein) is detectable in plasma and frequently in urine (Bence Jones protein).

myoblast: Undifferentiated mononucleated cell that develops into a fiber of a skeletal muscle cell.

myofibril: Contractile filament that consists of actin filaments, myosin and associated proteins within a muscle cell.

nebulin: Large fibrous polypeptide that is associated with the thin filament of muscle sarcomeres and stretches from the Z line to the M line. It is made up almost entirely of repeating actin-binding motifs.

necrosis: Death of cells or tissues from injury or disease while part of the body. The cells swell, burst, and spill their contents into their environment and may induce an inflammatory response.

negative feedback: Metabolic regulation in which a late product of a pathway inhibits an enzyme that functions early in that pathway. Also called feedback inhibition.

N-end rule: Rule stating that the half-life of a cytoplasmic protein is determined by the identity of its N-terminal residue. Also called Varshavsky rule.

network-forming collagen: Type of collagen (e.g., type IV) that forms a meshwork-like structure in the basal lamina of epithelia.

neurofilament: Type of cytoskeletal intermediate filament present in nerve cells and axons, being a heterodimer of neurofilament proteins NF-L, NF-M, or NF-H.

neuroglia: Supporting nonneural cells (microglia, oligodendrocytes, or astrocytes) of the central nervous system. These cells provide trophic substances to neurons, maintain a balance between glutamate and GABA, and are responsible for myelin formation. Also called glial cells.

neuromodulator: Neuropeptide secreted, usually with one or more neurotransmitters, that modulates the sensitivity of another neuron to specific neurotransmitters.

neuropeptide: Peptide secreted at synapses or elsewhere by a neuron to exert an effect on neighboring cells.

neurosecretory cell: Neural cell (e.g., in hypothalamus or neuronal plexuses of gastrointestinal tract) in which the axon ends against a blood vessel or sinus into which it secretes a hormone rather than transmitting an electrical impulse.

nicotinic receptor: Multimeric integral protein of plasma membrane that binds acetylcholine or the alkaloid nicotine and causes depolarization, thereby transmitting a nerve impulse. It consists of α, β, γ, and δ type of subunits.

N-linked glycoprotein: Glycoprotein that contains a high-mannose or complex oligosaccharide linked to the side-chain amide group of an asparagine residue.

N-linked glycosylation: Enzymatic transfer to the side-chain amide of an asparagine residue in a polypeptide of an oligosaccharide that has been synthesized in the ER lumen on dolichol present in the ER membrane.

nonconservative substitution: Replacement in a polypeptide of a residue by another of different characteristics (e.g., glutamate by valine).

nonsense codon: Nucleotide triplet that does not code for any amino acid but signals termination of translation of a mRNA. Also called stop codon.

nonshivering thermogenesis: Production of heat by oxidation of fatty acids in mitochondria of brown adipose tissue without synthesis of ATP.

Northern blotting: Technique in which RNA of a particular base sequence is identified, after electrophoretic separation from a complex mixture and transfer to a blotting surface, by hybridization with a labeled complementary nucleic acid probe.

N-terminus: End of a peptide or polypeptide that contains the (usually) free amino group of the first residue. Also called amino terminus.

nuclear export receptor: Soluble protein of the nuclear matrix that binds to the export signal of macromolecules for transfer from the nucleus into the cytoplasm. The receptor also binds to components of the nuclear pore complex and guides transport out of the nucleus across the nuclear pore complex.

nuclear export signal: Part of a macromolecule (e.g., ribosomal subunit, tRNA, or mRNA) that is bound by a nuclear export receptor as a prerequisite for passage across a nuclear pore complex into the cytoplasm.

nuclear import receptor: Soluble cytosolic protein that binds the nuclear localization signal of a protein to be transferred from cytoplasm into the nucleus. It also binds components of the nuclear pore complex and guides transport inward across the nuclear pore complex.

nuclear import signal: See nuclear localization signal.

nuclear lamina: Network of intermediate filaments composed of lamins that is anchored to the inner surface of the nuclear membrane and provides attachment sites for chromosomes and the nuclear pore complex.

nuclear localization signal: One or two basic oligopeptide regions which may be situated anywhere in the sequence of a nuclear protein and which signal its transfer from cytoplasm into the nucleus via the nuclear pore complex by an energy-dependent process. Also called nuclear import signal.

nuclear pore complex: Large structure composed of proteins (nucleoporins) in the nuclear membrane, that permits selective movement of proteins and nucleic acids between the nuclear matrix and the cytoplasm.

nuclear receptor superfamily: Family of intracellular receptors for hydrophobic hormones, (thyroid hormones, steroid hormones, retinoids, 1,25-dihydroxyvitamin D_3, and other signalling molecules. They contain zinc-finger motifs that bind at specific response elements in DNA and act as transcription factors. For some family members (orphan receptors), the ligand has not been characterized.

nuclease protection assay: Method for detection and quantitation of particular RNA species in a complex mixture of cellular RNA. A small antisense probe for the target RNA is used for hybridization, followed by nuclease digestion of unhybridized material, inhibition of the nuclease, and precipitation of the hybridized material.

nucleation: Formation of an initial structure during folding of a polypeptide, during renaturation of DNA or RNA, or during assembly of a polymeric structure.

nucleoid: Dense region that contains the DNA in prokaryotic cells. Also the cluster of DNA within a mitochondrion or chloroplast.

nucleolus: Structure within the nucleus where rRNA is transcribed from decondensed chromatin that contains highly amplified genes for rRNA and where ribosomal subunits are assembled from rRNA and specific proteins imported from the cytoplasm.

nucleoporin: Any protein component of the nuclear pore complex.

nucleosome: Fundamental structural subunit of chromatin, formed by wrapping of a segment of DNA twice around a histone core plus linker DNA, and its attached histone H1 that joins the adjacent nucleosomes.

nucleotide coenzyme: Coenzyme that resembles (e.g., FMN) or contains a nucleotide as a component (e.g., FAD, NAD, NADP, or CoA).

nucleotide excision repair: Correction of a lesion that distorts the helical structure of a DNA strand by removal of the abnormal segment by an excinulease and filling up of the gap by DNA polymerase and DNA ligase.

nucleotide sugar: Nucleoside diphosphate sugar, e.g., UDP-galactose, that is a substrate for a glycosyl transferase.

nucleotide-binding fold: Protein structural motif present in many enzymes that bind ATP or nucleotide coenzymes (e.g., NAD). It consists of a β–α–β–α–β fold. One fold is present in ATP-binding proteins, two in those which bind dinucleotide coenzymes. In each case the β-strands form a parallel sheet. Also called dinucleotide fold and Rossmann fold.

Okazaki fragment: DNA (100–200 nucleotides long in eukaryotic cells) produced on the lagging strand by extension of a primer RNA sequence.

oligomer: Short polymer consisting of amino acids, monosaccharides, or nucleotides. Also a protein that consists of more than one subunit.

oligopeptide: Peptide that contains up to 10 amino acid residues (approximately).

O-linked glycoprotein: Glycoprotein that contains a monosaccharide or an oligosaccharide bound to the side-chain hydroxyl group usually of serine or threonine.

O-linked glycosylation: Addition of a monosaccharide or stepwise addition of an oligosaccharide to a hydroxyl group, usually of a serine or threonine residue, in a polypeptide.

oncogene: Mutant version of DNA genetic sequence (a protooncogene), which by interfering with normal cell growth or division, results in uncontrolled cell proliferation and formation of a benign or malignant cancer.

oncogenesis: Conversion of a normal cell into a benign or malignant cancer cell, one in which cell proliferation is uncontrolled.

open-reading frame (ORF): Section of genomic DNA that contains about 100 or more nucleotide triplets that code for amino acids, beginning with an initiation codon and ending with a termination codon, that potentially codes for a polypeptide.

ordered reaction: Reaction in which binding of substrates to, and release of products from, an enzyme follow a particular sequence.

organelle: Intracellular structure that may be membrane bounded (e.g., a nucleus) or not (e.g., ribosomes) and performs a specific function or group of functions.

organic aciduria: Presence of abnormal amounts of an organic acid in urine (e.g., one or more amino acids, methylmalonic acid, orotic acid, or uric acid).

organogenesis: Formation of an organ during embryonic and fetal development as a result of programmed expression or repression of specific genes.

origin of replication complex (ORC): Multisubunit protein complex that binds at origins of replication in chromosomes throughout the cell cycle and recruits additional regulatory proteins during G_1 phase.

orphan receptor: Member of the nuclear receptor superfamily for which the ligand has not been identified.

osmotic pressure: Pressure generated by flow of solvent across a semipermeable membrane from a more concentrated solution on one side to a less concentrated solution on the other.

osteoblast: Bone-forming cell that produces and secretes collagen and other material of the bone matrix.

osteoclast: Macrophage-like cell that erodes bone by digesting and dissolving the bone matrix.

osteomalacia: Condition in adults characterized by softening of bones from lack of mineralization and excessive excretion of calcium and phosphate. It results from dietary deficiency or malabsorption of vitamin D.

oxidant: Reactant that accepts one or more electrons and becomes reduced in a redox reaction.

oxidative phosphorylation (oxphos): Phosphorylation of ADP to ATP that is coupled to electron transfer from metabolic fuels and dependent on the electron transfer chain and formation of a proton gradient across the inner mitochondrial membrane (respiration-linked phosphorylation).

oxidoreductase: Enzyme that catalyzes an oxidation–reduction reaction using NAD, NADP, FMN, or FAD as coenzyme.

oxyntic cell: Type of cell in the gastric mucosa that secretes hydrochloric acid and intrinsic factor. Also called parietal cell.

P site: See peptidyl site.

p53: Gene regulatory protein (53 kDa) that is activated by DNA damage and involved in cell cycle control, apoptosis, and maintaining genetic stability. It is mutated in about half of human cancers.

palindrome: Segment of double-stranded DNA in which the base sequences in both strands are inverted repeats that have the same sequence when read in the same chemical direction.

pantetheine: *N*-pantothenylcysteamine, derived from pantothenic acid and decarboxylated cysteine. A structural component of coenzyme A.

paracrine hormone: Hormone that is secreted by a cell into the extracellular space and acts on neighboring cells.

parathyroid gland: One of several (usually four) small glands embedded in the posterior surface of the thyroid gland that secrete parathyroid hormone that increases osteoclastic activity and raises calcium and decreases phosphate concentrations in plasma.

parietal cell: See oxyntic cell.

passive transport: See facilitated diffusion.

pathway: Particular sequence of metabolic reactions.

pentose phosphate pathway: Metabolic pathway for interconversion of hexose and pentose phosphates that generates NADPH and ribose-5-phosphate for biosynthetic processes

peptidyl site: Site on a ribosome that binds peptidyl-tRNA during protein synthesis. Also called P site.

peptidyl transferase: Catalytic activity that transfers the growing peptide chain from the peptidyl-tRNA to the amino group of the incoming aminoacyl-tRNA during polypeptide synthesis. The activity resides in the 23S rRNA of the large subunit of bacterial ribosomes.

peptidyl-tRNA: tRNA carrying the growing peptide chain during polypeptide synthesis.

peripheral protein: Protein that is associated with a membrane surface but does not span the membrane and can be released without disruption of the membrane. Also called extrinsic protein.

perlecan: Proteoglycan of the basal lamina that consists of heparin sulfate attached to a very large polypeptide.

peroxisomal signal sequence: Sequence Ser-Lys-Leu (SKL) at the C-terminus of many polypeptides synthesized on free ribosomes that targets them for import into peroxisomes.

PEST sequence: Sequence motif rich in proline, glutamate, serine, and threonine residues, which targets a polypeptide for rapid degradation within a cell.

phagocyte: Cell (e.g., a macrophage or neutrophil) specialized for engulfing and ingesting particles and microorganisms.

phagocytosis: Endocytosis of large particles and microorganisms by macrophages and neutrophils.

phagosome: Large membrane-bounded vesicle that contains material ingested by phagocytic cells. On fusing with a lysosome, the material is degraded or, if nondigestible, forms a residual body.

phase 1 reaction: Metabolic reaction (e.g., oxidation, reduction, or hydrolysis) in biotransformation that introduces or unmasks functional groups that make the product more water soluble.

phase II reaction: Metabolic reaction (e.g., acylation, sulfation, or conjugation with glucuronate) that usually follows a phase I reaction in biotransformation and inactivates the product and makes it water soluble for excretion.

phenotype: Observable characteristics of an individual determined by interaction of the environment with the genotype.

phosphagen: Compound such as creatine phosphate that stores high-energy phosphate which is used to form ATP when required.

phosphoinositide pathway: Sequence of reactions of signal transduction in which a hormone binding to a serpentine receptor activates a trimeric G protein to stimulate hydrolysis of phosphatidylinositol-4,5-bisphosphate (PIP_2) into the second messengers inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG).

ping-pong reaction: Group-transfer reaction in which a functional group of a substrate is transferred onto an enzyme with release of a product, and the group is then transferred onto a second substrate with release of second product. Also called double displacement reaction.

plaque: Deposit of insoluble material in a tissue, for example, the fatty degeneration in the middle coat of an artery in atherosclerosis and the β-amyloid fibrils in the brain in Alzheimer disease.

plasma cell: Fully differentiated B lymphocyte that secretes antibodies. It arises from bone marrow in adults and from the liver in the fetus.

plasma membrane: Outer bounding membrane of a cell.

plasma: Protein-rich fluid portion of whole blood that has been prevented from clotting.

platelet: Small cell fragment consisting of cytoplasm derived by fragmentation from megakaryocytes in the bone marrow, present in large numbers in blood and important for initiating clotting of blood on damage to a blood vessel.

platelet-derived growth factor (PDGF): Protein that consists of two homologous polypeptides joined by disulfide bonds, is secreted by platelets and several other tissues, and is mitogenic for mesenchymal and glial cells. It exerts its effect by binding to a receptor tyrosine kinase.

point mutation: Replacement of a complementary base pair in DNA by a different base pair. Also called base-pair substitution.

polar bond: Covalent bond in which electrons are unequally shared.

polarity: Nonuniform distribution of electrons or charge in a molecule, also the distinction between the 5′ and 3′ ends of a nucleic acid.

polyA tail: Polyadenylate (up to 250 nucleotides long) at the 3′ end of mRNA that is added during pre-mRNA processing.

polyclonal antibody: Mixture of antibodies produced by different B cells in response to an antigen, each recognizing a different part of the antigen.

polyhormone: Polypeptide that is cleaved into more than one copy of a peptide hormone or more than one peptide hormone.

polyprotein: Polypeptide that is cleaved into two or more distinct polypeptides.

polysome: Cluster of ribosomes on an mRNA molecule each in the process of translating the mRNA. Also called polyribosome.

polytopic protein: See multipass protein.

porphyria: Condition characterized by accumulation in the urine of porphyrins and/or of their intermediates in the heme synthesis pathway. It may be secondary to hepatic cirrhosis or to lead poisoning or primary and result from hereditary increase or decrease in activity of an enzyme in this pathway.

positive feedback: Intracellular signaling process in which the output increases its own production.

postabsorptive state: Physiological condition of the body 3–4 h after a meal until the mobilization of metabolic reserves commences.

posttranscriptional processing: Covalent modification of a primary RNA transcript into a functional molecule of mRNA, tRNA or rRNA.

posttranslational modification: Covalent modification of one or more residues of a polypeptide after its synthesis; also limited proteolysis of the polypeptide. Also called posttranslational processing.

posttranslational processing: See posttranslational modification.

precursor mRNA (pre-mRNA): Primary transcript of a gene that encodes a polypeptide.

prenylation: Enzymatic transfer of a prenyl moiety (i.e., geranyl, farnesyl, or geranylgeranyl) to a cysteine residue within the C-terminal region of a polypeptide.

preproprotein: Proprotein with an attached N-terminal signal peptide. The precursor of a secreted proprotein.

primary structure: Sequence of amino acids in a polypeptide or of nucleotides in a nucleic acid.

primary transcript: RNA as transcribed from a gene for a polypeptide or for functional RNA, before any posttranscriptional processing has occurred.

primase: Enzyme that synthesizes an RNA that is a primer for synthesis of DNA by DNA polymerase.

primer: Oligosaccharide or oligoribonucleotide on to which other monomers can be added by an appropriate enzyme.

primosome: Complex consisting of primase and DNA helicase that synthesizes an RNA primer that initiates DNA replication.

prion: Protein that can exist in two 3-dimensional conformations, a normal one that is noninfectious and an abnormal one that is infectious. The latter can then induce the former in a host organism to assume the infectious form.

probe: Labeled polynucleotide with sequence complementary to that of a gene or other piece of DNA that is used to hybridize and detect that DNA.

processive enzyme: Polymerase that remains bound to its growing product through many additions of monomeric units.

proenzyme: See zymogen.

prokaryote: Single-celled organism that lacks a membrane-bounded nucleus.

promoter: Specific segment of DNA adjacent to a gene at which RNA polymerase binds to initiate transcription of that gene; also a compound that promotes growth of a tumor.

propeptide: Peptide segment present at the N-terminus or within a polypeptide that must be removed to produce one or more functional polypeptides.

properdin: Plasma glycoprotein of the alternative pathway of the complement system that enhances binding of components of that system to bacterial cell walls without dependence on antibody binding.

prophase: Opening stage of cell division when chromosomes appear, the nuclear membrane starts to disintegrate and the mitotic spindle starts to form.

proprotein: Polypeptide that contains a propeptide segment that when removed, produces one or more functional polypeptides.

proteasome: Cylindrical ATP-dependent proteolytic protein complex that degrades cell proteins that are marked for degradation by ubiquitination or other means.

protein family: Group of proteins that resemble each other in primary structure and in their overall conformation.

protein targeting: Mechanism by which newly synthesized polypeptides are selected and directed to their proper final location.

protein translocator: Intrinsic protein that mediates transport of a protein across an organelle's membrane (e.g., TIM or TOM complexes).

proteogenic: α-Amino acid that is used in protein biosynthesis.

proteoglycan: Macromolecule consisting of one or more glycosaminoglycan chains attached to a core protein, the former making up the largest component.

proteomics: Study of the protein complement of a cell, tissue, organ, or organism under different conditions.

protofilament: End-to-end assemblage of protein subunits that associates laterally with similar structures so as to form fibrils such as cytoskeletal components.

proton pump: Ion channel, specific for rapid transport of protons across a membrane, that is coupled to hydrolysis or synthesis of ATP.

pseudogene: Segment of DNA that is homologous in sequence to a particular gene but contains several termination codons and, if transcribed, does not produce a functional product.

P-type ATPase: ATPase of plasma membrane of animal cells whose function is changed by reversible phosphorylation of an aspartate residue (e.g., Na^+-K^+-ATPase, Ca^{2+}-ATPase and H^+/K^+-ATPase) (of stomach). It usually consists of two α and two β transmembrane subunits.

purine nucleotide cycle: Metabolic cycle of muscle in which AMP is deaminated to IMP and is then reformed by transfer of the amino group of aspartate with production of fumarate.

Q cycle: Model proposed for the cyclic flow of electrons through complex III of the electron transport chain, cytochrome C and coenzyme Q.

quaternary structure: Overall structure of a protein that results from interaction between protein subunits.

ragged red fiber: Muscle fiber with enlarged and abnormal mitochondria that contain highly organized inclusions and appear red on special staining. Such fibers are usually associated with mitochondrial disease.

Ran: Monomeric G protein with GTPase activity that is required for active transport of macromolecules across a nuclear pore complex.

random reaction: Reaction in which there is no preference for the sequence of binding of substrates or release of products.

Ras: Monomeric G protein with GTPase activity that is attached to the inner surface of the plasma membrane and participates in transduction of signals for growth factor receptors along a variety of pathways. A hyperactive mutant is present in about 25% of human cancers.

rate-determining step: See rate-limiting step.

rate-limiting step: Slowest reaction in a metabolic pathway or the slowest step in an enzyme-catalyzed reaction. Also called rate-determining step.

reading frame: Sequence in mRNA of contiguous coding triplets that are preceded by a start codon and end in a stop codon.

receptor tyrosine kinase: Integral protein of plasma membrane that is a hormone receptor and has a tyrosine kinase domain in its intracellular portion.

receptosome: Cytoplasmic vesicle derived by receptor-mediated endocytosis from coated pits on the cell surface following ligand binding to the receptor.

recessive: Gene that affects the phenotype only when it is received from both parents, i.e. in a homozygote. It also describes a trait or character due to such a gene.

recombinant DNA: DNA molecule that consists of DNA sequences joined together from different sources.

redox reaction: Reaction in which oxidation of one reactant is coupled to reduction of a second reactant.

reductant: Reactant that donates one or more electrons and becomes oxidized in a redox reaction.

regulator gene: Gene that codes for a protein that determines the expression of another gene or group of genes.

relaxin: Protein hormone related in structure to insulin-like growth factors. It is secreted by the corpus luteum mainly during pregnancy, relaxes pelvic ligaments, and softens the cervix.

releasing hormone: Peptide hormone secreted by specific neurosecretory cells of the hypothalamus that causes secretion of a hormone of the anterior pituitary.

renin: Proteolytic enzyme secreted by cells of the juxtaglomerular apparatus when blood flow through the kidney decreases. It converts angiotensinogen to angiotensin I.

rennin: Proteolytic enzyme secreted by the stomach of young mammals. It converts the caseinogen of milk into casein, which coagulates and therefore takes longer to leave the stomach.

replisome: Multiprotein complex that contains DNA polymerase and synthesizes the leading and lagging strands of DNA at a replication fork.

repressor: Protein that prevents transcription of a gene or group of genes by binding to the promoter or regulatory sequence.

residue: Monomeric unit in a polypeptide, polysaccharide, or polynucleotide.

respiration-linked phosphorylation: Phosphorylation of ADP to ATP that is dependent on flow of electrons along the electron transfer chain and generation of a proton gradient across the inner mitochondrial membrane.

restriction fragment: Fragment that results from cleavage of DNA by a restriction endonuclease.

restriction-fragment-length polymorphism (RFLP): Inherited variation in length of certain DNA restriction fragments that arises from a change in the nucleotide sequence that destroys or creates a cleavage site for a restriction endonuclease.

restriction point: Time during G_1 phase of the cell cycle when a cell proceeds to the S phase or exits into the G_0 phase.

restriction site: Specific sequence of DNA that is recognized and cleaved by a restriction endonuclease.

retinoid X receptor: A nuclear receptor that is activated by the retinoid 9-cis retinoic acid.

retrograde transport: Transport away from the periphery of an axon.

retrovirus: Virus that has an RNA genome and is transcribed into DNA by its own reverse transcriptase for incorporation into the host cell genome.

reverse genetics: Study of gene function that starts from the DNA that encodes a polypeptide and then creates mutants of that gene.

reverse transcriptase: Retroviral zinc-containing enzyme that catalyses RNA-directed DNA synthesis, RNA-directed degradation, and DNA-directed DNA synthesis. It usually consists of two homologous subunits.

reverse turn: Usually a tetrapeptide segment in a polypeptide at which the chain abruptly changes its direction. Also called β-bend.

ribosomal protein: Protein of the small or the large ribosomal subunit. Generally located on the subunit surface filling gaps and crevices of the folded rRNA which the proteins stabilize.

ribozyme: Catalytic RNA.

Rieske iron–sulfur protein: Transmembrane protein component of complex III of the mitochondrial electron transport chain. It contains a 2Fe2S center in which one of the Fe atoms is coordinated to two histidine residues and the other is coordinated to two cysteine residues.

Rossmann fold: See nucleotide-binding fold.

S phase: Phase of the cell cycle in which DNA and chromosome replication occur.

salvage pathway: Metabolic pathway in which an intermediate (e.g., a purine or pyrimidine) in the degradation of a biomolecule (e.g.. a nucleotide) is reused in synthesis of that biomolecule.

sarcoplasmic reticulum (SR): Network of modified endoplasmic reticulum that surrounds striated and cardiac muscle fibrils, stores Ca^{2+}, and releases it during excitation to trigger contraction. With T tubules, it forms the sarcotubular system.

sarcotubular system: System composed of sarcoplasmic reticulum and T tubules in striated muscle.

satellite DNA: DNA that has a distinctive composition, consists of highly repetitive sequences, and is mostly associated with the centromeres. It forms bands (satellites) separate from those of other DNA on density gradient centrifugation.

saturated fatty acid: Fatty acid that contains a saturated alkyl chain.

Schiff base: See aldimine.

second law of thermodynamics: Law that requires that in any physical or chemical process, the entropy of the universe tends to increase.

second messenger: Ion or biomolecule released or produced at the cell plasma membrane in response to binding of a signal molecule (i.e., the first messenger) to its receptor located therein.

secondary structure: Pattern of regular local folding of a polymeric structure; in proteins formation of α-helices and/or β-sheets.

secretase: Proteolytic enzyme that cleaves certain integral membrane proteins (e.g., β-APP) within the transmembrane segment causing release of the extracellular portion of these proteins.

selectin: Integral carbohydrate-binding protein (or lectin) of leukocytes (L-), platelets (P-), and endothelial cells (E-) that mediates short-lasting Ca^{2+}-dependent cell–cell interactions in the blood stream.

sequential reaction: Reaction in which all substrates must be bound to the enzyme, in random or in specific order, before the reaction can proceed.

serpentine receptor: Integral protein that spans the plasma membrane seven times and binds a hormone, neurotransmitter, or other ligand to activate adenylate cyclase, ion channels, or phospholipase C.

serum: Fluid part of whole blood that is formed naturally when the blood has been allowed to clot. It is plasma that lacks fibrinogen and other proteins involved in clot formation.

sex hormone-binding globulin: Glycoprotein of the plasma globulin group that is secreted by the liver and transports testosterone and estradiol.

sex-linked: Gene that is located on a sex-determining chromosome, usually an X chromosome. Also the trait or characteristic due to such a gene.

sickle-cell anemia: Condition characterized by severe hemolytic anemia and circulating sickle-shaped erythrocytes. It is caused by homozygosity for the β-globin allele in which the normal glutamate in position 6 is replaced by valine.

sickle-cell trait: Usually benign condition associated with the heterozygous state for the hbS allele.

signal patch: Group of nonadjacent residues in a polypeptide that form a specific secondary or tertiary structure as a signal for import into mitochondria or export from the nucleus.

signal recognition particle (SRP): Ribonucleoprotein complex consisting of 7SL-RNA (300 nucleotides long) and six protein subunits that binds an ER signal sequence and directs the ribosome and partially synthesized polypeptide for binding to the surface of the rough ER.

signal sequence: Peptide sequence in a polypeptide that targets it to a specific destination in a cell.

silent mutation: Change in the sequence of a gene that produces no change in the sequence of the encoded protein or RNA.

simple protein: Protein that consists only of α-amino acids.

single nucleotide polymorphism: Change in a single nucleotide in DNA that distinguishes an individual from another of that species.

site-directed mutagenesis: Technique for creation of a specific alteration in a DNA genetic sequence

small-interfering RNA: Species of RNA, 21–26 nucleotides long, that inhibits gene expression by binding to, and leading to the destruction of, complementary mRNA

small nuclear ribonucleoprotein (snRNP): Complex of snRNA and several protein subunits. It forms the core of a spliceosome.

small nuclear RNA (snRNA): RNA component of a small nuclear ribonucleoprotein that is required for RNA splicing.

small nucleolar RNA (snoRNA): Small RNA present in the nucleolus that base pairs with parts of precursor rRNA and specifies methylation of ribose moieties or isomerization of uracil nucleotides to pseudouridine. Also called guide RNA.

SNARE: see synaptosome-associated protein receptor.

Southern blotting: Technique in which one or more DNA fragments in a complex mixture are transferred to a blotting surface and detected by hybridization with a complementary labeled nucleic acid probe.

spectrin: Major cytoskeletal protein of erythrocytes. It consists of two very large homologous polypeptides that each contains numerous copies of a repeat of ~106 residues that forms a triple helix.

spindle apparatus: Array of microtubules formed during cell division at the end of prophase. It radiates from a centriole at each pole to the centromeres of the duplicated chromosomes. It serves to move the sister chromosomes apart. Also called mitotic spindle.

spleen: Lymphoid organ in the abdomen that is perfused by blood and is important for lymphocyte production and for removal of effete, damaged, or abnormal erythrocytes and platelets.

spliceosome: Complex of snRNA and proteins that interacts with the ends of an intron in pre-mRNA causing release of the intron and joining of the freed ends of the adjacent exons.

Src homology 2 (SH2) domain: Module (~100 residues long) present in Src and other proteins that binds oligopeptide sequences that contain phosphotyrosine and are present in many intracellular signalling proteins.

Src homology 3 (SH3) domain: Module (50–75 residues long) present in Src and other proteins that binds a proline-rich oligopeptide sequence that is present in many intracellular signaling proteins.

Src: Family of protein tyrosine kinases anchored to the inner surface of the plasma membrane and associated with the intracellular domain of certain receptors that lack intrinsic catalytic activity. Each contains two important homology domains called SH2 and SH3 domains.

SRP receptor: Heterodimeric integral protein of the rough ER that binds the signal recognition particle bound to the ER signal sequence of a polypeptide being synthesized on a bound ribosome.

stem cell: Self-regenerating cell in a multicellular organism that can differentiate, if its source is an embryo, into any of the embryo's specialized tissues and, if its source is an adult, into the specialized tissue of its origin.

steroidogenic acute regulatory protein: Protein of mitochondrial matrix especially of steroid hormone-producing cells that regulates transfer of cholesterol into that organelle and regulates production of such hormones.

stimulatory G protein (Gs): Heterotrimeric G protein that on activation stimulates adenylate cyclase.

stop codon: See nonsense codon.

structural gene: Gene that codes for a polypeptide or a functional RNA.

substitution mutation: Replacement of one base pair by another in the coding part of a gene. It may be a missense or a nonsense mutation.

substrate-level phosphorylation: Transfer of a high-energy phosphate group from a metabolic intermediate directly to ADP or other nucleoside 5′-diphosphate, in contrast to oxidative phosphorylation.

suicide inhibitor: Molecule devised to inactivate a specific enzyme irreversibly but only after it has become activated by undergoing some chemical change at the active site. Also called suicide substrate, mechanism-based inhibitor.

suicide substrate: See suicide inhibitor.

suppressor T cell: Type of lymphocyte that inhibits activation of antibody synthesis and secretion by B cells.

surfactant: Secretion that coats the surface of pulmonary alveoli, preventing their collapse through lowering their surface tension. It contains phospholipids (mainly bispalmitoyl-phosphatidylcholine) and several specific proteins.

symport: Transport of two different solutes in the same direction across a membrane by a transport protein. Also called cotransport.

synaptosome-associated protein receptor (SNARE): Family of complementary transmembrane proteins involved in vesicle transport in the secretion and the endocytosis pathways. They function in pairs, v- on vesicle and t- on target membrane, and guide the vesicles to their destination. In nerve endings they mediate fusion of synaptic vesicles with presynaptic plasma membrane.

syndrome: Discrete set of signs and symptoms that occur together and indicate a particular disease.

synthase: Enzyme that catalyzes a condensation reaction without need for a nucleoside 5′-triphosphate as an energy source.

synthetase: Enzyme that catalyzes a condensation reaction and requires a nucleoside 5′-triphosphate as an energy source.

T cell: Type of lymphocyte derived from the thymus that is responsible for cell-mediated immunity and regulation of the immune response. It includes regulatory (helper or suppressor) and killer (cytotoxic) T cells.

T system: In skeletal and cardiac muscle a system of tubules formed by invagination of the sarcolemma that transversely contacts the myofibrils and as part of the sarcotubular system transmits the excitation signal to the sarcomeres thus ensuring speedy and synchronous contraction.

TATA box: Conserved DNA sequence rich in A and T that is present in promoter elements of many eukaryotic genes and occurs 25–30 nucleotides upstream of the transcription start site.

telomerase: Ribonucleoprotein complex whose RNA is a template for synthesis of the repetitive DNA of telomeres by the protein component which functions as a reverse transcriptase.

telophase: Final stage in cell division in which the spindle disappears, a nuclear membrane forms around each set of chromosomes which condense to form chromatin, and two daughter cells are formed by constriction of a cleavage furrow that consists mainly of actin filaments.

template strand: Strand of DNA that serves as a template for transcription of pre-mRNA; it is complementary to the sequence of the pre-mRNA.

template: Strand of DNA or RNA whose nucleotide sequence determines the sequence of the complementary strand or, in the case of mRNA, the sequence of the encoded polypeptide.

teratogen: Agent that causes congenital malformations.

tertiary structure: Three-dimensional form of a polymeric chain, especially a polypeptide or RNA molecule, that results from interaction between distant parts.

thymosin: Polypeptide hormone secreted by the thymus that is essential for development and differentiation of T cells.

thyroglobulin: Glycoprotein produced in epithelial cells of the thyroid gland and stored in thyroid vesicles where some of its tyrosine residues are modified to form thyroxine and triiodothyronine which are then released by proteolysis of the protein.

thyroid-stimulating hormone: Glycoprotein hormone secreted by the anterior pituitary gland that stimulates the thyroid gland to secrete thyroxine and triiodothyronine.

TIM complex: Multiprotein complex of inner mitochondrial membrane that translocates proteins into the matrix and in some cases mediates their insertion into that membrane.

titin: Very large fibrous protein that is partly associated with the thick filament of muscle sarcomeres and stretches from the Z disc to the M line. It contains a long series of Ig-like domains that act as a spring to protect the sarcomere against overstretching. Also called connectin.

TOM complex: Multiprotein complex of the outer mitochondrial membrane that mediates translocation of proteins across this membrane.

trans-acting regulatory element: Sequence of DNA that regulates expression of one or more genes on a variety of chromosomes.

transaminase: See aminotransferase.

transferase: Enzyme that catalyzes transfer of a functional group from one molecule to another.

transformation: Conversion of a normal cell into a cancerous cell; also the alteration of a cell's phenotype by incorporation of foreign DNA.

transgenic: Describing an organism into whose germ line one or more genes from another organism have been introduced by recombinant DNA technology

trans-Golgi network: Interconnected cisternae and tubules of the Golgi complex that are farthest away from the ER and release vesicles that contain proteins and lipids destined for lysosomes, secretory vesicles, or the plasma membrane.

translocation: Change in position during translation of mRNA on a ribosome of the peptidyl-tRNA and the deacylated tRNA; also transport of a protein across a membrane or to a different site in a cell, or of a portion of a chromosome onto a nonhomologous chromosome.

transmembrane protein: See integral protein.

transverse (T) tubule: In skeletal and cardiac muscle a tubular extension of the sarcolemma and a component of the sarcotubular system.

triplet: Trinucleotide in an exon in DNA, in the coding region of mRNA or in the anticodon region of tRNA, that specifies a particular residue in a polypeptide.

triplet repeat: Stretch of DNA in which the same three nucleotides, for example, (CAG), are repeated in tandem fashion. Expansion in the repeat number is associated with several human genetic disorders.

triskelion: See clathrin.

tumor-suppressor gene: Gene whose product prevents cell proliferation; its inactivation by mutation or deletion enhances susceptibility to cancer.

ubiquitin pathway: Sequence of reactions that require a ubiquitin-activating enzyme, a ubiquitin-conjugating enzyme, and a ubiquitin ligase to form a ubiquitinated or a polyubiquitinated target polypeptide. The former changes the activity of the polypeptide while the latter directs it to degradation by proteasomes.

ubiquitin: Intracellular, monomeric 76-residue protein that is highly conserved and ubiquitous in eukaryotic organisms. When covalently linked through its C-terminal residue to lysine side chains of other proteins, it targets them to degradation by proteasomes.

ubiquitination: Addition to the side chain of a lysine residue in a polypeptide of a ubiquitin monomer or of a series of such monomers joined together by isopeptide linkage.

uncoupling agent: Compound such as 2,4-dinitrophenol that dissociates phosphorylation of ADP from electron transport in mitochondria and dissipates the energy as heat.

uniport: Transport of one specific solute across a membrane by a transport protein.

up-regulation: Increase in transcription of a DNA genetic sequence in response to an external variable.

V(D)J joining: Bringing together during differentiation of a bone marrow stem cell into a mature B cell of V and J, or of V, D, and J segments to form a functional gene for the light chain and the heavy chain respectively of an immunoglobulin.

V(D)J recombinase: Enzyme complex that mediates V(D)J joining.

variable residue: Position of a residue that is occupied by different amino acids when the polypeptide is derived from different species. Also called hypervariable residue.

Varshavsky rule: See N-end rule.

vasopressin: See antidiuretic hormone.

vegan: Someone who eats only plant material.

V-type ATPase: ATPase of lysosomal, endosomal, and secretory vesicle membranes that functions to create an acidic pH in those compartments. It is similar in structure to F-type ATPases.

wobble: Relatively nonspecific pairing between the base at the 3′-end of a codon in mRNA with that at the 5′-end of the anticodon in tRNA.

Z-DNA: Double-helical DNA that contains 12 base pairs in a left-handed turn, has a diameter of ~18 A° and a zigzag appearance and is formed by sequences in which pyrimidine or purine bases alternate.

zinc finger: Protein motif common in DNA-binding proteins that contains four residues of cysteine or two each of cysteine and histidine that are coordinated to a zinc atom.

zwitterion: Molecule that contains charged groups of opposite polarity. Also called dipolar ion.

zymogen: Catalytically inactive protein that becomes an active enzyme on limited proteolytic cleavage. Also called proenzyme.

Anchoring sequences, secretory pathways, protein synthesis, **236**–237
Androgen-binding protein (ABP), steroid hormone transport, **928**–929, 929*f*
Androgens, cytochrome P450 synthesis, 434, 436*f*
Anemia
iron-deficiency anemia, 1090–1091, 1091cc
vitamin A and, **1067**
Angina pectoris
glycolysis regulation, 613cc
nitric oxide/cGMP signaling, 531cc
Angiogenesis, cancer cells, **1017–1020,** 1020*f*
Angiostatin, **1020**
Angiotensin-converting enzyme (ACE), **923,** 926*f*
Angiotensin II, **923,** 926*f*
Angiotensinogen, **923,** 926*f*
Animal cloning, 293–294
Animal proteins, 1115
Anion channel
antiport mechanism, 490, 490*f*
integral membrane proteins, **470**
Anion exchange protein, **490**
Anion-exchange resins, protein separation, **122,** 122*f*
Anionic surfaces, hemostasis, **982**
Anion(s), **5**
Anisotropic (A) band, skeletal muscles, **969**
Ankyrin, **470**
Annealing, double-helical DNA denaturation and renaturation, **37**
Annexin-1, steroid hormone receptors, **931**
Annotations, human genome, 298–**299**
Anomeric linkage, protein glycosylation, **232**–233, 233*t*, 234*f*–235*f*
Anomers, **1125**
Anserine metabolite, 787, 788*f*
Antagonists
cell surface receptors, intracellular signal transduction, **509**
glutamine nitrogen donors, 834, 834*f*
interleukin-1 receptors, inflammatory disease, 521cc
membrane channel control and selectivity, **478**
Anterior pituitary
hormonal cascade, **886**
polypeptide hormones, 887, 888*f*, 891
Anterior pituitary tropic hormones, hormonal cascade, **886**
Anterograde strands, semi-discontinuous DNA synthesis, **145,** 145*f*
Anti-association factor, protein synthesis, **221**–223, 221*t*, 222*f*
Antibiotic-resistant genes, **317**
Antibiotics
antitumor, 42cc
deafness induced by, rRNA/tRNA mutations, 229cc
RNA polymerase targeting, 185cc
topoisomerases as, 152cc
translation and targeting of, 229–230, 230*t*
Antibody(ies). *See also* Immunoglobulins
antigen-binding sites, 340–342, 341*f*
classes of, 338cc
molecules, immunoglobulin superfamily, 334–343
polypeptide chains in, 335–337
primary structure, constant and variable regions, 336
repeating sequences and homologous three-dimensional domains, 339–340, 339*f*–340*f*
Antibody microarray technology, brain tumor therapy, 296cc
Anticancer agents
molecular targeting, 1021cc
telomerase targeting, 46cc
Anticoagulant, heparin as, 665cc
Anticoagulation, **982**
extrinsic pathway inhibition, 990–993, 991*f*
hemostasis and, 989–993
Anti conformation, nucleoside/nucleotide structure, **29**
Anticonvertin, extrinsic pathway inhibition, 990–993, 991*f*
Anticonvulsant drugs, vitamin requirements, 1075cc
Antifolates, purine/pyrimidine nucleotide metabolism, 832–834
Antigen-binding fragment (F_{ab}), **341**
Antigen-binding sites, antibody molecules, 340–342, 341*f*
Antigenic region, steroid receptors, **934**
Antigens, **335**
Antimetabolites, purine/pyrimidine nucleotide metabolism, 832, 832*f*
Antiparallel strands
codon-anticodon interactions, 212–215, 213*t*–214*t*, 214*f*
DNA replication, 145, 145*f*
double-helical DNA structure, 32–33, 32*f*
Antiport mechanism
electrochemical-potential-driven transporters, 488

Antiport mechanism (*cont.*)
primary active transporters, 491–492, 491*f*–492*f*
solute molecule transport, **486,** 486*f*
Antisense nucleic acids
gene expression regulation, 290cc
recombinant DNA research and therapy, **289**–290, 289*f*
Antithrombin III inhibitors
extrinsic pathway inhibition, 991, 992*f*
heparin, 665cc
Antitumor antibiotics, DNA structural change and, 42cc
Antiviral agents, purines and pyrimidines, 834–835, 834*f*
Antivirus mechanisms, nucleic acid editing enzymes, 201cc
Antley-Bixler syndrome, NADPH-cytochrome P450 reductase genetic polymorphisms, 442, 443cc
Apaf1 protein, apoptosis, mitochondrial pathway, **1013**
AP endonuclease, DNA base excision repair, **168**
AP lyase, DNA base excision repair, **168**
ApoA-I, **108**
ApoCII deficiency, 109cc
ApoC protein, **109**
ApoE abnormalities, hyperlipoproteinemia, 109cc
Apoferritin
anemia and decreased immunocopmetence, **1087**
synthesis, 1089, 1089*f*
Apolarity
amino acid side chains, 86–89
edge in collagen, **104**
Apolipoprotein(s) (Apo), **108,** 108–109, 109*t*
B, A-β-lipoproteinemia, 1058cc
chemical composition, 111, 111*t*
lipid digestion, chylomicron incorporation, **1057**
nucleic acid editing enzymes, 201cc
side chains, 111, 111*f*
Apoptosis, 1010–1016, 1011*f*–1012*f*, 1014*f*–1015*f*
death receptor pathway, 1011, 1012*f*
MAPK pathways, 1015–1016, 1015*f*
mitochondrial pathways, 1012–1014, 1012*f*
p53 induction, 1014–1015, 1014*f*
proteolysis and, **249**
Apoptosome, **1013**
Apparent mineralocorticoid excess (AME) syndrome, 931cc
AP sites, DNA damage and mutation, **164**
Aptamers, **69, 297**
binding RNAs as, 69, 69*f*
microarray analysis, 297–298
small interfering RNAs, HIV-1 therapy, 290cc
Aquaglyceroporins, **479**
Aquaporins (AQP)
classification, **479,** 480*f*–481*f*, 481
expression sites, 479*t*
hydropathy plot, 469–470, 469*f*
mammalian kidney and, 480cc
Arachidonic acid
cytochrome P450 metabolism, 434
intracellular signaling pathways, 536
phospholipid fatty acid distribution, 716, 716*f*
prostaglandins and thromboxane derivatives, 737–738, 738*f*
Arginase
deficiency, 762cc
urea cycle synthesis, **760**
Arginine
biosynthesis, 763, 763*f*
glycogen formation, early refed state, 847–849, 848*f*–849*f*
metabolite derivation, 778, 780*f*
nitric oxide synthases, 445–446, 446*f*
side chain structure, **77,** 77–78, 78*f*–79*f*
urea cycle synthesis, 760
Arginine vasopressin (AVP), protein kinase A activity, 912, 912*f*, 913*t*
Argininosuccinate synthease and lyase deficiency, 762cc
Argonaute protein, translation regulation, **247**
Aromatase
aromatization reaction, 434, 436*f*
hormone biosynthesis, **920**
Aromatization reaction, cytochrome P450 hormone synthesis, 434, 436*f*
Arrestin, visual cycle, **963,** 963*f*
Arsenate, ATP synthesis prevention, 604, 604*f*
Arsenic poisoning, 605cc
Artificial chromosome vector, DNA fragment cloning, 278–279
Aryl hydrocarbon receptors
cytochrome P450 metabolism, 441, 442*f*
steroid hormones, **934**
ASAP1 gene, prostate cancer, 259cc
ASBT transporter, bile acids, 1058, 1059*f*
Ascorbic acid
glucuronic acid derivation, 656cc
reduction and hydroxylation functions, 1084, 1084*f*
L-Ascorbic acid, glucuronic acid formation, **655**
Asn-X-Thr/Ser sequence, N-linked glycosylation, **233**
Asparaginase
glutamine reaction, 756–757, 757*f*
leukemia and hydrolysis of, 381cc
Asparagine
glutamine-derived amide group, 756–757, 757*f*
glycosyl linkage, 112, 112*f*
N-glycosyl bonds, **659,** 659*f*–660*f*
side chain structure, **78,** 78*f*
Aspartate
degradation, 764
side chain structure, 77, 78*f*–79*f*
urea atoms from, 759
Aspartate proteases, **343**
Assay conditions, enzyme reactions, 404–405, 421cl
Atelectasis, dipalmitoyllecithin and, 710–711, 710*f*
Atherosclerosis, 728cc
Athletic endurance, carbohydrate loading, 1111cc
Atkins diet, 841cc, 864–865, 864*f*, 1117
ketone bodies and, 699cc
ATP. *See* Adenosine triphosphate (ATP)
ATPases
copper uptake, 1092–1093
gastric acid secretion, 1043, 1043*f*
myosin filaments, 970
primary active transporters, **491**
sodium/potassium (Na^+/K^+)-exchanging ATPase, **491**
ATP-binding cassette (ABC) transporters
disease and, 497cc
membrane transport, **494,** 494–495, 495*f*
reverse cholesterol transport, 725, 725*f*
ATP citrate lyase
citrate cleavage pathway, fatty acid lipogenesis, **684**
mitochondrial inner membrane transport, 580–581
ATP synthase
mitochondrial electron transport, 563
oxidative phosphorylation, 575–577, 575*f*–575*f*, 575*t*
subunit rotation, 578cl
Atrial natriuretic factor (ANF)
angiotensin synthesis, 923, 925*f*–926*f*
cyclic GMP-based signal transduction, **530**
Atropine, digestion and, 1034, 1035*f*
Attenuator region, tryptophan operon, **312,** 312–313, 312*f*–313*f*
AUG codon, mRNA genetic code, **211**–212
Autocrine hormones, **885**
Autocrine signaling, 505*f*, 506–507
cell cycle regulation, **1008**
Autoimmunity, connective tissue disease and, 198cc
Autolysis, serine proteases, **350**
Autonomic nervous system, cardiac muscle, 977–978, 977*f*
Autonomously Replicating Sequences (ARS), DNA replication, eukaryotic enzymes, **155,** 155*f*
Autophagy, lysosomal intracellular digestion and, 18–19, 19*f*
Autophosphorylation, insulin receptor, 909*f*, **910**
Autosomal recessive juvenile Parkisonism, ubiquitin-proteasome defects, 250cc
Axonal transport, precursor protein, **952**
Axons, **941,** 941*f*
Azaserine, glutamine nitrogen donor enzyme inhibition, 834, 834*f*
3′-Azido′3′-deoxythymidine (AZT), purine/pyrimidine analogs, 834–835, 834*f*
AZT therapy, resistance to, nucleoside analogs and, 144cc

B
BACs. *See* Bacterial artificial chromosomes
Bacteria
agrobacteria, 294–295
extreme general stress, **315**
foreign genes, expression vectors, 281–282, 282*f*
loss of antibiotic resistance and selection of, 266, 267*f*, 268
recombinant DNA transformation, 265–266
α-complementation, 268
toxins, heterotrimeric G proteins, 527
transcription units, 304–305
ribosomal protein synthesis, 314–315, 314*f*–315*f*
transposons, 316–317
Bacterial artificial chromosomes, DNA fragment cloning vectors, **278**–279
Bacterial chromosomes, nucleoid packaging, 53–54, 53*f*
Bacterial ribosome, as ribozyme, 69
Bacterial toxigenic diarrhea, electrolyte replacement therapy, 1041cc
Bacteriophages
lambda (λ)
chromosome walking, 279–280, 280*f*
cloning vectors, **277**–278, 277*f*
recombinant vectors, M13 series, 285–287, 286*f*–288*f*
screening libraries, 278, 278*f*
chromosome walking, 279–280, 280*f*
vectors, complementary DNA synthesis, **276**
Bak proteins, apoptosis, mitochondrial pathway, 1012–1014, 1012*f*

Barbiturates, alcohol and, 603cc
Baroreceptors, vasopressin activity, **912**
Basal lamina, **367,** 367–373
  cancer cell metastasis and, 1018–1019
  collagen network, 368–373
  protein composition, 368
Basal metabolic rate
  energy content of food, 1102–1103
  thyroid hormone iodine incorporation, 1091
Base excision repair (BER), DNA damage, **167**–168, 168*f,* 168*t*
Basement membrane, **334**
  basal lamina, **367,** 368, 368*f*
  extracellular matrix-cytoskeleton interconnection, 373
Base pairing, **33**
  codon-anticodon interactions, 212–215, 213*t*–214*t,* 214*f*
  DNA genetic information, 140
  double-stranded DNA (dsDNA), 33
  RNA secondary structure, 62, 62*f*
  RNA transcription, 182, 183*f*
  supercoiled DNA, 49–51, 50*f*
Bases
  catalysis, 385, 385*f*
  enzyme-substrate binding, pH levels, 387, 387*f*
  Henderson-Hasselbalch equation for pH and concentrations of, 9–10
  nucleosides, **1133**
  phospholipid synthesis and addition of phosphatidic acid, 713–715, 714*f*–715*f*
  as proton acceptors, 7
  purine/pyrimidine nucleotide metabolism, antimetabolites, 832
  purine synthesis and nucleotide formation, 815–817, 816*f*
Base stacking, polynucleotide conformations, **30,** 30–31, 31*f*
Basic amino acids, characteristics of, **83**
Basic proteins, characteristics of, **83**
Basic region-leucine zipper (bZIP) proteins, transcription regulation, 324–325, 324*f*
Bax proteins, apoptosis, mitochondrial pathway, 1012–1014, 1012*f*
Bcl-2 protein family, apoptosis
  MAPK pathway regulation, 1015–1016, 1015*f*
  mitochondrial pathway, 1012–1014, 1012*f,* 1013cl
Bcl-X_L protein, apoptosis, mitochondrial pathway, 1012–1014, 1012*f*
B-DNA, **38**
  conformation, 38–41, 39*f*–41*f,* 40*t*
Beer-Lambert law, x-ray diffraction, three-dimensional protein structure, 131cl
Bent DNA, 41–42
Benzo*(a)*pyrene
  cytochrome P450 metabolism, 438–439, 439*f*
  nucleotide excision repair, **164, 169,** 169*f*
Benzoate X receptor, **934**
Benzodiazepines (Valium), neuron-neuron interaction, 943, 944*f*
β-barrel motifs
  integral (intrinsic) membrane proteins, 469–470
  membrane channels, **478,** 478*f*
  nonhomologous amino acid sequences, **101**–102, 101*f*–102*f*
  serine protease tertiary structure, 348–350, 348*f*
β-domain structure, nonhomologous amino acid sequences, 102, 102*f*
Beta-blockers, cytochrome P450 metabolism, 442–443
β structure, secondary protein structure, 93, 94*f*
β cells
  diabetes mellitus type 2 and, 865–866, 865*f,* 866cc
  in well-fed state, 844
Betaglycan, **668**
β-sheet structure
  cytochrome P450, 427
  nonhomologous amino acid sequences, **102,** 102*f*
  polypeptides, 93, 94*f*–95*f*
β-strands, membrane channels, **478**
BH domain, apoptosis, mitochondrial pathway, 1012–1014, 1012*f,* 1013cl
Bicarbonate, antiport mechanism, 490, 490*f*
Bicarbonate ions, acid-base balance and, 876–877, 876*f*–877*f*
Bidirectional DNA replication, eukaryotic enzymes, **155,** 155*f*
Bile acids, **1131**
  cholesterol excretion, 728–729, 728*f*
  cholesterol stones, 1056cc
  cytochrome P450 synthesis, 434
  digestion and, 1032
  lipid digestion and absorption
    micelles, 1053–1057, 1054*f*–1055*f,* 1054*t*
    solubility, 1055, 1055*f*
  transport, 1058–1059, 1059*f*
Bile Salt Export Pump (BSEP), 1059*f*
Bile salts, cholesterol precursor, 718–719, 719*f*
Bilirubin
  glucuronide formation, 656cc
  heme formation, 797, 797*f*
  serum-conjugated elevation, 800cc
Bilirubin diglucuronide, **799,** 799*f*
  liver conjugation of, 797–801, 799*f*
Bilirubin UDP-glucuronosyltransferase deficiency, 799cc
Biliverdin IX, **797**
  heme oxygenase, 798cc
Biliverdin reductase, **797**
Bioenergetics, 541–587
Bioinformatics, protein gene product structure and function, **101**
Biological fluids, pH levels, 7, 7*t*
Biosynthetic intermediates, tricarboxylic acid cycle, 555–557
Biotin, coenzyme formation, **1079**
2,3-Bisphosphoglycerate (BPG)
  glycolysis, 597*f,* 598–600
  high altitude and, 601cl
  oxygen-hemoglobin binding, **365,** 365*f*
  shunt, glucose metabolism, 600
Blood
  coagulation mechanism, 982–997
    anticoagulation phase of hemostasis, 989–993, 991*f*–992*f,* 994*f*
    clot formation proteins, 985–989, 986*f*–989*f*
    fibrinolysis phase of hemostasis (phase 3), 994, 994*f*
    Gla residues, 994–996, 995*f*–997*f*
    hemostasis biochemistry, 982–983, 983*t*
    procoagulation phase of hemostasis, 983–986, 984*f*
  metabolic acidosis, 11cc
  neonatal isoimmune hemolysis, 798cc
  pH levels in, 7cc
  buffering capacity and, 10–11, 10*f*
  red blood cells, phosphatidylserine clearance, 710cc
Blood-brain barrier, **940–941,** 942*f*
  glucose transport, 941cc
Blood group substances, 658cc
Blood urea nitrogen (BUN), nitrogen balance and, 753cc
Bloom syndrome, direct DNA sequencing, 262cc
Body mass index (BMI), dietary and genetic components, 1107–1108, 1108*f*
Bohr effect protons
  blood pH and, **360**
  carbon dioxide and nitrogen transport, 360–366, 361*f*–366*f*
Bone morphogenetic proteins (BMP), **519**
Boron, nutritional function, **1094**
Botulinum toxin, **946**
Bradykinin, endothelial (NOSIII/eNOS), 451
Brain tumors, antibody microarray technology, 296cc
Branched-chain amino acids (BCAAs)
  enzyme deficiency disease, 778cc
  metabolism, 775–777, 777*f*
  protein-calorie malnutrition, 841cc
Branched-chain fatty acids, **675**
Branch migration, homologous recombination, Holliday model, **159**–160, 160*f*
Branch point, inosine 5′-monophosphate, purine synthesis, 815
Breast cancer
  cytochrome P450 inhibition, 444
  nucleic acid microarray analysis, 296cc
  ubiquitin-proteasome defects, 250cc
Brevican, **668**
Brown adipose tissue, mitochondrial innermembrane transport, 581–582, 581*f*
Brush border membrane
  peptide digestion, 1046
  sodium chloride absorption, 1039, 1039*f*
Buffering capacity, **10**
  pH levels and, 10–11, 10cl, 10*f*
α-Bungarotoxin, **483**
Buthionine sulfoximine, glutathione response, 790, 790*f*
Bypass (translesion) synthesis, DNA repair, **174,** 174*f*

C
CAAT box
  eukaryotic transcription, 322, 322*f*
  mRNA synthesis promoters, **190**
CAAX prenylated proteins
  lipid anchors, **471**
  lipid rafts, 473, 473*f*
Cachexia, cancer-induced, 869cc
Cahn-Ingold-Prelog system, 1125
Calbindins, vitamin D synthesis, **928**
Calcitonin, vitamin D synthesis, **1070**
Calcitrol, vitamin D synthesis, **1068**
Calcium
  endothelial (NOSIII/eNOS), 447*t,* 450–453, 450*f*
  glycogenolysis in liver, 640–641, 640*f*
  mitochondrial inner membrane transport, 581, 581*f*
  neuronal (NOSI/nNOS) activation, 447–448, 447*t,* 448*f*
  neurotransmitter synthesis, 945, 947*f*
  physiological roles, 1085–1086
  pyruvate dehydrogenase regulation, 551
  smooth muscle contraction, 978–979

Calcium (*cont.*)
visual cycle, **963,** 963*f*
vitamin D synthesis, 1070–1071, 1071*f*
Calcium-calmodulin (CaM) kinase I, neurotransmitter synthesis, 945, 947*f*
Calcium (Ca^{2+}) channel
intracellular signal transduction, cell surface receptors, 510
Lambert-Eaton myasthenic syndrome, 948cc
primary active transporter translocation, **492,** 492–493
signal transduction, 532–534, 533*f*
skeletal muscle contraction, 974–977, 975*f*–977*f*
subunit composition, 481–482, 481*t*
Calcium channel blockers, cytochrome P450 metabolism, 442–443
Calcium-transporting ATPases (Ca^{2+}-ATPase), **492,** 492–493, 493*f*–494*f*
Caldesmon, smooth muscle contraction, 978–979
Calmodulin
calcium-transporting ATPases (Ca^{2+}-ATPase) in plasma membranes, **493,** 493–494, 494*f*
inducible (NOSII/iNOS), 447*t,* 449
myosin filament, 969–970
neuronal (NOSI/nNOS) activation, 447–448, 447*t,* 448*f*
nitric oxide synthases, 445–446, 446*f*
protein kinases and phosphatases, calcium activation, **534**
secondary protein structure, 94–95, 95*f*
Caloric homeostasis, metabolic energy requirements, 849–850, 849*t*–850*t*
Calories, requirements in hospitalized patients, 1106cc
Calpains, proteolysis and apoptosis, 249
cAMP-dependent protein kinase, neurotransmitter synthesis, 945
cAMP receptor protein (CRP), lactose operons, **309**
cAMP response element (CRE), second messenger system, **900**
cAMP-response-element (CRE)-binding (CREB) protein
second messenger system, **900**
transcription regulation, 861–862, 861*f*
cAMP-sensitive regulatory elements (CRE), cyclic AMP intracellular signaling, **530**
Camptothecin, 52cc
Cancer
biochemical analysis, 1023, 1023*f*–1024*f*
cachexia and, 869cc
cell cycle and, 158cc
cell properties, 1017–1020, 1018*f*–1020*f*
cisplatin therapy and, 165cc
DNA recombination and, 159cc
environmental causes, 1022cc
epigenetic therapy, 57cc
histone targeting and gene modification, 328cc
ErB/HER receptor tyrosine kinases, 518cc
genetic and biochemical heterogeneity, 1023
glycolysis regulation, 6-phosphofructo-1-kinase/fructose 2,6-bisphosphate, 617
hexokinase II and, 607cl
immortality in cancer cells, **1017–1018**
mismatch DNA repair and, 172cc
multiple mutations requirement, 1020–1021
mutagens and promoters in, 1023
oncogenes and tumor suppressor genes and, 1016–1017, 1016*t*
6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase, 618cl
pyruvate kinase in, 619, 619cl
starve-feed cycle and, 868–869, 869*f*
TIGAR regulation and, 618cl
Capacity, ligand-receptor interaction, **512**
Cap-binding complex, eukaryotic translation, **223**
Capillary electrophoresis, protein separation, 122, 123*f*
Capping enzyme complex, RNA polymerase II, eukaryotic transcription, 196–198, 197*f*
"Cap" structure, eukaryotic mRNA, 67–68, 67*f*
translation, **210**
Carbamino-hemoglobin formation, **364,** 364*f*
Carbamoyl phosphate, urea cycle, 759, 759*f*
Carbamoyl phosphate synthetase I (CPSI)
deficiencies, 762cc
glutamine *de novo* synthesis, **810**
pyrimidine metabolism, 821–823, 822*f*–824*f*
urea cycle synthesis, **759,** 759*f*–760*f,* 760
Carbohydrate intolerance, **1111**
Carbohydrate metabolism
gluconeogenesis, 619–629
alcohol oxidation, 628–629
ATP expenditure, 626
glucose synthesis, 619–626
hormonal control, 627–628
regulation site, 626–627
glycogenolysis and glycogenesis, 629–643
debranching enzyme, 631–632, 631*f*
effector control, 638–639
enzyme requirements, 632–633, 632*f*
epinephrine in heart and skeletal muscle, 641, 641*f*
glucagon and epinephrine in liver, 640–641, 640*f*–641*f*
glucose storage, 629–630, 629*f*–630*f,* 633–634, 634*f*
glycogen degradation and synthesis, 635–638
glycogenin requirement, 634–635, 635*f*
glycogen phosphorylase inhibition, 630–631, 630*f,* 636
glycogen phosphorylase regulation, 635–636, 636*f*
glycogen synthase regulation, 636–638, 636*f*–638*f*
glycogen synthesis limits, 635
hormonal/normal glycogen synthesis and degradation, 640–643
insulin stimulation in muscle and liver, 642, 643*f*
negative feedback control, glycogen synthesis, 639
neural control in skeletal muscle, 641–642, 642*f*
pathway, 632*f*
phosphorylase receptor in liver, 639–640, 639*f*
glycolysis pathways, 592–596, 592*f*–595*f*
arsenate prevention of ATP synthesis, 604, 604*f*
ATP yield and anaerobic balanced equation, 601
hexokinase and glucokinase, 606–608, 606*f*
hyperglycemia inhibition, 603–604
NADH oxidation to NAD, 601–602
6-phosphofructo-1-kinase regulation, 608–617
pyruvate kinase regulation, 617–619
regulation, 604–619, 605*f*
stages, 596–600, 597*f,* 599*f*–600*f*
substrate shuttle, 601–603
sulfhydryl reagents and fluoride inhibition, 603, 603*f*
glycoproteins, 659–663
dolichol phosphate N-linked glycoprotein synthesis, 660–663, 660*f*–661*f*
glycan function, 663
N- and *O*-glycosyl bonds, 659–660, 659*f*
major pathways, 592–643
pentose phosphate pathway, 648–652
carbon dioxide oxidation of glucose 6-phosphate, 651
glucose 6-phosphate oxidization, 648–649, 649*f*
interconversions and glycolysis intermediates, 649–651, 650*f*
NADPH regeneration, 651–652, 651*f*
polysaccharide biosynthesis, 658
proteoglycans, 663–668
chondroitin sulfates, 664, 666–667, 666*f*
dermatan sulfate, 664–665
glycosaminoglycans, 664–665, 665*f,* 666–667
heparin and heparan sulfate, 665
hyaluronate, 664
keratan sulfate, 665–666
sleep and, 775cl
special pathways, 648–668
sugar interconversions and nucleotide sugar formation, 652–658
N-acetylglucosamine sialic acid derivation, 657–658, 657*f*
decarboxylation, oxidoreduction and transamidation, 656, 657*f*
intermediate transformation, 653–654, 653*f*
isomerization and phosphorylation, 652–653, 652*f*
nucleotide-linked glucose/galactose epimerization, 654, 654*f*
UDP-glucose oxidation and glucuronic acid formation, 654–655, 655*f*
Carbohydrate-response-element-binding protein (ChREBP), **860**
Carbohydrate(s)
dietary sources, 1048*t,* 1111–1112
for diabetics, 1112cc
glycemic index/glycemic load, 1115, 1115*t*
digestion and absorption, 1048*t,* 1049–1051
disaccharides and polysaccharides, 1049–1051, 1050*f,* 1050*t*
functional groups, 1125–1128
glycoprotein covalent bonds, 112, 112*f*
intake, serum triacylglycerols and, 1118cc
loading and athletic endurance, 1111cc
in membranes, 463
nutrients, 1030, 1030*t*
Carbon, pyrimidine synthesis, 823, 824*f*
Carbon-carbon bonds, enzyme transition states, 385–386, 385*f*
Carbon dioxide
acetyl group-acetyl CoA conversion, 555
acid-base balance, 876–877, 876*f*–877*f*
fatty acid synthesis, malonyl coA formation, 680, 680*f*
glucose synthesis from fatty acids, 625, 625*f*
glycolysis, 593
hemoglobin transport, 360–366, 361*f*–366*f*

pentose phosphate pathway, glucose 6-phosphate oxidation, 651, 651*f*
Carbonic acid/bicarbonate system, characteristics of, 8–9, 9cl
Carbon monoxide
heme catabolism, **797**
heme oxygenase, 798cc
nitric oxide synthases, 445–446, 445*f*–446*f*
Carbonyl groups, enzyme transition states, 385–386, 385*f*–386*f*
γ-Carboxyglutamate formation, **243**
clot formation, residues, 987, 987*f*
γ-Carboxyglutamic acid
vitamin K and, **1073**–1075
zymogen synthesis, **347,** 348*f*
γ-Carboxyglutamyl (Gla)
clot formation, residues, 987, 987*f*
coagulation initiation, 983–984
residues, factor modification, 994–996, 995*f*–997*f*
vitamin K and, 994–995, 995cl, 996*f*
Carboxyl groups, fatty acid alkyl chains, 674–675
Carboxylic acids, 1123
Carboxypeptidase A, zinc ions and, 394, 394*f*
Carcinogenesis
multiple mutations and, 1020–1021
transcriptional factors and, 191cc
Cardiac isoenzymes, glycolysis regulation, 6-phosphofructo-1-kinase/fructose 2,6-bisphosphate, 616–617, 617*f*
Cardiac muscle
disease, ion channels and, 978cc
structure and contraction, 977–978, 977*f*
Cardiolipin
in membranes, 462–463
mitochondrial inner membrane, **560,** 560*f*
in phospholipids, **709,** 709*f*
Cardiotonic steroids, sodium/potassium (Na^+/K^+)-exchanging ATPase, **492**
Cardiovascular disease
nitric oxide/cGMP signaling, 531cc
transcription factors, 326cc
Carnitine
acyl group transport, fatty acid oxidation, 691–692, 692*f*
biosynthesis, 786, 788*f*
functions of, 1085, 1085*f*
glycogen formation, early refed state, 848–849, 849*f*
serine metabolite derivation, 778
transport deficiencies, 693cc
Carnitine-acylcarnitine translocase, **691**
Carnitine palmitoyltransferase I and II, **691**
allosteric effector regulation, **853**
genetic deficiencies, 693cc
Carnosine metabolite, 787, 788*f*
β-Carotene, **958**
vitamin A sources, **1066**
Carotenoids, vitamin A, 1065–1067, 1066*f*
Cascade systems
glycogen phosphorylase, 636
hormonal, 885–891, 885*f*–886*f*
intracellular hormone cascades, 909–914
atrial natriuretic factor, protein kinase C, 913–914, 914*f*–916*f*
gonadotropin-releasing hormine, protein kinase C, 912–913, 913*t*
insulin receptor, tyrosine kinase transduction, 909*f*–912*f*, 910–911
vasopressin activity, protein kinase A, 912, 912*f*, 913*t*
intracellular signaling cascade, protein hormones, 899–901, 900*f*
intracellular signal transduction, 511, 512*f*
MAP kinase cascade, **519,** 519*f*
protein kinases, **511**
signal transduction, **508**
Caspase 9 protein, 1012*f*, **1013**
Caspases
apoptosis and, **1011**
cascade, apoptosis death receptor pathway, 1011, 1012*f*
proteolysis and apoptosis, **249**
Catabolic pathway, **13**
glycoprotein defects, 663cc
lysosomal enzymes, 734–735, 735*f*
Catabolic response, protein requirements, 1106
Catabolism
heme proteins, 797–801
bilirubin conjugation, 797–801, 797*f*, 799*f*
intravascular hemolysis, iron scavenging, 801
NAD/NADPH in, 543, 543*f*
Catabolite activator protein (CAP), lactose operons, **309**
promoter binding, 309, 309*f*
Catalase, **20**
peroxisomal fatty acid oxidation, **701**
peroxisomal formation of, 20–21, 20*f*
Catalysis
enzyme transition states, 385, 385*f*
stereochemistry, enzyme-catalyzed reactions, 389cl
Catalytic receptors, **508**
signal transduction, 516–520, 517*f*
Catalytic RNA, ribozymes, 68–69, 68*f*–69*f*
Catalytic subunits, enzyme activity, 417, 417*f*
Catalyzed reaction energy diagram, 384*f*
Cataracts, **955**
Catecholamines
amino acid-derived hormones, 895–897
hormones, **884**
signal termination, 950, 950*f*–951*f*
tyrosine metabolites, 781–782, 783*f*
Catechol-*O*-methyltransferase, signal termination, **950**
Cation-exchange resins, protein separation, **122,** 122*f*
Cationic amino acid transport 1 (CAT-1), endothelial (NOSIII/eNOS), 451
Cations, **5**
Caveolae
endothelial (NOSIII/eNOS), 451
plasma membranes, **473–474**
Caveolin proteins, **474**
CCR5 chemokine receptor, HIV and, 523cc
CD36 receptor, cholesterol absorption, 1057cc
CD44 molecule, **668**
CDC25 phosphatase, cell cycle regulation, **1006,** 1006*f*
Cdk inhibitors (CKIs)
apoptosis induction by p53, 1014–1015, 1014*f*
cell cycle regulation, 1007–1008, **1008,** 1008*f*
CDP-choline, phospholipid synthesis, **713,** 714*f*
CDP-ethanolamine, phospholipid synthesis, 715, 715*f*
Celiac disease, 1046cc
Cell communication. *See* Signal transduction
Cell cycle
cancer and, 158cc
division cycle, 1004–1010
DNA replication, 157–158, 157*f*
growth factor signal transduction pathway, 1008–1010, 1009*f*–1010*f*
M phase, 1004, 1004*f*, 1005*t*
nucleotide metabolizing enzymes, 828–829
regulation, 1005–1008
Cell(s)
cancer cells, 1017–1024
classification, 2–4
differentiation, enzyme-linked receptors, **517**
division, enzyme-linked receptors, **517**
DNA transformation of, 26
electrolyte water dissociation, 5–6, 5*f*
functional integration and control, 21–22
hydrogen bonds in water molecules, 4, 4*f*
immortality, in cancer cells, **1017–1018**
MAPK regulation of death and survival, 1015–1016, 1015*f*
motility, metastasis and, **1018**
pH levels, weak acids, and conjugate bases, 6–11, 6*t*–8*t*, 10*f*
quiescent cell, **1005**
senescent cell, **1005**
solvent properties of water, 5, 5*f*
structure, 2, 3*f*
water and solute environment, 3–6
Cell surface receptors, **884**
intracellular signal transduction, 509–514
effectors and second messengers, 509–510, 510*f*
GTP-binding proteins, 511
ligand-receptor interaction and downstream signaling, 512–513, 512*f*–513*f*
ligands and receptor-ligand interactions, 509
protein phosphorylation, 510–511, 510*f*
signaling components and cascades, 511, 512*f*
termination, 513–514
secreted molecules, **507–508,** 507*f*–508*f*
Cellular enzyme concentration, metabolic pathways, 417
Cellular RNA, DNA synthesis, 276, 276*f*
Cellulose, **1113**
Centimorgan (cM), homologous recombination, **159**
Central dogma of molecular biology, **26,** 26*f*
Centromere, eukaryotic chromosomes, **54,** 54–55, 54*f*
Ceramides, **460,** 462*f*
lipid rafts, 473
oligosaccharides, globosides as, 733, 733*f*, **1131**
in sphingomyelin, 730–731, 731*f*–732*f*
sphingosine derivation, 730, 730*f*
Cerebrocan, **668**
Cerebrosides, **462, 1130**
in glycosphingolipids, 732, 732*f*
Ceruloplasmin, **1088**
iron metabolism, 1089cc
Cervical cancer, ubiquitin-proteasome defects, 250cc
cGMP-sensitive protein kinases (PKG), intracellular signal transduction, **531**
Chain elongation chemistry, DNA replication, 141–142, 141*f*
Chain termination codon, mRNA, **200**–201
Chaperone proteins
crystallins, 954, 954*t*
in endoplasmic reticulum, 232cl
folding process, **116,** 117*f*, 231
ion channel receptors, 516
Chaperonins, chaperone protein folding, **116,** 117*f*

Charge gradient, oxidative phosphorylation, **572–573**
Charge properties, amino acid and protein pH, 85, 85*f*, 85*t*
Chemical reactions
  complex reactions, 398cl
  kinetics of, 395–397
    one-substrate reactions, 397, 399–405
Chemical synapses, neuron-neuron interaction, 943, 944*f*–945*f*
Chemotherapy
  biochemical basis, 835–836
  cell cycle and, 158
  cisplatin, 165cc
  DNA damage and mutation, 164
  DNA synthesis, precursor targeting, 142cc
  ErB/HER receptor tyrosine kinases, 518cc
  purine/pyrimidine nucleotide metabolism inhibition, 831–835
Chenic acids, lipid digestion and absorption, 1054*t*
Chenodeoxycholic acid
  chemistry and synthesis, 1058
  lipid digestion and absorption, 1054*t*
Children, protein-energy requirements in, 1105cc
Chloramphenicol, **230**
Chloride (Cl^-) channel
  antiport mechanism, 490, 490*f*
  cystic fibrosis and, 496cc
  neuron-neuron interaction, 943, 945*f*
  sodium chloride, secretion, 1039–1040, 1040*f*–1041*f*
  subunit composition, 481–482, 481*t*
Cholanic acid, cholesterol excretion, 728–729, 728*f*
Cholecalciferol, 926–928, 927*f*, **1067**
Cholecystokinin, digestion and, 1035–**1036,** 1035cl, 1035*t*
Cholera toxin, **462**
Cholesterol, **674, 1131**
  absorption, 1057cc
  acetyl coA synthesis, 719–722, 719*f*–722*f*
  adrenal cortical hormone conversion, 919–921, 919*f*
  asymmetric distribution, 467–468
  bile acid excretion, 728–729, 728*f*
  diet and, 1114–1115
  free and esterified forms, 718–719, 718*f*–719*f*
  membrane leaflets, 472–473, 472*f*
  mevalonic acid intermediate, 719–720, 719*f*–720*f*
  plasma lipoproteins and, 722–726, 722*t*, 724*f*–725*f*
  as plasma membrane component, **462,** 464*f*
  sex hormone conversion, 919–921, 920*f*
  sterol-response-element-binding protein regulation, 862
  stones, 1056cc
  synthesis regulation, 726–727, 726*f*
Cholesteryl ester storage disease (CESD), 20cc
Cholesteryl ester transfer protein (CETP), plasma lipoprotein synthesis, **724,** 724*f*
Cholic acid
  chemistry and synthesis, 1058
  lipid digestion and absorption, 1053–1054, 1054*f*, 1054*t*
Choline
  acetylcholine synthesis, 948, 948*f*
  functions of, **1085,** 1085*f*
  serine metabolite derivation, 778
Choline acetyltransferase, acetylcholine synthesis, 948, 948*f*
Choline-containing sphingomyelin, 460, 462*t*, 463*f*
Choline phosphotransferase, phospholipid synthesis, **713,** 714*f*
Choline plasmalogen, **460**
  phosphoplipids, **709**
Chondrodystrophies, sulfation defects, 667cc
Chondroitin sulfate, **664**
  biosynthesis, 666–668, 666*f*–667*f*
Chorionic gonadotropin (CG), fertilization, **904**
Chromaffin granules, epinephrine, **895,** 895*f*–896*f*
Chromatids, polynucleosome packing, 57
Chromatin
  eukaryotic organization, 54–55, 54*f*
  eukaryotic transcription, 188, 188*f*
    RNA polymerase recruitment, 188–189, 188*f*–189*f*
  fragile X syndrome and, 189cc
  gene expression, eukaryotes, **317**
  histone eukaryotic DNA binding and formation of, 317–319, 318*f*
  remodeling, epigenetic cancer treatments, 57cc
  structure and function, **16**
Chromatosome, nucleosomes and polynucleosomes, 55*f*, **56**
Chromium, **1093**
Chromomodulin, **1093**
Chromophore, protein structure, ultraviolet light spectroscopy, **131**–133, 131*f*–133*f*
Chromosomes, **45, 49, 54**
  four-stranded DNA, 45–46, 45*f*
  genomic linear/circular DNA, 49, 49*f*
  homologous recombination, 158–159, 158*f*
  human genome, 140
  trichromatic color vision, 966
Chromosome walking
  cystic fibrosis gene identification, 281cc
  gene arrangement on DNA, **279**–280, 280*f*
Chronic myelogenous leukemia (CML), molecular targeting of anticancer agents, 1021cc
Chronotropic control, cyclic hormone systems, **901**
Chylomicrons, **679**
  cholesterol synthesis, **722,** 722*t*, 723–726, 724*f*–725*f*
  lipid digestion, **1052**
    incorporation, 1057–1058
  in well-fed state, 843*f*, 844
Chymotrypsin
  proteolysis, 240, 241*f*
  sequencing, **128**
  zymogen activation, 1044*t*, **1046**
α-Chymotrypsin, reactivity, 346*t*
Chymotrypsinogen, proteolysis, **240,** 241*f*
Ciprofloxacin, 52cc
Circular dichroism (CD) spectroscopy, protein structure, **133,** 133*f*
Circular DNA, 49, 49*f*
Circular genomes, DNA replication termination, 150
Cirrhosis
  metabolism in, 873–874, 873*f*–874*f*
  protein-calorie malnutrition and, 841cc
Cis-aconitate, tricarboxylic acid cycle, **553**
Cisapride, CYP3A4 inhibition, 438cc
Cis configuration, amino acid peptide bonds, **81,** 81*f*
Cis-dominant operator mutations, **308**
Cisplatin
  cancer therapy and, 165cc
  DNA structural alteration, 42cc
  nucleotide excision repair, **169,** 169*f*
Cis regulation, RNA control, 70
Cis-trans isomerism, **1125**
Cis-trans-prolyl isomerases, chaperone protein folding, **116**
Citrate
  allosteric effector regulation, 853–855, 853*f*–855*f*
  fatty acid cleavage pathway, **684**–685, 684*f*
  6-phosphofructo-1-kinase regulation, 612
Citrate cleavage enzyme, **684**
Citrate lyase
  mitochondrial inner membrane transport, 579–581, 580*f*
  tricarboxylic acid cycle, **557**
Citrate synthase, tricarboxylic acid cycle, **553,** 553*f*, 558–559
Citric acid cycle, **552**
Citrulline
  glycogen formation, early refed state, 847–849, 848*f*–849*f*
  nitric oxide synthases, 445–446, 446*f*
  urea atoms, **759**
Clamp-loading factors, DNA replication
  eukaryotic enzymes, **153**–157
  replication fork movement, **149**
Class, proteins, **101**
Clathrin, hormone-receptor complexes, **907,** 909
Cleavage
  eukaryotic mRNA precursors, 198, 199*f*
  interrupted enzymatic cleavage, Sanger procedure, 260–261, 260*f*
  proteolytic cleaving, proinsulin, 90cl
  transfer RNA, 193–194, 194*f*
Cloning. *See also* Subcloning

Coenzyme(s), **390,** 390–393, 390cl, 390*t*
  coenzyme Q, mitochondrial electron transport, 563, 565, 565*f*
  mutations, 390cc
  niacin formation NAD/NADP coenzymes, 390–391, 391*f*, 1077–1078
  nucleotide synthesis, 829–831, 829*f*–831*f*
  pantothenic acid/biotin formation, 1079
  pyridoxal phosphate-pyridoxal formation, **392**–393, 393*f*, 1078–1079, 1078*f*
  riboflavin formation, 392, 392*f*
    FAD/FMN formation, 1077, 1077*f*
Cofactor required for Sp1 activation (CRSP), transcription activation, 327
Cofactors, **390**
  copper requirements, 1092–1093
  metal ions as, 393–395, 393*f*–395*f*
  nitric oxide synthases, 444–446, 444*f*–446*f*
Coiled-coil structure, in keratin and tropomyosin, 106–**107,** 107*f*
Co-immunoprecipitation, **99**–100, 99*f*–100*f*
Colicin E3, translation targeting of, 230
Colipase, **1053**
Collagen, **103**
  amino acid composition, 103, 103*f*, 104*t*
  basal lamina and, 368–373
  covalent cross-link formation, 105, 107*f*
  maturation of, 245
  posttranslational modifications, 243–245, 244*f*, 245*t*
  site-directed mutagenesis, type VII collagen, 286cc
  structure and conformation, 103, 103*t*
  synthesis defects, 246cc–247cc
  type IV collagen network, 369–373, **370,** 371*f*–373*f*
Colon, metabolism and, 877–878, 878*f*
Colonocytes, 877–878, 878*f*
Color blindness, 967cl
Color vision
  cone cells, 963, 965–966
  trichomatic properties, 966
Commitment step, metabolic pathway regulation, **417**
Compartmentation, **418**
Competitive inhibition/competitive inhibitors, enzyme inhibition, **407,** 407*f*, 409
α-Complementation, bacterial transformation, recombinant plasmids, **268,** 270*f*
Complement activation pathways, 337cc
Complementarity, **33**
  double-stranded DNA (dsDNA), 33–34, 34*f*
  nucleic acid probes, DNA/RNA sequencing, 268, 270–271, 271*f*
Complementarity-determining regions (CDRs), antibody molecules, **336,** 339–340
Complementary DNA (cDNA)
  bacterial expression vector, 281–282, 282*f*
  basic properties, **275**
  DNA synthesis, total cellular RNA, 276, 276*f*
  mRNA template for DNA synthesis using reverse transcriptase, 275–276, 275*f*–276*f*
  synthesis, 275–276, 275*f*–275*f*
Complementary primers, polymerase chain reaction, **257**
Complement proteins, 336cc–337cc
Complex reactions, 398cl
Concerted model of enzyme cooperativity, **416**–417, 416*f*
Cone cells
  color vision in, 963, 965–966
  outer segments of, **958**
  photoreceptor cells, 957*f*, 958–963, 959*f*, 961*f*–963*f*
  sensitivity and response time, 967cl
Conformation
  double-helical DNA, 38–41, 39*f*–40*f*, 41*t*
  hemoglobin deoxy-conformation, 360, 361*f*–362*f*
  lactose operon, **306**
  ligand-gated ion channels, 515, 515*f*
  P_i and ADP release, 977cl
  rhodopsin formation, 963cc
Congenital adrenal hyperplasia, cytochrome P450 CYP21A2 deficiency, 435cc
Congenital disorders of glycosylation syndrome (CDGS), **652**
  N-linked glycoproteins, 661, 662cc
Congestive heart failure, β-adrenergic receptor signaling, 528cc
Conjugate acid, **9**
Conjugate pair, **7**
  buffering capacity, 10–11, 10*f*
  classification, 7–8, 8*t*
  Henderson-Hasselbalch equation for pH and concentrations of, 9–10
Connecting peptide (C-peptide), proteolysis, **240,** 241*f*
Connective tissue disease, autoimmunity in, 198cc
Connexins (gap junction proteins), **484**
Connexons, **484**
Consensus promoter sequence
  prokaryotic transcription, 185–186, 186*f*
  RNA synthesis, 183, 183*f*
Conservative substitution, protein primary structure, 90
Constant (C) regions, antibody molecules, **336**
Constitutive androstane receptor (CAR)
  cytochrome P450 metabolism, 442
  steroid hormones, **934**
Contact-dependent signal transduction, **504,** 505, 505*f*
Contact factor pathway, hemostasis, **982**
Continuous strands
  replication fork movement, 145, 146*f*
  semi-discontinuous DNA synthesis, **145,** 145*f*
Contour length, higher-order DNA structures, **48,** 48–49
Control elements, **304**
Control strength, glycolysis regulation, 604–605
Convergent evolution, serine protease sequence homology, **351,** 351*t*
Cooperativity
  double-helical DNA denaturation and renaturation, 37
  hemoglobin-oxygen binding, 358–359, 358*f*
  multi-subunit enzymes, 414–417, 415*f*–416*f*
Cooperativity index, hemoglobin/myoglobin oxygen binding, **359,** 359*f*, 359*t*
Coordinate gene expression, lactose operons, **306**
Copper
  deficiency, **1092**
  as enzyme cofactor, 1092–1093
  enzyme reactions, 394–395, 395*f*
  metabolic diseases, 1093cc
  mitochondrial electron transport, **564**
    cytochrome *c* oxidase, 569–570, 570*f*
Copper transporter (CTR1), 1092
Coproporphyrinogen oxidase, **795**
Coreceptors, **475**
Corepressor molecules, **305**
  nuclear hormone receptors, 935
  tryptophan operon, **310**
Cori cycle
  gluconeogenesis, fasting state, 845–847, 845*f*–846*f*
  glucose synthesis, 619–621, 620*f*
  hepatic glycogenolysis and, 844, 844*f*
Cori disease, 633cc
Cornea, aerobic metabolism, ATP derivation, 953–954
Corticosteroid-binding α2-globulin (CBG), steroid hormone transport, **928**–929, 929*f*
Corticotropin-like intermediary peptide (CLIP), 888*f*, 889*t*–891*t*, 891
Corticotropin-releasing hormone (CRH), hormonal cascade, 886
Cortisol, **916**
  amino acid synthesis, 895
  cytochrome P450 synthesis, 433*f*, 434
COS cells, foreign gene expression, 283–284, 283*f*
Cosmid vectors, DNA fragment cloning, **278**–279
Co-substrates, **390**
Cotransfection, eukaryotic cell expression vectors, **283**
Cotranslational N-linked glycosylation, 233
Coupling proteins, intracellular signal transduction, cell surface receptors, **509,** 509–510, 510*f*
Covalent bonds
  enzyme-substrate binding, 386–387, 387*f*
  metabolic pathway regulation, 417
  folded proteins, van der Waals radii, 119, 119*f*, 119*t*
  glycoproteins, 112, 112*f*
Covalent cross-links
  in collagen, 105, 107*f*
  elastin, 106, 107*f*
Covalent modification, enzyme(s), 855–859, 855*f*–858*f*
C-peptide
  primary structure, 90, 91*f*
  proteolytic cleavage, 90
CpG islands, DNA methylation, 319
Creatine, 789, 789*f*
Creatine phosphokinase, muscle contraction, **979**
Creatinine, blood urea nitrogen and, 753cc
CREBs, cyclic AMP intracellular signaling, **530**
Creutzfeldt-Jakob Disease (CJD), 115
Cristae, mitochondrial structure, 17, **17, 559–560**
Critical micelle concentration (CMC), **464**
  lipid digestion and absorption, **1054,** 1055*f*
Cross-linked polyacrylamide, polyacrylamide gel electrophoresis, **124**
Cross-regulation, metabolic pathways, **417,** 417*f*
Cross-talk, signal transduction pathway-network integration, 537, 537*f*
Cruciform DNA, structure of, 42–43, 43*f*
Crystallins, in lens, 954–956, 954*t*–955*t*, 955*f*
Crystallizable fragment (F_c), **341**
Crystallization technique, three-dimensional protein structure, **129**–131
CSPs, neurotransmitter synthesis, **947**
C-terminal domain (CTD), RNA polymerase II, eukaryotic transcription, 196–198, 197*f*
Cultural causes of cancer, 1022cc
Curare, **483**

CXCR4 receptor, HIV and, 523cc
Cyanide poisoning
  cysteine metabolism, 781, 783*f*
  mitochondrial electron transport, 572cc
Cyanogen bromide, sequencing, **128,** 128*f*
Cyclic AMP (cAMP)
  allosteric effector regulation, 854–855, 854*f*
  covalent modification of enzymes, 855–859, 855*f*–858*f*
  gluconeogenesis hormonal control, 627–628, 627*f*–628*f*
  glycogenolysis in liver, 640–641, 640*f*
  glycogen phosphorylase cascade, 636
  heterotrimeric G proteins, **525**
  high-energy compounds, **546**
  intracellular signaling cascade, 898–901, 900*f*
  lactose operons, promoter binding, **309,** 310*f*
  6-phosphofructo-1-kinase regulation, 612–614, 612*f*–614*f*
  signal transduction
    intracellular signaling, 529–530, 530*f*
    signaling mechanisms, 529–530, 529*f*–530*f*
    synthesis and degradation, 528–529, 529*f*
  sildenafil and, 449cc
Cyclic GMP (cGMP)
  cardiovascular disease, 531cc
  endothelial (NOSIII/eNOS), 447*t*, 450–453, 450*f*
  intracellular signaling cascade, 898–901, 900*f*
  intracellular signaling mechanisms, 531
  nitric oxide mediation, 447
  rod cells, 961
  signal transduction, 530–531
  sildenafil and, 449cc
  synthesis and degradation, 530–531
Cyclic GMP phosphodiesterase, **525**
Cyclic hemiacetals, **1126**
Cyclic nucleotide phosphodiesterasese (PDEs), cyclic AMP-based signal transduction, 529
Cyclic secretion, ovarian cycle control, 901–905, 902*f*–905*f*
Cyclin B, cell cycle regulation, **1006,** 1006*f*
Cyclin-dependent activating kinase (CAK), cell cycle regulation, **1006,** 1006*f*
Cyclin-dependent kinases (CDKs), cell cycle and DNA replication, 158
  regulation, **1005–1006,** 1005*f*–1007*f*
Cyclin proteins, cell cycle regulation, **1005,** 1005*f*–1006*f*
Cycloglutamic acid, amino acid-derived hormone degradation, **896,** 898*t*
Cyclooxygenase (COX) inhibitors, 408cc
  prostaglandins synthesis, 738–741, 739*f*–741*f*
  steroid hormone receptors, **931**
Cyclopentanoperhydrophenanthrene, steroid hormones, **916,** 916*f*
Cyclopentenophenanthrene ring, cholesterol distribution, 718*f*
Cysteine
  conformation changes, 977cl
  cystine bond formation, 79, 80*f*
  degradation, 771, 772*f*
  metabolite derivation, 781, 782*f*–783*f*
  side chain structure, **77**
Cysteine proteases, **343**
Cysteine sulfinate, 781
Cystic fibrosis
  chloride (Cl^-) channel and, 496cc
  chromosome walking and jumping and gene identification, 281cc
  codon deletion, protein folding, and premature degradation, 231cc
  nutritional considerations, 1068cc
  of pancreas, 1040cc
Cystic fibrosis transmembrane conductance regulator (CFTR) protein
  ATP-binding cassette (ABC) transporters, 494–495, 495*f*
  ATP-dependent proteolysis in proteasomes, 248–249
  chloride channel and, 496cc
  chromosome walking and jumping and gene identification, 281cc
  pancreatic fibrosis, 1040cc
  sodium chloride secretion, 1040
Cystine
  cysteine residue oxidation, 79, 80*f*
  diseases, 774cc
Cystine aminopeptidase, amino acid-derived hormone degradation, **896,** 898*t*, 899*f*
Cystine disulfide bonds, amino acid-derived hormone degradation, 896, 898*t*
Cytidine, **27**
  nucleic acid structure, 27–30, 27*f*–30*f*
Cytidylyltransferase reaction, phospholipid synthesis, 714, 714*f*
Cytochrome *c* oxidase, mitochondrial electron transport, 563, 569–570, 569*f*–570*f*, 570cl
Cytochrome P450, 16
  2C19, 436, 436*f*
  carbon monoxide absorbance spectrum, 427, 427*f*
  CYP1A1, 440
  CYP1A2, 436, 440
  CYP2A6, 436
  CYP2B6, 436
  CYP2C9, 436
  CYP2D6, 436, 442
  CYP2E1, 439, 439*f*, 440cc, 441
  CYP3A4, 436, 436*f*, 438cc, 441, 441cc
  CYP4A, 434
  CYP4F, 434
  CYP7A1, 434
  CYP11A1, 433*f*–434*f*, 434
  CYP11B1, 433*f*, 434
  CYP11B2, 433*f*, 434
  CYP17A1, 433*f*, 434
  CYP19A1, 434, 436*f*
  CYP21A2, 433*f*, 434, 442cc
  CYP21A2, congenital adrenal hyperplasia and deficiency of, 435cc
  CYP27B1, 434
  CYP51, 444
  CYP51A1, 444
  drug-drug interactions, 438cc, 440–442, 441cc, 442*f*
  electron transport systems, 427–430, 428*f*
    mitochondrial NADPH-adrenodoxin reductase donor, 430, 430*f*
    NADPH-cytochrome P45 reductase, 428–429, 428*f*–429*f*
  endogenous metabolism, 430–432, 431*t*
    compound oxygenation, 432, 433*f*–434*f*, 434–435
    oxygenation, 432, 433*f*–434*f*, 435, 435cc
    substrates and physiological functions, 431–440, 432*t*, 433*f*
  exogenous metabolism
    lipophilic substrates, 436–440, 437*f*–439*f*, 437*t*
    substrates and physiological functions, 431–440, 432*t*, 433*f*
  genetic polymorphisms, 442–443, 443cc
  induction, 440–443
  inhibition, 444
    drug-drug interactions and adverse effects, 438cc
  nomenclature and isoforms, 430–431, 431*t*–432*t*
  properties and function, 426–427, 427*f*
  reaction cycle, 428, 429*f*
  substrates and physiological functions, 431–440, 432*t*, 433*f*
    lipophilic substrates, 436–440, 437*f*–439*f*, 437*t*
    steroid hormone synthesis, 432, 433*f*–434*f*, 435, 435cc
Cytochrome(s). *See also* Cytochrome P450

Diet
  adult protein requirements, 1104, 1106
  amino acids in, 752, 752*f*–753*f,* 753*t*
  caloric value and thermodynamics, 545–546, 545*t*
  cancer and, 1022cc
  carbohydrates in, 1048*t,* 1111–1112
    protein sparing and, 1104
  energy content of food, 1102–1103, 1102*f,* 1102*t*
  epigenetic cancer treatments, 57cc
  facts and fallacies concerning, 1094
  fat in, carbohydrates in, 1104
  fiber in, 1113, 1113*t*
  high-carbohydrate *vs.* high-fat, for diabetics, 1112cc
  intake studies, 1065, 1095
  nutrient sources in, 1030, 1030*t*
  nutrigenetics and, 1118–1119
  obesity and, 840cc–841cc, 1107–1108, 1108*f*
  osteoporosis and, 1086cc
  protein in, 1103
  recommended guidelines, 1116–1119, 1116*f*–1117*f*
  serum cholesterol and, 1114–1115
  vegetarian diet, 1103–1104, 1103*t,* 1104*f*
  weight loss and tissue interrelationships, 864–865, 864*f*
Dietary protein intake, renal disease and, 1105cc
Dietary reference intakes (DRI), 1065, 1065*f*
Diffusion
  membrane transport energetics, 487
  molecule translocation, **475**–476, 476*f*
Digestion
  carbohydrates, 1048*t,* 1049–1051
  lipids, 1051–1058
  protein digestion, 1043–1049, 1044*f*–1045*f,* 1044*t,* 1047*t,* 1049*f*
  sites of, 1031*f,* 1032–1033
Digestive vacuoles, **18**
  lysosomes and, 18–19
Digitalis, sodium/potassium (Na^+/K^+)-exchanging ATPase, **492**
Dihydrofolate reductase (DHFR)
  folic acid formation, **1080,** 1080*f*
  methotrexation inhibition, 832–833, 833*f*
Dihydrolipoyl transsuccinylase, tricarboxylic acid cycle, **554**
Dihydroorotate dehydrogenase (DHODH), pyrimidine metabolism, **821**–822
Dihydroquinone, vitamin K and, 995
Dihydrosphingosine, **460,** 462*f*
Dihydrotestosterone, 922
Dihydroxyacetone phosphate (DHAP), **653**
  plasmalogen-fatty alcohol synthesis, 716, 717*f,* 718
Dihydroxyeicosatetraenoic acids (DiHETEs), cytochrome P450 metabolism, 434
Dihydroxyphenylalanine (DOPA), **782**–783
Diisopropylfluorophosphate (DFP), 343, 344*f*
  chymotrypsin reactivity, 349–350
Dimer formation, transcription factor, 325, 325*f*
Dimeric complex, G protein subunits, 526
Dipalmitoyllecithin
  lung function and, 710–711, 710*f*
  phospholipid fatty acid distribution, 716, 716*f*–717*f*
Dipeptidases, peptide digestion, **1046**
Dipeptide, amino acid peptide bond, **80,** 80*f*
Dipeptide transporters, amino acid absorption, 1046–1048, 1047*t,* 1048*f*
2,3-Diphosphoglycerate (DPG), oxygen-hemoglobin binding, **365,** 365*f*
Diphthamide residue
  ADP-ribosylation, **243,** 243*f*
  translation targeting of, **230**
Diphtheria toxin
  ADP-ribosylation, **243,** 243*f*
  translation targeting of, 230

Direct bilirubin, **800**
Direct demethylation, DNA repair, 172–173, 173*f*
Directional cloning, recombinant DNA, 265, 265*f*
Directionality, polynucleotides, **30**
Disaccharidase, **1051**
  deficiency, 1051cc
Disaccharides, 1049–1051, 1050*f*, 1050*t*
Discontinuous strands, semi-discontinuous DNA synthesis, **145,** 145*f*
Disease(s). *See also* specific diseases
  amino acid diagnosis, 127cc
  ATP-binding cassette (ABC) transporters and, 497cc
  cell membrane fluidity and, 472cc
  coenzyme mutations, 390cc
  collagen biosynthesis and, 245*t*
  liver disease, 873–874, 873*f*-874*f*
  membrane transport and, 488cc
  microarray detection of, 296cc
  mitochondrial genes, 582–583, 582*f*, 582*t*
  mitochondrial protein import and, 239cc
  NADPH oxidase in, 585cc
  plasma proteins and diagnosis of, 87cc
  protein requirements in, 1106, 1106cc
  renal disease, 874–875, 875*f*
  splicing mutations and, 198, 199*f*
  topoisomerases and treatment of, 52cc
Dissociation constant
  biochemical compounds, 8*t*
  ionizable amino acids and proteins, 82–83, 83*t*
  ligand-receptor interaction, downstream signaling, **512,** 512*f*
Distal histidine, heme-oxygen binding, **355**
Distributive process, replication fork movement, **148**–149, 149*f*
Disulfide bonds, stereochemistry, **1125**
Disulfide isomerase, protein modification, **242**
Disulfuram, 412cc
Diurnal variation, cyclic hormone systems, **901**
Divalent metal transporter (DMT-1), iron transport, 1087–1088, 1088*f*, 1088*t*
Dizao-5-oxo-L-norleucine (DON), glutamine nitrogen donor enzyme inhibition, 834, 834*f*
DNA, **16, 26**. *See also* DNA recombination; DNA repair; DNA replication
  cell structure, 2
  cell transformation, 26
  damage and mutation, 164–167, 165*f*-166*f*
  double-helical structure, 32–41
    conformations, 38–41, 39*f*-41*f*, 40*t*
    denaturation and renaturation, 36–37, 36*f*-37*f*
    hybridization, 38, 38*f*
    stabilization factors, 34–36, 35*t*, 36*f*
    tautomeric forms, 32, 32*f*
    Watson-Crick model, 33–34, 33*f*-34*f*
  fragments, cosmid and artificial chromosome vector cloning, 278–279
  function, 26, 58–62
    eukaryotic functional genes, 59–61, 60*f*
    prokaryotic DNA protein coding, 58–59
    repeated sequences, 61–62
    restriction endonucleases and palindromes, 58, 58*f*-59*f*
    RNA synthesis, 182–183
  genome, **2**
  higher-order structures, 48–57
    epigenetic cancer treatments, 57
    eukaryotic chromatin organization, 54–55, 54*f*
    genomic DNA, 49, 49*f*
    nucleosomes and polynucleosomes, 55–57, 55*f*-56*f*
    superhelical DNA, 49–51, 50*f*-51*f*
    topoisomerases, 51–53, 51*t*, 53*f*
  information capacity, 27
  methylation
    fragile X syndrome, 189cc
    gene inactivation and, 319–320, 319*f*
    mismatch repair, **170**–172, 170*f*-171*f*
  microarray analysis, 296–298, 297*f*-298*f*
  mitochondrial DNA, 18
  modification, epigenetic cancer therapy and targeting of, 328cc
  noncanonical structures, 41–48
    antitumor antibiotics, 42
    bent DNA, 41–42
    cruciform DNA, 42–43, 43*f*
    four-stranded DNA, 45–46, 45*f*
    slipped DNA, 46, 47*f*
    telomerase targeting, anticancer agents, 46
    triple repeats and human disease, 48cc
    triple-stranded DNA, 43–45, 44*f*-45*f*
  nuclear structure and function, 15–16, 15*f*
  polynucleotide structure and bonding, 30–32, 30*f*-31*f*
  random primer labeling, 270–271
  recombinant (*See* Recombinant DNA)
  restriction endonuclease
    hydrolyzation, 258–259, 259*f*
    segment definition, 259–260
  segment definition
    restriction endonuclease, 259–260
    subcloning, 279
  segments, chromosome walking, 279–280, 280*f*
  sequencing
    Bloom syndrome diagnosis, 262cc
    direct, 261
    dye-terminator sequencing, 262, 263*f*
    Maxam-Gilbert procedure, 260
    nucleic acid probes, 268, 270–271, 271*f*
    Sanger procedure, enzymatic cleavage, 260–261, 260*f*-261*f*
  site-directed mutagenesis, deletion/insertion mutations, flanking regions, 284, 284*f*-285*f*
  structure, 30–48, 30*f*
  vaccines, 28
DnaA initiator protein, DNA replication, eukaryotic enzymes, **155,** 155*f*
DNA arrays, diagnostic applications, 39cc
DnaB, DNA replication, eukaryotic enzymes, 152, **155,** 155*f*
DNA-binding domain (DBD)
  protein-protein interactions, *99*, 99*f*
  steroid receptors, 932–934, 933*f*
DNA-binding proteins, sequence-specific proteins, detection of, 272–273, 274*f*, 275
DNA chip, microarray analysis, **296**–298, 297*f*-298*f*
DnaC initiator protein, DNA replication, eukaryotic enzymes, **155,** 155*f*
DNA gyrase, superhelical DNA, **152**–153
DNA ligase
  DNA replication, **152**–153
  linear and circular DNA, **49,** 49*f*
  replication fork movement, **146**–147, 147*f*
DNA methyltransferases
  DNA replication, epigenetics, 151
  epigenetic cancer therapy, 328cc
DNA-PK, nonhomologous recombination, **163**–164
DNA polymerases, **140, 142**
  bypass (translesion) synthesis, 174, 174*f*
  DNA replication, 140–143, 142*t*, 143*f*
    DNA polymerase α, **153**–157, 154*f*, 156*f*
    DNA polymerase δ, **153**–157, 156*f*
    DNA polymerase I, **152**–153
    DNA polymerase III, **151**–153, 151*f*
DNA recombination. *See also* Recombinant DNA
  basic principles, 158–159
  cancer and, 159cc
  E. coli recombination proteins, 162
  gene therapy and, 164cc
  homologous recombination, 158–162, 158*f*
  nonhomologous recombination, 158, 163–164
  overview, 140
  pseudogenes, 164
DNA repair
  direct demethylation, 172–173, 173*f*
  double-strand break repair, 175
  excision repair, 167–172
    base excision repair, 167–168, 168*f*, 168*t*
    nucleotide excision repair, 169, 169*f*
  mismatch repair, 170–172, 170*f*-171*f*
  overview, 140

    epigenetics, 151
    linear genome termination, telomeres, 150–151, 151*f*
    replication fork movement, 145–149, 146*f*-150*f*
    replisome three-dimensional choreography, 150
    semi-discontinuous DNA synthesis, 145, 145*f*
  initiation of, 155–156, 156*f*
  lesion blockage of, 174–175
  overview, 140
DNase-hypersensitive sites, eukaryotic transcription, 187–188, 188*f*
DNA synthesis
  chemotherapy and precursor targeting, 142cc
  eukaryotic enzymes, 156–157, 156*f*
  replication fork movement, 145–149, 146*f*
  semi-discontinuous, DNA replication, 145, 145*f*
DNA vaccines, 28cc
DNA viruses, oncogenesis and, 1017cc
Docking protein, secretory pathway, **232**
Dolichol phosphate
  N-linked glycoproteins, **660**–663, 660*f*-661*f*
  N-linked glycosylation, **233**
  vitamin A, **1066**

Domains
secondary protein structure, **94,** 94–95, 95*f*
steroid receptors, 932–934, 933*f*
Donor atom, hydrogen bonds, folded proteins, **118,** 118*f*
Donor molecule, protein structure, spectroscopic analysis, **132**
Donor sites, elongation and peptide bond formation, 223, 224*f*-225*f*, 226
Dopamine
neuronal reuptake, 950cl
signal termination, 950, 950*f*
tyrosine metabolites, **781**
Dopamine hydroxylase, coper activation, 394–395, 395*f*
Dopamine synthesis, lyase reaction, 381, 381*f*
Dopamine transporter, cocaine and, **950,** 950*f*
Dose-response curve, ligand-receptor interaction, downstream signaling, **513**
Double-helical DNA structure, **32,** 32–41
conformations, 38–41, 39*f*-41*f*, 40*t*
denaturation and renaturation, 36–37, 36*f*-37*f*
hybridization, 38, 38*f*
stabilization factors, 34–36, 35*t*, 36*f*
tautomeric forms, 32, 32*f*
Watson-Crick model, 33–34, 33*f*-34*f*
Double-helical RNA structure, intramolecular base pairing, 62, 62*f*
Double-reciprocal plot, ping-pong mechanism, enzyme two-substrate reactions, 405–407, 406*f*
Double-stranded break (DSB) model
DNA repair, **175**
homologous recombination, 159*t*, 161–162, 162*f*
Double-stranded DNA (dsDNA), **33**
hydrogen bonding in, 33
site-directed mutagenesis, 287, 288*f*
Double-stranded RNA-dependent kinase, translation regulation, **247**
Downregulation
hormone-receptor complexes, 909
membrane receptors, **475**
Downstream signaling, ligand-receptor interaction, 512–513, 512*f*-513*f*
DRA gene, familial chloridorrhea, 1039cc
Drosha nuclease, translation regulation, **247**
Drug compounds
cytochrome P450 exogenous metabolism, 431, 436–440, 436*f*, 437*t*
genetic polymorphisms, 442–443
therapeutic inhibition, 444
enzyme inhibitors, 411–413, 412*f*, 412*t*
liposome carriers for, 466cc
Drug-drug interactions, cytochrome P450, 438cc, 440–442, 441cc, 442*f*
Drug-nutrient interactions, 1094–1095, 1095*t*
Drug resistance
chemotherapy, biochemical basis, 835–836
HIV therapy, nucleoside analogs and, 144cc
Dubin-Johnson syndrome, 495
serum-conjugated bilirubin, 800cc
Dyad symmetry, lactose operon operator and promoter, **308,** 308*f*
Dye-terminator sequencing, 262, 263*f*
Dynamic flexibility, three-dimensional protein structure, **129**–131
Dynein, 981, 981*f*
Dystrophic epidermolysis bullosa (DEB), site-directed mutagenesis, type VII collagen, 286cc

E
Edman cycle, **128**
Edman reaction, polypeptide sequencing, **127**–128, 128*f*
Effector proteins
cell surface receptors, intracellular signal transduction, **509,** 509–510, 510*f*
glycogen metabolism, 638–639, 638*f*
EF-G factor, **226**
EF-hand, calmodulin domain, 95, 95*f*
Ehlers-Danlos syndromes, collagen synthesis defect, 246cc
Ehrlich tumor cells, nucleotide distribution, 809
Eicosanoids, **674**
intracellular signaling pathways, **536**
Eicosatrienoic acids, physiological effects, 745
eIF4E initiation factor, translation regulation, **221,** 223, 247
Elastase
reactivity, 346*t*
zymogen activation, 1044*t*, **1046**
Elastin, allysine-generated cross-links, **106,** 107*f*
Elderly, nutritional needs of, 1083cc
Electrically silent transport, **486**
Electrical potentials, nutrient transport, 1041–1042, 1041*f*
Electrical synapses, neuron-neuron interaction, 943, 944*f*-945*f*
Electrochemical-potential-driven transporters
anion exchange protein, 490, 490*f*
glucose translocation, 488–489, 489*f*, 489*t*
mammalian membranes, **487**
mitochondria, 490
sodium/glucose transporter, 489–490, 489*f*
sodium/hydrogen exchanger, cytoplasmic pH regulation, 490
utilization mechanisms, 487–490
Electrogenic transport, **486**
Electrolytes, **5**
bacterial toxigenic diarrhea, replacement therapy, 1041cc
digestion and, 1032
water molecule dissociation, 5–6, 5*f*
Electromotive force (emf), electron transport chain oxidation-reduction, **561**
Electron-density mapping, x-ray diffraction, three-dimensional protein structure, **130**–131, 130*f*
Electron distribution, x-ray diffraction, three-dimensional protein structure, **129**–131, 130*f*-131*f*
Electron transferring flavoprotein (EFT), mitochondrial electron transport, 566
Electron transport
cytochrome P450, 427–430, 428*f*
mitochondria, 561–572, 561*f*
cyanide poisoning, 572cc
cytochrome *c* oxidase, 563, 569–570, 569*f*-570*f*, 570cl
inhibitors, 570–572, 571*f*
mitochondrial electron transport, 563–564, 563*f*
NADH-ubiquinone oxidoreductase, 564–565, 564*f*-565*f*
oxidation-reduction reactions, 561–563, 562*t*
oxidative phosphorylation, 573–575, 573*f*-575*f*
succinate-ubiquinone oxidoreductase, 565–566, 566*f*
ubiquinol-cytochrome *c* oxidoreductase, 566–569, 567*f*-569*f*
mitochondrial multi-component system, 563–564, 563*f*
nitric oxide synthases, 445–446, 446*f*
tricarboxylic acid cycle, **552**
Electro-osmotic flow, capillary electrophoresis, protein separation, 122, 123*f*
Electrophoresis. *See also* specific electrophoretic techniques, e.g., Polyacrylamide gel electrophoresis
plasma proteins, 85–87, 86*f*-87*f*
density correspondence, 108, 108*f*
disease diagnosis, 87cc, 88*f*
protein separation, **121**–122, 122*f*-123*f*
Electrophoretic mobility shift assay (EMSA), sequence-specific DNA-binding protein detection, **272**–273, 274*f*, 275
Electrostatic interactions
cytochrome P450 binding, 429
folded proteins, **118**–119, 119*f*
macromolecular structures, **1125**
Elejalde syndrome, 980cc
Elongation
fatty acids, **685,** 685*f*
peptide bond formation, 223, 224*f*-225*f*, 226
RNA transcription, **182,** 183*f*, 196, 196*f*
prokaryotes, 187
Elongation factor 1 (EF1), peptide bond formation, **223,** 224*f*-225*f*, 226, 227*f*
Elongation factor 2 (EF2), peptide bond formation, **226**
Embden-Myerhoff pathway, carbohydrate metabolism, 592
Embryonic stem cells, **13, 294**
Emulsion droplets, lipid digestion, **1052**
bile acid micelles, 1055–1057
Enantiomers, **1124–1125, 1125**
Endocrine diseases, G protein mutations in, 525cc
Endocrine hormones, **885**
Endocrine signaling, **505,** 505–506, 505*f*
Endocytosis, **18**
cell death and, 15
lysosomes and, 18–19, 19*f*
membrane receptor internalization, 906–907, 908*f*
Endogenous compounds, cytochrome P450 oxygenation, 432, 433*f*-434*f*, 434–435
Endonucleases, cytoplasmic mRNA turnover, 203–204
Endopeptidases, protein digestion, **1043**–1044, 1044*f*-1045*f*, 1044*t*
Endoplasmic reticulum (ER), **11, 16, 219**
chaperone proteins, 232cl
membrane and organelle targeting, 235–240
NADPH-cytochrome P450 reductase in, 428–429, 428*f*-429*f*
procollagen formation in, 244–245
protein glycosylation in, 232–233, 233*t*, 234*f*-235*f*
protein synthesis and synthetic pathways, 16, 16*f*-17*f*
protein topology, 239*f*
ribosomes in, 219
β-Endorphin, 887, 888*f*, 889*t*–891*t*, 891
Endorphins, neuropeptide derivation, **953**
Endostatin, **1020**
Endothelial (NOSIII/eNOS), 447*t*, 450–453, 450*f*
endothelial dysfunction and, 452cc
Endothelial lining, hemostasis, **982**
Endothelial system, endothelial (NOSIII/eNOS) and dysfunction in, 452cc

Energetics of membrane transport, 486–487
Energy costs of translation, 229
Energy metabolism, 1102–1103, 1102*f*
Energy-producing/energy-utilizing systems, 542–543, 542*f*-543*f*
  fatty acids, 691–701
    energy yield from β-oxidation, 693
    ketone bodies, acetyl coA formation, 697–700, 697*f*-698*f*, 700*f*
    nonhepatic tissue ketone body utilization, acetoacetyl coA formation, 700
    β-oxidation of straight-chain fatty acids, 691–693, 692*f*
    β-oxidation process, 694–697, 695*f*-696*f*
    proxisomal oxidation, 700–701, 701*f*
    synthesis *vs.* oxidation, 694, 694*t*
  metabolic energy requirements, reserves, and caloric homeostasis, 849–850, 849*t*-850*t*
Energy-rich compounds, thermodynamics, 543–548
  dietary components, caloric value, 545–546
  enzyme reactions, energy changes, 547
  free energy availability, 544–545
  high-energy bond energies, 547–548, 548*f*
  hydrolysis groups, 546
Energy units, 382cl
Enhancers
  eukaryotic transcription, **188**–189, **322**
  RNA synthesis, **183**
Enkephalins
  hormone gene encoding, **895,** 895*f*
  neuropeptide derivation, **952–953**
Enoyl CoA isomerase, unsaturated fatty acid oxidation, **695**
Entactin, laminin and type IV collagen networks, 372, 372*f*
Enterocytes
  glucose transporters in, 1051*t*
  sodium chloride absorption, 1037–1039, 1038*f*-1039*f*
Enteropeptidase, pancreatic zymogen activation, **1045**
Entropy, thermodynamics of energy-rich components, 544
Environmental cause of cancer, 1022cc
Enzyme deficiency identification and treatment, 419cc
Enzyme-linked immunosorbent assay (ELISA), 421cl
Enzyme-linked receptors, **508**
  signal transduction, 516–520, 517*f*
Enzyme replacement therapy, lysosomal storage diseases, 238cc
Enzyme(s)
  acid-base reactions, pH levels, 387, 387*f*
  active sites, 387–389, 387*f*-388*f*
    stereochemistry, 388, 388*f*-389*f*, 389cl
    substrate distal bonds, 388–389, 389*f*
  activity regulation, 413–417
    allosteric control, 413–414, 414*f*
    catalytic subunit modulation, 417, 417*f*
    covalent modification, 413
    metabolic pathways, 417
    multi-subunit cooperativity, 414–417, 415*f*-416*f*
  assays, ambiguity with mutations, 415cc
  basic properties, 378
  classification, 378–379, 379*t*
  clinical applications, 418–421
    enzyme deficiency identification and treatment, 419cc
    enzyme-linked immunoassays, 421cl
    laboratory assays, 421cc
    metabolomics and proteomics, 420–421
    plasma enzyme measurement, 418–419, 419*f*-420*f*
  copper cofactors, 1092–1093
  coupled reactions, Gibbs free energy, 547
  covalent modification, 417
  debranching enzymes, glycogenolysis, 631–632, 631*f*
  digestive enzymes, 1031–1033, 1032*t*-1033*t*, 1034*f*
  DNA replication, 151–158
    cell cycle, 157–158, 157*f*
    eukaryotic enzymes, 153–157, 154*f*-155*f*
    prokaryotic enzymes, 151–153, 151*f*
  energy units, 382cl
  glycogenesis requirements, 632–633, 632*f*
  heme biosynthesis, 791–796, 791*f*-795*f*, 796*t*
  hydrolases, 380, 380*f*
  inhibitors, 407–413
    competitive inhibition, **407,** 407*f*, 409
    as drugs, 411–412, 412*t*
    high-throughput screening, 413cl
    irreversible inhibitors, **410,** 411*f*
    Lineweaver-Burk plots, 409–410, 409*f*-410*f*
    mechanism-based (suicide) inhibitors, 410
    metabolic pathway regulation, 417
    mushrooms and alcohol metabolism, 412cc
    natural products, 413cc
    noncompetitive inhibition, 408–409, 409*f*
    poisoning, 411cc
    selective inhibitor, 408cc
    testosterone and prostate cancer, 412cc
    transition-state inhibitors, 410
    two-substrate reactions, 410
    uncompetitive inhibition, **408,** 408*f*
  isomerases, 381–382, 381*f*-382*f*
  ligases, 382, 382*f*
  lyases, 380–381, 381*f*
  lysosomal
    gout and, 19cc
    table of, 19*t*
  metabolic pathway regulation, 417–418, 417*f*
    allosteric effectors, 853–855, 853*f*-855*f*
    covalent modification, 855–859, 855*f*-858*f*
  metal cofactors, 393–395, 393*f*-395*f*
  mitochondrial subcompartment, 560*t*
  nucleic acid editing enzymes, 201cc
  nucleotide metabolism, 828–829
  one-substrate reactions, 399–405
  oxidoreductases, 379–380, 380*f*
  reaction kinetics, 397, 399–405
    constant calculations, 404, 404*f*
    Michaelis-Menten equation, 400–402
  RNA as, 68–69, 68*f*
  secretagogue regulation, 1033–1034, 1033*t*, 1034*f*-1035*f*, 1036
  substrate binding, 383, 383*f*
    covalent binding, 386–387, 387*f*
  thermodynamics, 382–383
  transferases, 380, 380*f*-381*f*
  transition state, 383–386, 384*f*-386*f*
  two-substrate reactions
    inhibitors, 410
    ping-pong mechanism, 405–407, 406*f*
    sequential mechanism, 405, 406*f*
  urea cycle synthesis, 759–760
Epidermal growth factor (EGF), hemostasis, **982**
Epigenetics, **57**
  cancer therapy, 57cc
  DNA replication, 151
  gene expression regulation, 328
  nutritional epigenetics, **1095**
Epimerase, 381, 382*f*
Epimers, **1125, 1126**
Epinephrine
  glycogenolysis
    in heart and skeletal muscle, 641, 641*f*
    in liver, 640–641, 640*f*
  neuronal reuptake, 950cl
  phenylalanine/tyrosine synthesis, 895, 895*f*-896*f*
  signal termination, 950, 950*f*
  tyrosine metabolites, **781**
Epithelial cells
  multiple mutations and cancer in, 1020–1021
  transport, 1036–1043
    gastric parietal cell gastric acid secretion, 1042–1043, 1043*f*
    nutrient transport mechanisms, 1041–1042, 1041*f*-1042*f*
    sodium absorption mechanisms, 1037–1039, 1038*f*-1039*f*
    sodium secretion mechanisms, 1039–1040, 1040*f*-1041*f*
    transcellular/paracellular solute transport, 1036–1037, 1036*f*, 1037*t*
Epoxide, vitamin K and, 995
Epoxyeicosatetraenoic acids (EETs), cytochrome P450 metabolism, 434
Equilibrium constant
  conjugate pair, 7–8
  glycolysis regulation, 605
  thermodynamics, 544–545, 544*f*
  water molecule dissociation, 6
Erabutoxin, **483**
ER-associated degradation (ERAD), protein synthesis, **235**
ErB/HER receptor tyrosine kinases, cancer chemotheraphy, 518cc
Ergosterol, 719, 719*f*
Erythrocytes
  glucose transporters (GLUT), 489, 489*f*
  polysaccharide biosynthesis, 658
Erythromycin
  staphylococcal resistance, 66cc
  translation targeting of, **230**
Erythrose 4-phosphate, pentose phosphate interconversions, **650**–651, 650*f*
Escherichia coli (E. coli)
  fatty acid biosynthesis, 682–683, 682*f*
  genome map, 304, 305*f*
  lactose operon of, 305–306, 306*f*
  mismatch repair in, 170–172, 170*f*-171*f*
  plasmid pSC101, 264
  recombination proteins, DNA recombination, 162
  replication enzymes of, 151–153, 151*f*
  tryptophan operon of, **310,** 310–314, 311*f*
Essential amino acids (EFAs)
  deficiency, 1112–1113
  degradation, 767–775
  in diet, 1103–1104, 1103*t*, 1104*f*
  metabolism, 753*f*
  sources of, 753*t*

Essential fatty acids, formation and modification, **685–686**
Esters, 1123
Estimated Average Requirements (EARs), malnutrition assessment, 1064–1065
Estradiol
  ovarian cycle control, **901**
  synthesis of, 924–925, 926*f*
17β-Estradiol, **916,** 926*f,* **930**
Estrogen/progesterone ratio, fertilization, 905
Estrogen receptors (ERαERβ), **930**
Estrogens, cytochrome P450 synthesis, 434, 435cc, 436*f*
  breast cancer and, 444
ETF-ubiquinone oxidoreductase, mitochondrial electron transport, 566, 566*f*
Ethanolamine plasmalogen, **460**
Etoposide, 52cc
E2F transcription factor
  apoptosis induction by p53, 1014–1015, 1014*f*
  Rb protein regulation of, **1007,** 1007*f*
Euchromatin, polynucleosome packing, **57**
Eukaryotes, **2**
  bypass (translesion) synthesis, 174, 174*f*
  chromatin organization, 54–55, 54*f*
  classification and cellular organization, 2, 3*f*
  DNA functional genes, 59–61, 60*f*
  expression vector
    bacterial plasmids, 281–282, 282*f*
    cells, 282–284, 283*f*
  functional integration and control, 21–22
  gene expression in, 304, 317–320
    histone-bound DNA and chromatin formation, 317–319, 318*f*
    regulation of, 325–328
  genome sequencing, 295*t*
  glycosyltransferases in, 232, 233*t*
  mammalian cells and tissues, 11–14, 12*f,* 13*t,* 14*f,* 15*t*
  membrane transport proteins, 488, 488*t*
  mRNA structures, 67–68, 67*f*
    translation, 210
  RNA transcription, mechanisms of, 182, 183*f*
  subcellular organelles and membrane systems, 14–21
    cytoskeleton intracellular organization, 21
    cytosol components, 21
    endoplasmic reticulum structure and function, 16, 16*f*–17*f*
    Golgi complex structure and function, 17, 17*f*
    lysosomes, intracellular digestion and, 18–20, 18*f*–19*f,* 19*t*
    mitochondrial ATP supply, 17–18, 17*f*
    nuclear sites, DNA/RNA synthesis, 15–16, 15*f*
    peroxisome structure and function, 20–21, 20*f*
    plasma membrane boundary, 14–15, 14*f*
  supercoiled DNA in, 56*f*
  transcription factors
    modular design, 322
    preinitiation complex, 320–325, 320*t*
    promoters, 321–322, 322*f*
  transcription in, 187–193, 188*f*–189*f*
    enzymatic RNA polymerase action, 192–193, 193*f*
    promoters and other sequences, 321–322, 322*f*
    RNA polymerase I, 190–191, 191*f*
    RNA polymerase III, 191–192
  translation initiation in, 221–223, 222*f*
Eukaryotic enzymes
  DNA replication, 153–157, 154*f*–156*f*
  transcription, 183–184
    RNA polymerase III, 192–193, 193*f*
Eukaryotic initiation factor 2 (eIF2), protein synthesis, **221**–223, 221*t,* 222*f*
Evolution, restriction mapping and, 260cc
Excision repair, DNA damage, **167**–172
  base excision repair, 167–168, 168*f,* 168*t*
Excitation transfer, protein structure, spectroscopic analysis, **132**
Excitatory neurotransmitters
  ligand-gated ion channels, **515,** 515*f*
  neuron-neuron interaction, **943**
Exciton system, protein structure, ultraviolet light spectroscopy, **131**–133, 131*f*–133*f*
Exercise
  aerobic/anaerobic, 868–871, 870*f*
  basal metabolic rate and, 1102–1103
  carbohydrate loading, 1111cc
  covalent enzyme modification and, 859
  intolerance, cytochrome *b* mutations, 584cc
Exit site (E site), elongation and peptide bond formation, **226**
Exocrine cells
  digestive enzymes, 1033, 1034*f*
  secretagogues and, 1033–1034, 1033*t,* 1034*f*–1035*f,* 1036
Exocytosis, **946**
  digestive enzymes and, 1033, 1034*f*
Exogenous lipophilic substrates, cytochrome P450 oxidation, 436–440, 436*f,* 437*t*
Exon-intron patterns, serine proteases, **350,** 350*f*
Exons, eukaryotic functional gene sequencing, 60–61
Exonucleases, cytoplasmic mRNA turnover, 203–204
Exonucleolytic activity, proofreading, DNA polymerases, **143**
Exopeptidases, **344**
Exosome, **203**
Expression vector
  bacterial foreign genes, protein synthesis, **281–282,** 282*f*
  complementary DNA synthesis, 276
  eukaryotic cells, 282–284, 283*f*
  site-directed mutagenesis, DNA flanking regions, 284*f*
Extensive metabolizers, cytochrome P450 genetic polymorphisms, 442–443
Extracellular matrix, cytoskeleton interconnection, 373
Extreme general stress, bacteria, **315**
Extrinsic factor, cobalamin structure and function, 1082–1083, 1082*f*
Extrinsic pathway
  apoptosis, death receptor pathway, 1011, 1012*f*
  coagulation initiation, 983–984
  hemostasis, **982**
  inhibition, anticoagulation and, 990–993, 991*f*
Eye(s)
  anatomy, 952*f*
  metabolism and vision, 953–966
Ezetimibe, cholesterol absorption, 1057cc

F
F_1F_0-ATP synthase, mitochondrial electron transport, oxidative phosphorylation, 575–577, 575*f,* 575*t,* 576cl
Fabry disease, enzyme replacement therapy, 238cc
Facilitated diffusion, membrane transport energetics, **487**
F-actin, **971–972**
Factor III, hemostasis, **982**
Factor IV, platelet plug formation, **985**
Factor V, 984, 984*f*
  clot formation, 987
Factor Va, inactivation, 993–994
Factor VIIa, extrinsic pathway inhibition, 990–993, 991*f*
Factor VII, **983**–985, 984*f*
  clot formation, 986, 986*f*–987*f*
  recombinant form, coagulation and, 990cc
  vitamin K and, 994–995, 996*f*
Factor VIII
  clot formation, 988, 989*f*
  thrombin formation, 984, 984*f*
Factor VIIIa
  inactivation, 993–994
  intrinsic pathway reactions, 984–985, 984*f*
Factor IX
  intrinsic pathway reactions, 984–985, 984*f*
  vitamin K and, 994–995, 996*f*
Factor X
  clot formation, 986, 987*f*
  intrinsic pathway reactions, 984–985, 984*f*
  vitamin K and, 994–995, 996*f*
Factor Xa
  backbone structure, 987*f*
  extrinsic pathway inhibition, 991, 992*f*
  thrombin formation, 984, 984*f*
Factor XIa, intrinsic pathway reactions, 984–985, 984*f*
Factor XI
  clot formation, 989, 989*f*
  intrinsic pathway reactions, 984–985, 984*f,* 985cc
Factor XIIa, intrinsic pathway reactions, 984–985, 984*f*
Factor XII, intrinsic pathway reactions, 984–985, 984*f,* 985cc
Factor XIII
  clot formation, 988, 989*f*
  intrinsic pathway reactions, 984*f,* 985
  thrombin formation, 984, 984*f*
Factor XIIIa, clot formation, **988**
Factors (protein), RNA transcription, **182**
FADD adaptor protein, apoptosis death receptor pathway, 1011, 1012*f*
Familial chloridorrhea, 1039cc
Familial hyperproinsulinemia, 241cc
Familial hypertrophic cardiomyopathies, 971cc
Faraday constant, membrane transport energetics, 486–487
Farnesyl pyrophosphate, cholesterol synthesis
  mevalonic acid precursor, **720**–721, 720*f*
  squalene formation, 721–722, 721*f*–722*f*
Fasting state. *See also* Starve-feed cycle
  energy requirements and hormone homeostasis, 849–850, 850*t*
  enzyme induction in, 859–860, 859*f*
  gluconeogenesis in, 845–847, 845*f*–846*f*
  lipid regulation, 701–702
  lipid transport, 679–680
  lipogenic enzymes in, 860
  triacylglycerol synthesis, 689, 690*f*
Fatal familial insomnia, 115

Fat(s)
absorption, pharmacological interventions in, 1053cc
for diabetics, 1112cc
dieting and consumption of, 864–865, 864*f*
metabolic energy requirements, 849–850, 849*t*–850*t*
metabolism of, 1112–1113
protein sparing, 1104
Fat-soluble vitamins, 1065–1075
Fatty-acid-binding protein (FABP), bilirubin conjugation, 798–799
Fatty acids, **1129**. *See also* Triacylglycerol-fatty acid cycle
alkyl chain termination, carboxyl group, 674–675
basic structure, **674,** 674*f*
branched-chain fatty acids, **675**
ceramide derivatives, sphingosine, 730, 730*f*
energy production, 691–701
energy yield from β-oxidation, 693
ketone bodies, acetyl coA formation, 697–700, 697*f*–698*f*, 700*f*
nonhepatic tissue ketone body utilization, acetoacetyl coA formation, 700
β-oxidation of straight-chain fatty acids, 691–693, 692*f*
β-oxidation process, 694–697, 695*f*–696*f*
proxisomal oxidation, 700–701, 701*f*
synthesis *vs.* oxidation, 694, 694*t*
gluconeogenesis and, 626–627, 627*f*
fasting state, 846–847
glucose metabolism, 594*f*–595*f*, 595–596
glucose synthesis, 625, 625*f*
glycerophospholipids, 459–460, 461*f*, 461*t*
membrane leaflets, 472–473, 472*f*
in humans, 675*t*
interorgan transport, 678–680, 678*f*
lipid digestion, 1052, 1052*f*
chylomicron incorporation, 1057–1058
lipogenesis, 680–687
biosynthesis pathway, 680–683, 680*f*–682*f*, 683*t*
citrate cleavage pathway, acetyl CoA and NADPH formation, 684–685
elongation reactions, 685, 685*f*
fatty acid synthase, 686–687
fatty acyl coA reduction to fatty alcohols, 687, 687*f*
glucose precursor, 680
hydroxy fatty acid formation in nerve tissue, 686
monoenoic acid formation, 685
palmitic acid synthesis, 681, 681*f*
polyunsaturated fatty acid formation, 685–686, 685*f*–686*f*
obesity and insulin resistance, 1109–1110, 1109*f*
odd-chain fatty acids, 695, 695*f*
oxidation, gene transcription regulation, 862, 862*f*
phospholipid asymmetric distribution, 716, 716*f*
prostaglandins precursors, 738–739, 739*f*
as regulatory molecules, 701, 702cc
in sphingomyelin, 730–731, 731*f*–732*f*
sphingomyelins, 460
straight-chain fatty acids, β-oxidation, 691–693, 692*f*
triacylglycerol storage, 687–689, 690*f*
type 2 diabetes and, 677cc
unsaturated fatty acids, 695
very-long-chain fatty acids, 674–675, 675*f*
Fatty acid synthase, fatty acid biosynthesis, 682–683, 682*f*, 686–687
Fatty acyl CoA:cholesterol acyltransferase (ACAT), cholesterol synthesis, **727**
Fatty acyl coAs
fatty acid oxidation, 691
fatty alcohol reduction, 687, 687*f*
phosphatidic acid synthesis, 712–713, 713*f*
triacylglycerol synthesis, 688, 688*f*
Fatty alcohols
fatty acyl coA production, 687, 687*f*
plasmalogen synthesis, 716, 717*f*, 718
Fed state. *See also* Starve-feed cycle
early refed state, glycogen formation, 847
energy requirements and hormone homeostasis, 849–850, 850*t*
enzyme induction in, 859–860, 859*f*
lipid regulation, 701
lipid transport, 678–679
liver metabolism, well-fed to starved state switching, 852–862
Feedback inhibition
metabolic pathway regulation, **417,** 417*f*
tryptophan operon, **310**
Fenton reactions, reactive oxygen species, 584, 584*f*
Ferrireductase duodenal cytochrome b, 1087
Ferrireductases, anemia and immunocompetence, **1087**
Ferritin receptor
anemia and decreased immunocompetence, **1087**
translation regulation, **247**
Ferrochelatase, **796**
Ferroxidases, anemia and immunocompetence, **1087**
Fertilization, ovarian cycle, 902–905, 904*f*–905*f*
Fexofenadine, CYP3A4 inhibition, 438cc
Fiber
dietary metabolism of, 1113, 1113*t*
variable sources of, 1116
Fibrin formation
clot formation and, 987–988, 988*f*
myocardial infarction, 344cc
Fibrinogen, clot formation, 987–988, 988*f*
Fibrinolysis, **982**
hemostasis and, 994, 994*f*
Fibroblast growth factor (FGF), angiogenesis and, **1019–1020,** 1020*f*
Fibrous proteins
elastin, 106
keratin and tropomyosine, 106–107, 107*f*
structure and conformation, **103**
Fick's first law of diffusion, membrane translocation, 476
First law of thermodynamics, energy-rich components, **543,** 544
First-order reactions, product formation, 396–397, 396*f*
Fischer projections, 1125–1126
Fischer ratio, cirrhosis and, 874
Flap endonuclease I (FEN1)
DNA mutation, short-patch repair, 168
DNA replication, **153**–157, 154*f*
Flavin adenine dinucleotide (FAD)
cytochrome P450 electron transport, 427–430, 428*f*–429*f*
multienzyme complex, **550**
nitric oxide synthases, 444–446, 444*f*–446*f*
nucleotide coenzyme synthesis, 829–831, 829*f*–831*f*
riboflavin coenzyme, **392,** 392*f*, **1077,** 1077*f*
tricarboxylic acid regulation, 558–559, 558*f*
Flavin adenine dinucleotide hydrogenase (FADH)
branched-chain amino acid degradation, 775–777
fatty acid synthesis, β-oxidation, 693
Flavin mononucleotide (FMN)
amino acid oxidases, 757, 757*f*
cytochrome P450 electron transport, 427–430, 428*f*–429*f*
mitochondrial electron transport, **565,** 565*f*
nitric oxide synthases, 444–446, 444*f*–446*f*
riboflavin coenzyme, **392,** 392*f*, **1077,** 1077*f*
Flavin reductase domain, nitric oxide synthases, 444–446, 444*f*–446*f*
Flavoprotein dehydrogenases, mitochondrial electron transport, 565–566, 566*f*
Flavoprotein reductase, cytochrome P450 electron transport, 427–430, 428*f*
Flavoproteins
cytochrome P450 electron transport
NADPH-adrenodoxin reductase in mitochondria, 430, 430*f*
NADPH-cytochrome P450 reductase in endoplasmic reticulum, 428–429, 428*f*–429*f*
mitochondrial electron transport, **563**
Flippases, **468**
Floppase, **468**
Fluorescence spectroscopy, protein structures, 132–133, 132*f*–133*f*
Fluorescent emission, protein structure, spectroscopic analysis, **132**
Fluoride
glycolysis inhibition, 603
nutritional function, **1094**
Fluoroacetate, tricarboxylic acid cycle inhibition, 554
Fluorophore, protein structure, spectroscopic analysis, **132**
5-Fluorouracil (Fura), purine/pyrimidine nucleotide metabolism, 832, 832*f*
fMet-tRNA$_i^{met}$, protein synthesis in mitochondria, **229**
FMRP protein, fragile X syndrome, 189cc
Folate
deficiency, cancer and, 1022cc
methotrexation inhibition, 832–833, 833*f*
Folate deficiency, **1081**
Folic acid, genetic polymorphisms, 1082cc
Follicle-stimulating hormone (FSH), 888*f*, 889*t*–891*t*, 891
estradiol synthesis, 924–925, 926*f*
membrane receptors, **905**
oral contraception, 926cc
ovarian cycle control, **901**
Folypoly-γ-glutamate carboxylase II, folic acid formation, **1079,** 1080*f*
Food Guide Pyramid, **1116,** 1117*f*
Foreign genes
bacterial expression vectors, protein synthesis, 281–282, 282*f*
virus-transformed eukaryotic cells, 283–284, 283*f*
Formiminoglutamate (FIGLU), histidine degradation, 774, 777*f*
Formiminotransferase deficiency, 777cc
45S RNA, precursor products, 195, 195*f*

Fos transcription factor, growth factor signal transduction, **1010**
Fourier synthesis, x-ray diffraction, three-dimensional protein structure, 130–131
Four-letter alphabet, genetic code, **211**–215, 211*t*, 212*f*
Four-stranded DNA, 45–46, 45*f*
Fovea centralis, **956**
Fragile X syndrome, 166*f*, 167, **167**
  chromatin and, 189cc
Frameshift mutations
  DNA mutation, **167**
  genetic code and, **213**
  hemoglobinopathies, 213, 215*t*
  HIV protein translation, 216cc
  slipped DNA, 46, 47*f*
Free energy
  caloric value of dietary components, 545–546, 545*t*
  coupled enzyme reactions, 547
  redox reactions, 562–563
  thermodynamics and availability of, 544–545
Free enzyme concentration, 401
  competitive inhibitors, 407, 407*f*
Free fatty acids
  transport in fed state, **678**
  triacylglycerol-fatty acid cycle, 690cc
Free iron, anemia and decreased immunocopmetence, **1087**
Fructokinase, 653cc
Fructose
  glucose synthesis, 625–626, 625*f*–626*f*
  glucose utilization, 608, 608*f*
  intolerance, 607cc
  lens contents, **956**
Fructose 1-phosphate aldolase, **653,** 653cc
Fructose 2,6-bisphosphatase
  allosteric effector regulation, 853–855, 853*f*–855*f*
  covalent modification, 856–859, 856*f*
  gluconeogenesis, 622, 622*f*
  glycolysis regulation
    cancer and, 618cl
    cardiac isoenzymes, 616–617, 617*f*
    6-phosphofructo-1-kinase regulation, 612–614, 612*f*–614*f*
    phosphorylation, bifunctional 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase, 614–615, 614*f*–616*f*
    pyruvate kinase, 617, 619, 619*f*
Fructose 6-phosphate
  glucokinase inhibition, 607
  pentose phosphate interconversions, **650**–651, 650*f*
Fructose intolerance, 653cc
Fructosuria, 653cc
F-type transporters, **491**
Fuel sparing, fatty acids and, 677cc
Fumarase, tricarboxylic acid cycle, **555**
Fumarase deficiency, 555cc
Fumarate, urea cycle synthesis, 760, 760*f*
Functional groups, 1123–1124
Furosemide, sodium chloride secretion, 1040, 1040*f*
Fusion proteins, expression vectors, **281**–282

G
G0, G1, and G2 phases. *See* Gap phases
G_1S Cdks, transition, cell cycle regulation, 1007, 1007*f*
GABA (gamma-aminobutyric acid)
  glutamate metabolites, 778
  neuron-neuron interaction, 942*t*, **943,** 944*f*
  signal termination, 950–951
GABA shunt, **950**
G-actin, 971, 973*f*
G-actin-ATP-Mg^{2+} complex, **972**
Galactocerebrosides, **462,** 464*f*
  in glycosphingolipids, **732,** 732*f*
  sulfatide sulfuruc acid ester, **732–733,** 733*f*
Galactokinase, carbohydrate interconversion, **653–654**
Galactose
  carbohydrate interconversion, 652–653
  galactosemia and, 654cc
  in glycosphingolipids, 732–734, 732*f*–733*f*, 734*t*
  nucleotide-linked, epimerization, 654, 654*f*
Galactose 1-phosphate uridylyltransferase, carbohydrate interconversion, **654**
Galactosemia, 654cc
β-Galactosidase, **304**
  glucose presence in *E. coli*, synthesis repression, 309*f*
  hydrolysis, **1050**
  lactose operon, 305–306, 306*f*
Gallbladder, cholesterol stones in, 1056cc
GalNAc, carbohydrate-glycoprotein linkage, 659–663, 659*f*
GalNAc-transferase, O-linked glycosylation, **233**
γ-Glutamyl cycle, group translocation, 477cl
Gangliosides, **462**
  sialic acid in, 733–734, 733*f*, 734*t*
Gangliosidoses, 733–734
Gap 0 (G_0) phase, cell cycle regulation, **1005**
Gap 1 (G_1) phase, cell cycle
  DNA replication, **157**–158, 157*f*
  regulation, **1004,** 1004*f*, 1005*t*
Gap 2 (G_2) phase, cell cycle
  DNA replication, **157**–158, 157*f*
  regulation, **1004,** 1004*f*, 1005*t*
Gap junctions, nuclear pores and, **484**–485, 484*f*
GAP^{Ras} protein, growth factor signal transduction, **1010**
Gaps, **145**
  DNA repair, daughter-strand-gap DNA repair, 174–175, 175*f*
  DNA replication
    eukaryotic enzymes, 153–157, 154*f*
    replication fork movement and filling of, 145–146
Gases, molecule translocation, 476
Gastric acid
  food digestion and, 1030–1032, 1031*f*, 1032*t*
  gastric parietal cell secretion, 1042–1043, 1043*f*
  histamine stimulation of, **1034**–1035, 1035*f*
  prostaglandins effects on, 742
Gastric lipases
  lipid digestion, 1052–1053, 1052*f*–1053*f*
  transport in fed state, **678**
Gastric mucosa, digestive enzyme secretion, 1033, 1034*f*
Gastric parietal cells, gastric acid secretion, 1042–1043, 1043*f*
Gastrin, digestion and, 1035*t*, **1036**
Gastrointestional system
  epithelial cell transport, 1037, 1037*t*
  food digestion and, 1030–1032, 1031*f*, 1032*t*
  glycogen formation, early refed state, 847–849, 848*f*
  neuronal (NOSI/nNOS) activation, 447–448, 448*f*
  secretions, ionic composition, 1039–1040, 1040*f*
Gaucher disease
  diagnosis, 737cc
  enzyme replacement therapy, 238cc
GDP-4-keto-6-deoxymannose 3,5-epimerase-4-reductase, **654**
GDP-mannose-4,6-dehydratase, **654**
GEF^{Ras} protein, growth factor signal transduction, **1010**
Gemifloxacin, 52cc
Gene coding, polypeptide hormones, 892–895, 892*f*–894*f*
Gene conversion, homologous recombination, Holliday model, **160**
Gene duplication, immunoglobulin genetics, **342**
Gene expression
  epigenetic control, 328
  eukaryotes, 304, 317–320
    regulation of, 325–328
  four-letter alphabet, 211–215, 211*t*, 212*f*
  microarray analysis, 297–298, 298*f*
  nucleic acid editing enzymes, 201cc
  overview, 304
  prokaryotes, 304
  small-interfering RNA regulation, 290cc
Gene library, recombinant DNA molecules in, **266**
Gene products, protein structure and function, 101
Gene(s)
  cancer and, 1023
  mitochondrial disease, 582–583, 582*f*, 582*t*
  obesity and, 1107–1108, 1108*f*
Gene therapy
  DNA recombination and, 164cc
  Leber congenital amaurosis, 291cc
  normal gene introduction into defective gene, **290,** 291cc
  severe combined immune deficiency, 291cc
Genetic code
  breaking of, 212–213
  nucleotide four-letter alphabet, 211–215, 211*t*, 212*f*
  punctuation, 211–212
Genetic polymorphisms
  cytochrome P450, 442–443, 443cc
  folic acid requirement, 1082cc
Genomes
  DNA mutation, 167
  RNA genome replication, 158
Genomics
  defined, 295
  microarray analysis, 296–298, 297*f*–298*f*
  nutrigenomics, 1095
  prokaryotic/eukaryotic species, 295*t*
Gentamycins, translation targeting of, **230**
Gerstmann-Sträussler-Scheinker synddrome, amyloid fibrils, 115
G factor, **226**
Gibbs free energy
  coupled enzyme reactions, 547
  folded proteins, 113
  membrane transport energetics, 486–487
  RNA synthesis, transcription and, 182–183, 183*f*
  thermodynamics and availability of, 544–545, 544*f*
Gla-containing proteins, 994, 995*f*, 996, 997*f*
GlcNac phosphodiester glycosidase, **661**
GlcNac-phosphotransferase
  lysosomal protein targeting, 238cc
  N-linked glycoproteins, **661**

α-Globin chains
hemoglobin structures, 353–355, 353*f*, 354*t*, 355*f*
splicing mutations and human disease, 198, 199*f*
termination codons and hemoglobinopathies, 214cc–215cc, 215*t*
β-Globin chains
hemoglobin structures, 353–355, 353*f*, 354*t*, 355*f*
splicing mutations and human disease, 198, 199*f*
termination codons and hemoglobinopathies, 214cc–215cc, 215*t*
Globin genes, hereditary persistence of fetal hemoglobin, 46cc
Globosides, 732*f*, **733, 1131**
Globular proteins
collagen comparisons with, 103, 104*t*
domain structures, 97, 97*f*
structure and conformation, **103**
α_2-Globulin, **923,** 926*f*
Glucagon
covalent modification of enzymes, 855–859, 856*f*–858*f*
gene transcription regulation, 861–862, 861*f*
gluconeogenesis hormonal control, 627–628, 627*f*–628*f*
glycogenolysis in liver, 640–641, 640*f*
glycolysis regulation, pyruvate kinase, 617, 619*f*
6-phosphofructo-1-kinase regulation, 612–614, 612*f*–614*f*
phosphorylation, bifunctional 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase, 614–615, 614*f*–616*f*
Glucocereborosides, **462,** 464*f*
in glycosphingolipids, **732,** 732*f*
Glucocorticoids, receptors, 932, 932*f*
Glucokinase, glycolysis regulation, 606–608, 606*f*, 608*f*
Glucokinase inhibitory protein (GK-RP), glycolysis regulation, 606–608, 606*f*
Gluconeogenesis, **557**
allosteric effector regulation, 853–855, 853*f*–855*f*
Atkins diet and, 864–865
carbohydrate metabolism, 619–629, 619*f*
alcohol oxidation, 628–629
ATP expenditure, 626
glucose synthesis, 619–626
hormonal control, 627–628
regulation site, 626–627
enzymes in, 860
in fasting state, 845–847, 845*f*–846*f*
glucose homeostasis and, 851–852, 851*f*
glycogen formation, early refed state, 847
Glucosamine 6-phosphate, **656**
Glucose
acid-base balance and, 876–877, 876*f*–877*f*
blood-brain barrier and transport of, 941cc
epithelial cell absorption, 1041–1042, 1041*f*–1042*f*
as fatty acid synthesis precursor, 680
galactosemia and galactose transformation, 654cc
gene transcription regulation, 860–861, 861*f*
gluconeogenesis
Cori and alanine cycles, 619–621, 620*f*
fasting state, 845–847, 845*f*–846*f*
fatty acids, 625, 625*f*
fructose, 625–626, 625*f*
lactate, 621–622, 621*f*–622*f*
glycogenolysis and maintenance in early fasting state, 844, 844*f*
glycogen storage, 629–630, 629*f*–630*f*, 633–634, 634*f*
in glycosphingolipids, 732–734, 732*f*–733*f*, 734*t*
homeostasis, phases of, 850–852, 851*f*
K_m (Michaelis constant) and utilization of, 401
metabolism, 594*f*–595*f*, 595–596
allosteric effectors, 853–855, 853*f*–855*f*
covalent enzyme modification, 858–859
energy requirements, reserves, and homeostasis, 849–850, 849*t*–850*t*
in lactation, 871–872, 872*f*
nucleotide-linked, epimerization, 654, 654*f*
priming of, 596–598, 597*f*
in well-fed state, 842–843, 843*f*
Glucose 6-phosphatase
glucokinase reaction and, 608
gluconeogenesis, 622, 622*f*–623*f*
gluconeogenesis and, 622, 622*f*–623*f*, 626–628, 627*f*
glycogenolysis and glycogenesis, 630–631, 630*f*
glycogen synthase, 636–638, 637*f*
Glucose 6-phosphate
free energy changes, 547–548, 547*f*
gluconeogenesis and, 619, 621*f*
glycolysis, 593, 594*f*, 596–597, 597*f*
hexokinase and glucokinase and, 606, 606*f*, 608
hydrolysis, 546
pentose phosphate pathway
carbon dioxide oxidation, 651, 651*f*
oxidation, 648–649, 649*f*
6-phosphofructo-1-kinase and, 608–609, 608*f*
Von Gierke disease, 633cc
Glucose-6-phosphate
glycogen metabolism, 638, 638*f*
glycogenolysis and glycogenesis, 629, 630*f*, 631–632, 632*f*, 641
glycogen phosphorylase regulation, 636
glycogen synthase regulation, 636, 637*f*
Glucose 6-phosphate dehydrogenase (G6PD)
deficiency, 648cc
hemolytic anemia, 404cc
oxidation, pentose phosphate pathway, **648**–649, 649*f*
reactive oxygen species, 587
Glucose intolerance, enzyme induction of, 862
Glucose transporters (GLUT)
glucose metabolism, 594*f*–595*f*, 595–596
monosaccharides, 1050*f*, 1051, 1051*t*
nutrient transport, 1042
obesity and insulin resistance, 1109–1110
uniport mechanism, **488,** 488–489, 489*f*, 489*t*
Glucuronic acid
ascorbic acid derivation, 656cc
glucuronide formation, 656cc
hyaluronate copolymer, **664,** 665*f*
UDP-glucose oxidation, 654–655, 654*f*–655*f*
Glucuronide
glucuronic acid formation, 656cc
glycolysis, 603
Glutamate
degradation, 764
metabolite derivation, 778
neuronal (NOSI/nNOS) activation, 447–448, 447*t*, 448*f*
side chain structure, **77,** 78*f*–79*f*
Glutamate alanine aminotransferase (ALT), transfer reactions, **754**
Glutamate aspartate aminotransferase (AST), transfer reactions, **754**
Glutamate conjugase, folic acid formation, **1079,** 1080*f*
Glutamate dehydrogenase, ammonia incorporation and production, 755–756, 756*f*
Glutamic acid, titration curve, 85, 85*f*
Glutamic semialdehyde
biosynthesis, 763, 763*f*
deficiencies in, 767cc
Glutamine
acid-base balance and, 876–877, 877*f*
ammonia incorporation and production, 756, 756*f*
asparagine amide group, 756–757, 757*f*
de novo synthesis, 810, 810*t*
gluconeogenesis, fasting state, 845–847, 846*f*
glycogen formation, early refed state, 847–849, 848*f*–849*f*
intercellular cycle, 759cc
nitrogen donor antagonists, 834, 834*f*
side chain structure, **78,** 78*f*
γ-Glutamyl cycle, amino acid transport, 790, 790*f*
Glutaric acid, diseases of, 774cc
Glutaric aciduria, 774cc
Glutaryl-CoA oxidase deficiency, 774cc
Glutathione
cornea ATP derivation, 954
glycogen formation, early refed state, 848–849, 848*f*–849*f*
metabolites, 789–790, 789*f*–790*f*
toxicity response, 790, 790*f*
Glutathione peroxidase
mitochondrial defenses, 587, 587*f*
selenium in, 1093–1094
Glutathione reductase, cornea ATP derivation, **953–954**
Glutathione transferase, drug conjugation, 789–790, 790*f*
Glutathione transhydrogenase, amino acid-derived hormone degradation, **896,** 898*t*, 899*f*
Gluten enteropathy, 1046cc
Glycan, **470,** 663
Glycation, protein, hyperglycemia and, 852cc
Glycemic index, carbohydrates and, 1115, 1115*t*
Glycemic load, carbohydrates and, 1115, 1115*t*
Glyceraldehyde 3-phosphate, pentose phosphate interconversions, **650**–651, 650*f*
Glyceraldehyde 3-phosphate dehydrogenase
glucose metabolism, 598–600
hyperglycemia and, 604cl
Glycerol
gluconeogenesis, 625, 625*f*
gluconeogenesis and glucose synthesis, fasting state, 845–847, 845*f*–846*f*
sphingosine *vs.*, 729, 729*f*
L-Glycerol3-phosphate, **458,** 459*f*
Glycerol 3-phosphate
hydrolysis, 546
triacylglycerol synthesis, **688**–689, 688*f*–689*f*
Glycerol 3-phosphate:acyltransferase, phosphatidic acid synthesis, **713**
Glycerol 3-phosphate dehydrogenase, mitochondrial electron transport, 565–566, 566*f*
Glycerol ether phospholipids, **460,** 461*f*
Glycerol kinase, glycerol 3-phosphate derivation, **688,** 688*f*

Glycerol-phosphate shuttle, mitochondrial inner membrane transport, 579, 580*f*
Glyceroneogenesis
  glycerol 3-phosphate derivation, **688,** 688*f*
  triacylglycerol-fatty acid cycle, 689, 690*f*
α-Glycerophosphate, phosphatidic acid synthesis, 712–713, 713*f*
Glycerophospholipids
  as membrane components, 458–460, 459*f*–461*f*, 461*t*–462*t*
  membrane leaflets, 472–473, 472*f*
Glyceryl trinitrate (GTN), 451cc
Glycine
  biosynthesis, 763, 764*f*
  collagen structure and, 105, 106*f*
  degradation, 764, 765*f*
  encephalopathy, nonketotic hyperglycinemia, 766cc
  metabolite derivation, 778, 780, 780*f*
  neuron-neuron interaction, 942*t*, **943,** 944*f*
  side chain structure, **77**
Glycine-proline-alanine (GPA) domain, myosin 1, 980
Glycocholic acid, cholesterol excretion, 728–729, 728*f*
Glycogen
  allosteric effector regulation, 853–855, 853*f*–855*f*
  early refed state and formation of, 847
  effector control, 638–639, 638*f*
  exercise and, 869–871
  glycogenin synthesis, 634–635, 635*f*
  glycolysis, 593
  phosphorylation and Lafora disease, 635cl
  synthesis, degradation and limitation, 635–638
  synthesis limits, 635
  in well-fed state, 842–843, 843*f*
Glycogenesis, 629–643
  debranching enzyme, 631–632, 631*f*
  effector control, 638–639
  enzyme requirements, 632–633, 632*f*
  epinephrine in heart and skeletal muscle, 641, 641*f*
  glucagon and epinephrine in liver, 640–641, 640*f*–641*f*
  glucose storage, 629–630, 629*f*–630*f*, 633–634, 634*f*
  glycogen degradation and synthesis, 635–638
  glycogenin requirement, 634–635, 635*f*
  glycogen phosphorylase inhibition, 630–631, 630*f*, 636
  glycogen phosphorylase regulation, 635–636, 636*f*
  glycogen synthase regulation, 636–638, 636*f*–638*f*
  glycogen synthesis limits, 635
  hormonal/normal glycogen synthesis and degradation, 640–643
  insulin stimulation in muscle and liver, 642, 643*f*
  negative feedback control, glycogen synthesis, 639
  neural control in skeletal muscle, 641–642, 642*f*
  pathway, 632*f*
  phosphorylase receptor in liver, 639–640, 639*f*
  in well-fed state, 842–843, 843*f*
Glycogenin, glycogen synthesis and, 634–635, 635*f*
Glycogenolysis, 629–643
  covalent modification, 856–859, 856*f*
  debranching enzyme, 631–632, 631*f*
  effector control, 638–639
  enzyme requirements, 632–633, 632*f*
  epinephrine in heart and skeletal muscle, 641, 641*f*
  glucagon and epinephrine in liver, 640–641, 640*f*–641*f*
  glucose homeostasis and, 850–852, 851*f*
  glucose storage, 629–630, 629*f*–630*f*, 633–634, 634*f*
  glycogen degradation and synthesis, 635–638
  glycogenin requirement, 634–635, 635*f*
  glycogen phosphorylase inhibition, 630–631, 630*f*, 636
  glycogen phosphorylase regulation, 635–636, 636*f*
  glycogen synthase regulation, 636–638, 636*f*–638*f*
  glycogen synthesis limits, 635
  hepatic, in early fasting state, 844, 844*f*
  hormonal/normal glycogen synthesis and degradation, 640–643
  insulin stimulation in muscle and liver, 642, 643*f*
  negative feedback control, glycogen synthesis, 639
  neural control in skeletal muscle, 641–642, 642*f*
  pathway, 632*f*
  phosphorylase receptor in liver, 639–640, 639*f*
Glycogen phosphorylase
  allosteric effector regulation, 853–855, 853*f*–855*f*
  cascade regulation, 636
  covalent modification, 856–859, 856*f*
  glycogenolysis initiation, 630–632, 630*f*–631*f*
  regulation of, 635–636, 636*f*
Glycogen storage diseasese, 633cc
Glycogen synthase
  allosteric effector regulation, 853–855, 853*f*–855*f*
  covalent modification, 856–859, 856*f*
  glycogenesis, 632–633, 632*f*
  regulation of, 636–637, 637*f*
Glycolipid(s), **674**
  disorders, 664cc
Glycolysis
  acetyl coenzyme A, **548**
  allosteric effector regulation, 853–855, 853*f*–855*f*
  anaerobic, retinal ATP derivation, 956
  cancer and, 868–869
  carbohydrate metabolic pathways, 592–596, 592*f*–595*f*
    arsenate prevention of ATP synthesis, 604, 604*f*
    ATP yield and anaerobic balanced equation, 601
    hexokinase and glucokinase, 606–608, 606*f*
    hyperglycemia inhibition, 603–604
    NADH oxidation to NAD, 601–602
    6-phosphofructo-1-kinase regulation, 608–617
    pyruvate kinase regulation, 617–619
    regulation, 604–619, 606*f*
    stages, 596–600, 597*f*, 599*f*–600*f*
    substrate shuttle, 601–603
    sulfhydryl reagents and fluoride inhibition, 603, 603*f*
  pentose phosphate interconversions, 649–651, 650*f*
  in well-fed state, 842–843, 843*f*
Glycolytic enzymes, gluconeogenesis, 622, 622*f*–623*f*
Glycophorin, **469**
Glycoproteins
  carbohydrate metabolism, 659–663
    dolichol phosphate N-linked glycoprotein synthesis, 660–663, 660*f*–661*f*
    glycan function, 663
    N- and *O*-glycosyl bonds, 659–660, 659*f*
  catabolism defects, 663cc
  covalent bonds, carbohydrates, 112, 112*f*
  membrane carbohydrates, 463
  phospholipids and, 712
Glycosaminoglycans (GAGs), **664**
  chains, laminin and type IV collagen networks, 372–373, 373*f*
Glycosidases, protein folding, **233**
Glycosidic linkages
  carbohydrate-proteins, 112, 112*f*
  digestion and, 1051
  hemoglobin, 113
Glycosphingolipids, **462, 1130**
  galactose/glucose in, 732–734, 732*f*–733*f*, 734*t*
  lipid rafts, 473
Glycosylase, DNA base excision repair, **168,** 168*f*
Glycosylated hemoglobin (HbA_{1c}), 113cc
Glycosylation
  congenital disorders of glycosylation, 661, 662cc
  endoplasmic reticulum and Golgi apparatus proteins, **232**–233, 233*t*, 234*f*–235*f*
  glycan function, 663
Glycosylceramides, in glycosphingolipids, 732, 732*f*
N-glycosyl bonds
  carbohydrate-glycoprotein linkage, 659–663, 659*f*
  dolichol phosphate synthesis, 660–663, 660*f*–661*f*
O-glycosyl bonds, carbohydrate-glycoprotein linkage, 659–663, 659*f*
Glycosylphosphatidylinositol (GPI), **470**
  lipid rafts, 473, 473*f*
Glycosyltransferases
  polysaccharide biosynthesis, **658**
  protein glycosylation, **232–233,** 233*t*, 234*f*–235*f*
Gly-Pro-Y tripeptide, in collagen, **103**
Gly-X-Hyp tripeptide, in collagen, **103**
GM_1 gangliosidosis, 733–734
GnRH-associated peptide (GAP), 895
Golgi apparatus, **11, 17**
  procollagen formation in, 244–245
  protein glycosylation in, 232–233, 233*t*, 234*f*–235*f*
  protein secretion and, 17, 17*f*
Gonadotropes
  estradiol synthesis, 924, 926*f*
  ovarian cycle control, **901**
Gonadotropin-releasing hormone (GnRH)
  gene encoding, 895
  ovarian cycle control, 901–905, 902*f*–905*f*
    absence of fertilization, 902–904, 904*f*
  precocious puberty, 901cc
  protein kinase C, 912–913, 913*t*
Gout
  allosteric enzyme control, 414cc
  enzyme action in, 400cc
  lysosomal enzymes and, 19cc
  purine nucleotides, 811cc
  xanthine oxidase inhibitors, 407cc
GPCR-specific protein kinases (TRKs), signaling termination, **527**
G protein-coupled receptors (GPCR), 475
  HIV targeting, 523cc
  intracellular signaling cascade, 899–901, 900*f*
  ion channels, 516
  physiological roles and extracellular ligands, 522–523, 522*f*
  signaling termination, 527
  signal transduction, **508**
  structure, 523–525, 524*f*
G proteins
  cycle, 526–527, 526*f*
  pituitary gland tumor/endocrine disease mutations, 525cc
  rod cells, **961**
  subunits, 525–526
G-quartets, four-stranded DNA, **45,** 45–46, 45*f*
Gramicidin A, **497,** 497*f*
Gratuitous inducers, lactose operon, **307**
Grb2 protein, growth factor signal transduction, **1010**
GroEL-GroES chaperonin system, 116, 117*f*
Group translocation, γ-glutamyl cycle, 477cl

Growth factor receptors, cell cycle regulation, **1008**–1010, 1008*f*-1010*f*
Growth factors, signal transduction, **517**
  cell cycle regulation, 1008–1010, 1008*f*-1010*f*
  receptor tyrosine kinase, 517–519, 517*f*-518*f*
  serine/threonine kinases, 519–520
Growth hormone (GH), 887, 888*f*, 889*t*–891*t*, 891
GTPases
  Ras protein, 518–519, 519*f*
  signal transduction, **511**
GTP-binding regulatory proteins
  Rab3, **947**
  signal transduction, 510*f*, 511
GTP cyclohydrolase I, tetrahydrobiopterin synthesis, 817–819, 818*f*-819*f*
Guanine
  nucleic acid structure, 27–30, 27*f*-30*f*
  purine nucleotide interconversion, 817
Guanosine, **27**
  nucleic acid structure, 27–30, 27*f*-30*f*
Guanosine monophosphate (GMP), inosine 5′-monophosphate precursor, 813, 814*f*
Guanosine pentaphosphate (pppGpp), **315**
Guanosine tetraphosphate (ppGpp), **315**
Guanosine triphosphate (GTP), tetrahydrobiopterin precursor, 817–819, 818*f*
Guanylate cyclase
  cardiovascular disease, 531cc
  cyclic GMP-based signal transduction, 530–531, 530*f*
  endothelial (NOSIII/eNOS), 447*t*, 450–453, 450*f*
  nitric oxide mediation, 447, 447*f*
  signal transduction, **517**
  visual cycle, **963,** 963*f*
Guanylin, digestion and, 1035*t*, **1036**
Guide RNA, **195**
Gums, **1113**
Gutathione reductase, mitochondrial defenses, 587, 587*f*
Gyrases, structure, **52**

H
Haber-Weiss reactions, reactive oxygen species, 584, 584*f*
Hairpin structure, RNA intramolecular base pairing, 62, 62*f*
Haldane relationship, **403**
Half-maximal concentration, ligand-receptor interaction, downstream signaling, 512*f*, 513
Hammerhead ribozyme, three-dimensional structure, 69, 69*f*
Hapten, **335**
Haptoglobins, **801**
Hartnup disease, 1049cc
Haworth formulas, carbohydrates, 1126
H band, skeletal muscles, **969**
H-DNA, triple-stranded DNA structure, **44,** 44–45
Head-tail junction, myosin filament, 968*f*, 970, 970cl
Heart, glycogenolysis in, 641, 641*f*
Heart disease, polyunsaturated fatty acids and, 1114cc
Heat shock proteins (hsps)
  chaperone protein folding, **116**
  crystallins, 954, 954*t*
  steroid hormone receptors, **929,** 930*f*
Heats of formation, **382**
Heavy filaments, skeletal muscles, **969**
α-Helical conformation
  cytochrome P450, 427
  integral (intrinsic) membrane proteins, 469–470, 470*f*
  membrane channels, **477**
  secondary protein structure, 93–96, 93*f*-94*f*
Helical structure
  RNA, 62, 62*f*
  secondary protein structure, 92–96, 92*f*, 93*t*
Helicases
  DNA replication, DnaB, 152
  parental strand separation, DNA replication, **144,** 144*f*
Helicobacter pylori, 317cc
Helix-loop-helix (HLH) protein
  calcium-transporting ATPases (Ca^{2+}-ATPase) in plasma membranes, 494, 494*f*
  transcription regulation and DNA binding, **322,** 325, 325*f*
Helix-turn-helix (HTH) proteins, transcription regulation and DNA binding, **322,** 322–325, 323*f*
Hematopoietic cells, cytokine receptors, **520**
Hematopoietic water-soluble vitamins, 1079–1083
  folic acid metabolism, 1079–1082, 1080*f*-1081*f*
  vitamin B_{12}, 1082–1083
Heme
  biosynthesis, 791–797, 791*f*-793*f*
    enzymes in, 791–796, 791*f*-795*f*, 796*t*
    porphyrias, 796*t*, 797
    rate-limiting step, 796–797
  catabolism, 797–801
    bilirubin conjugation, 797–801, 797*f*, 799*f*
    intravascular hemolysis, iron scavenging, 801
  mitochondrial electron transport, 568–570, 568*f*
  prosthetic group
    nitric oxide synthases, 445–446, 445*f*-446*f*
    oxygen binding, 355, 355*f*
Heme oxygenase, **797**
  cytoprotective role, 798cc
Heme-regulated kinase, translation regulation, **247**
Hemiacetals, 1124
  cyclic hemiacetals, **1126**
Hemicelluloses, **1113**
Hemiketals, **1126**
Hemimethylated DNA, mismatch repair, 170–172, 170*f*-171*f*, **171**
Hemochromatosis, 1090cc–1091cc
Hemoglobin, **334,** 353–367
  carbon dioxide-nitrogen oxide transport, 360
  chain structures, 356, 356*f*, 357*t*
  cirrhosis and, 874
  forms of, 353–354, 353*f*, 354*t*
  glycosylated hemoglobin (HbA_{1c}), 113cc
  isoelectric focusing, 121–122, 122*f*-123*f*
  nitric oxide transport and oxygen delivery, 366–367, 366*f*-367*f*
  oxygen binding, 358–359, 358*f*
  quaternary structure, 97–98, 361*f*
  secondary and tertiary structure, 355, 355*f*
  terminator codon formation, 214cc
  X-ray crystallography, 355–357, 356*f*, 357*t*
Hemoglobinopathies, 354cc
  missense mutations, 214cc
Hemoglobin Wayne, 213, 215*t*
Hemojuvelin, hepcidin synthesis, 1090, 1090*f*
Hemolytic anemia
  glucose-6-phosphate dehydrogenase, 404cc
  pyruvate kinase deficiency, 618cc
Hemopexin, **801**
Hemophilia, 990cc
Hemostasis
  anticoagulation, 989–993
  biochemistry, 982–983, 983*t*
  clot forming proteins, 985–989
  fibrinolysis phase, 994, 994*f*
  procoagulation phase, 983–985, 984*f*
Henderson-Hasselbalch equation, **9**
  conjugate acid and base concentrations and pH, 9–10, 10*f*
  ionizable amino acids and proteins, 83, 83*f*
  monoamino monocarboxylic acid titration, isoelectric pH, 84, 84*f*
Heparan sulfate, **664–665**
Heparan sulfate proteoglycan perlecan, laminin and type IV collagen networks, 372–373, 373*f*
Heparin, **664–665,** 665cc, 665*f*
  pentasaccharide structure, 992*f*
Heparin-binding protein, platelet plug formation, **985**
Hepatic nuclear factor 4α (HNF4α), gene transcription regulation, 862
Hepcidin, iron homeostasis, 1090, 1090*f*
Hephasetin, **1088**
Heptahelical structure, G protein-coupled receptors, **524**
Hereditary coproporphyria, **795**
Hereditary nonpolyposis colon cancer (HNPCC), mismatch repair, **172,** 172cc
Hereditary orotic aciduria, 823cc
Hereditary persistence of fetal hemoglobin (HPFH), DNA structure and, 46cc
Herpesvirus (HSV), purine/pyrimidine analogs, 834–835, 834*f*
Heterochromatin, polynucleosome packing, **57**
Heteroduplex region, homologous recombination
  Holliday model, **159**–160, 160*f*
  Meselson-Radding model, 161
Heterogeneity, O-linked glycosylation, **233**
Heterologous up-regulation, steroid hormone receptors, **935**
Heteromeric amino acid transporter, 1047, 1049*f*
Hetero-oligomeric complex, cytokine receptors, **521**
Heterophagy, lysosomal intracellular digestion and, 18–19, 19*f*
Heterotrameric protein(s), 962
Heterotrimeric G proteins, **525,** 526*f*
  bacterial toxins, 527
Heterotrimeric GTP-binding regulatory proteins (G proteins), 522*f*, 523–524
Heterotropic interaction, enzyme allosteric control, 414
Hexokinase
  cancer, 607cl
  classification, 380, 380*f*
  glycolysis regulation, 606–608, 606*f*
  tertiary structure, 97, 97*f*
β-Hexosaminidase reaction, sphingolipidoses testing, 737, 737*f*
HGPRTase gene defect, Lyesch-Nyhan syndrome, multiplex PCR analysis, 268cc
High-density lipoproteins (HDLs), **108,** 109*t*
  atherosclerosis, 728cc
  cholesterol synthesis, **722,** 722*t*, 723–726, 724*f*-725*f*
  diet and cholesterol, 1114–1115
  niacin deficiency, 1078

High-energy bonds
  energy-producing/energy-utilizing systems, **543**
  variations in, 547–548, 548*f*
High-energy compounds, hydrolysis of specific groups, 546, 546*f*
Highly reiterated DNA sequences, 61–62
High-mannose residues, protein folding, **233**
High-molecular-weight kininogen (HMWK)
  clot formation, 989, 989*f*
  intrinsic pathway reactions, 984–985, 984*f*, 985cc
High-performance liquid chromatography (HPLC), protein separation, 124, 125*f*
High-throughput screening, enzyme inhibitors and activators, 413cl
Hill coefficient
  hemoglobin/myoglobin oxygen binding, **358,** 359*t*
  multi-subunit enzymes, 415, 416*f*
Hill equation
  hemoglobin/myoglobin oxygen binding, **358**
  multi-subunit enzymes, 415, 416*f*
Hill plots, hemoglobin/myoglobin oxygen binding, 358*f*
Histamine
  digestion and, **1034**–1035, 1035*f*
  histidine metabolites, 786–787, 788*f*
Histidine
  metabolism, 773–774, 776*f*
  metabolites, 786–787, 788*f*
  side chain structure, **77,** 77–78, 78*f*–79*f*
Histidinemia deficiency, 777cc
Histone code, polynucleosome packing, **57**
Histone deacetylase inhibitors, epigenetic cancer therapy, 328cc
Histones, **54**
  bent DNA and, 42
  epigenetic cancer therapy and targeting of, 328cc
  eukaryotic chromatin organization, 54–55, 55*f*
  eukaryotic DNA binding, 317–319, 318*f*
  nucleosomes and polynucleosomes, 55–56, 55*f*–56*f*
  polynucleosome packing, 57
HIV, **158**
  aptamer-small-interfering RNA HIV1 therapy, 290cc
  drug therapy resistance, nucleoside analogs and, 144cc
  G protein-coupled receptors and, 523cc
  polymerase chain reaction screening, 258cc
  protein biosynthesis, frameshifting, 216cc
  RNA genome replication and, 158
HMG CoA reductase, cholesterol synthesis, **720**
H-NS proteins, prokaryotic DNA, **53,** 53–54, 53*f*
Holliday junction, homologous recombination, **159**–160, 160*f*
Holliday model, **159,** 159–160, 160*f*
Homeodomain protein, transcription regulation, 322–323
Homeostasis
  in animals, 9cl
  gluconeogenesis hormonal control, 627–628
  iron, 1087–1088, 1088*f*, 1088*t*
  vitamin D synthesis, 1071
Homocysteine, methionine degradation, **767**
Homocysteinemia, 771cc
Homocysteinuria, 771cc
Homologous C_H regions, antibody molecules, 336*t*, 338, 339*f*
Homologous recombination
  basic principles, **158**–159, 158*f*, 159*t*
  double-strand break model, 161–162, 162*f*
  DNA repair, 175
  Holliday junction, 159–160, 160*f*
  knockout mice, **292**
  Meselson-Radding model, 160–161, 161*f*
Homologous sequencing, **90**
  protein primary structure, 90
Homologous three-dimensional domain, antibody molecules, 339–340, 339*f*–340*f*
Homologous up-regulation, steroid hormone receptors, **935**
Homotropic interaction, enzyme allosteric control, 414
Homovanillic acid, **950**
Hoogsteen hydrogen bonds, four-stranded DNA, **43,** 45–46, 45*f*
Hoogsteen triplets, triple-stranded DNA structure, 43–45, 44*f*–45*f*
Hormone response elements (HREs), steroid hormone intracellular receptor proteins, 929–934, 930*f*, **931,** 931*t*
Hormone(s), **885**
  amino acid-derived
    inactivation and degradation, 896, 897*f*
    synthesis, 895–896, 895*f*–896*f*
  cascade system, 885–891, 885*f*–886*f*
    atrial natriuretic factor, protein kinase G, 913–914, 914*f*–916*f*
    gonadotropin-releasing hormone, protein kinase C, 912–913, 913*t*, 914*f*
    insulin receptor, tyrosine kinase transduction, 909–911, 909*f*–912*f*
    intracellular cascades, 909–916
    polypeptide hormones, 887–891, 888*f*, 889*t*–891*t*
    specific signals, 885–887, 885*f*, 886*t*
    vasopressin activity, protein kinase A, 912, 912*f*, 913*t*
  categories, 884, 884*f*
  cell surface receptors, **884**
  cyclic hormonal systems, 901
  endocrine signal transduction, 505–506, 505*f*
  gluconeogenesis control, 627–628, 627*f*–628*f*
  glycogen synthesis and degradation, 640–643
    glucagon and epinephrine glycogenolysis stimulation in liver, 640–641, 640*f*
  HPETE derivation, 743–744, 744*f*
  membrane receptors, 905–909
    internalization, 906–909, 907*f*–908*f*
    multiple subunits, 905–906, 905*f*–906*f*
  ovarian control, 901–905, 902*f*–905*f*
  6-phosphofructo-1-kinase regulation, 612–614, 612*f*–614*f*
  polypeptide hormones
    anterior pituitary, 887, 891
    gene coding, 892–895, 892*f*–894*f*
    overview, 888*f*, 889*t*–891*t*
  protein hormone signaling, 897–901, 898*f*–900*f*, 898*t*
    intracellular signal cascade, second messengers, 899–901, 900*f*
    membrane receptors, 897–898
  secretory intestinal, 1035–1306, 1035cl, 1035*t*
  steroid hormones (*See* Steroid hormones)
Hormone-sensitive lipase, lipid transport, fasted state, **679**
Hubs, protein complexes, **99**–100, 99*f*–100*f*
Human chorionic gonadotropin, fertilization, 904–905, 905*f*
Human embryonic stem cells (hESC), cloning and, **294**
Human genome
  chromosomes on, 140
  elements of, 298–299
Human immunodeficiency virus. *See* HIV
Human lysosomal acid lipase (hLAL), 20cc
Hunter syndrome, 668cc
Huntington disease, **167**
  amyloid fibrils, 114–115cc, 114*f*–115*f*
  DNA mutations, 166*f*, 167
  protein misfolding and aggregation, 250cc
  yeast artificial chromosome transgenic mice research on, 279cc

  in well-fed state, 842–843, 843*f*
Lactate dehydrogenase
  anaerobic glycolysis, 601–602
  glycolysis, 597*f,* 600
  isozymes, 379, 379*t,* 418, 420*f*
Lactation, metabolism during, 871–872, 872*f*
Lactic acidosis, 611cc
Lactones, 1124
Lactose
  hydrolysis, **1050**
  operons
    of *E. coli,* 305–306, 306*f*
    operator sequence, 307–309, 308*f*
    repressor protein, 306–307, 307*f*
    RNA polymerase and regulator protein promoter sequence recognition, 309
  repressor, 306
Lafora disease, 635cl
Lagging strands
  DNA replication, eukaryotic enzymes, 153–157
  semi-discontinuous DNA synthesis, **145,** 145*f*
λ-integrase, site-specific recombination, **163**
Lambert-Eaton mysthenic syndrome, 948cc
Laminin, 369–373, 369*f*–370*f*
  heparan sulfate proteoglycan perlecan networks, 372–373, 373*f*
  nidogen/entactin network, 372, 372*f*
Lanosterol, cholesterol synthesis, 722, 723*f*
Lanosterol cyclase, squalene formation, cholesterol synthesis, 721–722, 722*f*
Large intestine, sodium chloride absorption, 1038–1039, 1038*f*
Lariat RNA structure, messenger RNA intron removal, **197**–198, 198*f*
LDL receptors
  cholesterol synthesis, **727**
  transcription activation, 326–328, 327*f*–328*f*
Leader peptide, amino acid biosynthesis, **313,** 313–314, 313*f*
Leader sequence, tryptophan operon attenuator region, **312**
Leading strands, semi-discontinuous DNA synthesis, **145,** 145*f*
Lead poisoning, heme biosynthesis, **793**
Leber congenital amaurosis
  gene therapy for, 291cc
  retinal dystrophy, 965cc
Leber hereditary optic neuropathy (LHON), 18cc, 583cc
Lecithin:cholesterol acyltransferase (LCAT)
  cholesterol synthesis, **725,** 725–726, 725*f*
  obesity and insulin resistance, 1109–1110
Lecithin:cholesterol acyltransferase deficiency, 110cc
Lecithin(s). *See* Phosphatidylcholine
Left-handed DNA, 49–51, 50*f*
Lens (eye), water and protein in, 954–956, 954*t*–955*t,* 955*f*
Leptin, 840cc, 842
  appetite suppression, 1108*f*
  obesity and insulin resistance, 1108–1110
Lesch-Nyhan syndrome
  HGPRTase gene defect, 268cc
  nucleotide metabolsim, **808**
  purine synthesis, 816cc
Leucine
  gluconeogenesis and glucose synthesis, 623–624, 623*t*
  isoelectric pH determination, 84, 84*f*
  metabolism, 776, 779*f*
  side chain structure, 77, 78*f*–79*f*
  zipper proteins, 324, 324*f*
Leucine-enkephalin (Leu-ENK), **895,** 895*f*
Leukemia, asparaginase hydrolysis, 381cc
Leukotrienes, **1129**
  HPETE derivation, 743–744, 744*f*
  physiological effects, 744–745
LeuT-desimpramine, 950cl
LexA protein, SOS response, DNA repair, 175–176, 176*f*
Liddle syndrome, ubiquitin-proteasome defects, 250cc
Lifestyle, cancer and, 1022cc
Li-Fraumeni syndrome, 191
Ligand-activated transcription factors, **884**
Ligand-binding domains
  β-adrenergic receptor, 905–906, 907*f*
  steroid receptors, 932–934, 933*f*
Ligand-gated ion channels
  control and selectivity, **478**
  receptors, **508, 514,** 514–516, 514*f*–515*f*
Ligand-receptor interaction
  downstream signaling, 512–513, 512*f*–513*f*
  membrane receptors, 474, 474*t*
Ligand(s)
  cell surface receptors, intracellular signal transduction, **509**
  ion channel receptors, 516
  membrane receptors, **474,** 474–475, 474*t*–475*t*
  steroid hormone receptor down-regulation, 934–935
Ligases, 382, 382*f*
Ligation, replication fork movement, 146–148, 147*f*
Light/dark cycles, melatonin and serotonin synthesis, 901, 902*f*
Lignins, **1113**
Limited proteolysis, **344**
Linear DNA, 49, 49*f*
Linear genomes, DNA replication termination, 150–151
Lineweaver-Burk equation
  enzyme inhibition, 409–410, 409*f*
  K_m (Michaelis constant) calculation, 404, 404*f*

Linker DNA, **56**
  histone eukaryotic DNA binding and formation of, **318**
  nucleosomes and polynucleosomes, 56
Linking number, replication fork and parental strand untwisting, **148**
Linoleic acid/linolenic acid
  polyunsaturated fatty acids, 685, 685*f*
  prostaglandins derivation, 738
Linoleoyl CoA, oxidation, 696*f*
Lipases, lipid digestion, **1052,** 1052*f*
Lipid-linked oligosaccharide, **660**
Lipid rafts, **473,** 473*f,* 474
Lipid(s). *See also* Acylglycerols; Fatty acids; specific lipids
  digestion and absorption, 1051–1058
    bile acid chemistry and synthesis, 1054*t,* 1058
    bile acid micelles, 1053–1057, 1054*f*–1055*f,* 1054*t*
    bile acid transport, 1058–1059, 1059*f*
    chylomicron incorporation, 1057–1058
    gastric and pancreatic lipases, 1052–1053, 1052*f*–1053*f*
    water solubility limits, 1051–1052, 1052*f*
  functional groups, 1128–1132
  as membrane components, 458
    anchors, 470–472, 471*f,* 471*t*
    asymmetric distribution, 467–468, 467*f*
    bilayers, 464–465, 465*f*–466*f*
    membrane leaflet diffusion, 472–473, 472*f*
    microdomains, 473–474, 473*f*
    synthetic bilayers and liposomes, 464–465, 465*f,* 466cc
    variability in, 462–463, 464*f,* 466*f*
    vesicular structures, 463–465, 465*f*
  metabolism, 674–702
    peroxisomes and, 20–21
    regulation, 701–702
    special pathways, 708–745
  plasma lipoproteins, 107–109, 108*f,* 108*t*–109*t,* 110*f*–111*f,* 111, 111*t*
  second messengers, intracellular signal transduction, **510**
  transport
    fasted state, 679–680
    fed state, 678–679
Lipid transporters, **468**
Lipoamide, **550**
Lipocortin, steroid hormone receptors, **931**
Lipofuscin, **20**
Lipogenesis, fatty acids, 680–687
  biosynthesis pathway, 680–683, 680*f*–682*f,* 683*t*
  citrate cleavage pathway, acetyl CoA and NADPH formation, 684–685
  elongation reactions, 685, 685*f*
  fatty acid synthase, 686–687
  fatty acyl coA reduction to fatty alcohols, 687, 687*f*
  glucose precursor, 680
  hydroxy fatty acid formation in nerve tissue, 686
  monoenoic acid formation, 685
  polyunsaturated fatty acid formation, 685–686, 685*f*–686*f*
Lipoic acid, tricarboxylic acid cycle, **554**
α-Lipoic acid, nutritional function, **1079**
Lipoid congenital adrenal hyperplasia (LCAH), steroid hormone synthesis, 922–923, 922*f*
Lipolysis
  gluconeogenesis, fasting state, 846–847
  lipid transport in fasted state, 679–680
Lipophilin, **463**
A-β-Lipoproteinemia, 1058cc
Lipoprotein-associated coagulation inhibitor (LACI), extrinsic pathway inhibition, 990–993, 991*f*
Lipoprotein lipase
  deficiency, 109cc
  in fed state, **679**
  in lactation, 871–872, 872*f*
Lipoproteins
  apolipoproteins, **108,** 108–109, 109*t*
  high-density lipoproteins, **108,** 109*t*
    cholesterol synthesis, **722,** 722*t*
  intermediate-density lipoproteins, **108,** 109*t*
    cholesterol synthesis, **722,** 722*t*
  low-density lipoproteins, **108,** 109*t*
    cholesterol synthesis, **722,** 722*t*
    hyperlipoproteinemia, 109cc
    receptor gene, 326–327
  plasma lipoproteins
    chemical composition, 111, 111*t*
    cholesterol and, 722–726
    generalized structure, 110*f*
    hydrated density classes, 108*t*
    hyperlipoproteinemias, 109
    hypolipoproteinemias, 110
    structure and conformation, 107–109, 108*f,* 108*t*–109*t,* 110*f*–111*f,* 111, 111*t*
  very-low-density lipoproteins, **108–109,** 109*t*
    type IV hyperlipoproteinemia, 109cc
Liposomes
  as drug carriers, 466cc
  synthetic lipid bilayers, 464–465, **465,** 465*f*–466*f*
β-Lipotropin hormone, 887, 888*f,* 889*t*–891*t,* 891
Lipoxins, HPETE derivation, 743–744, 744*f*
Lipoxygenase, 742–745
  leukotrienes, hydroxyeicosatetraenoic acids, and lipoxins, 743–744, 744*f*
  monohydroperoxyeicosatetraenoic acids, 742–743, 743*f*
  physiological processes, 744–745
Lithocholate, secondary bile acids, 1058
Liver
  bile acid transport, 1058–1059, 1059*f*
  gene transcription in, 860–863, 861*f*–863*f*
  gluconeogenesis and glycolysis, 619, 620*f*
  glucose metabolism, 594*f,* 596
  glucose regulation, 608, 608*f*
    bifunctional 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase, 614–615, 615*f*
    pyruvate kinase, 617, 619, 619*f*
  glycerol 3-phosphate derivation, 688
  glycogen content, 630, 630*f*
  glycogenesis, insulin control, 642, 643*f*
  glycogen formation, early refed state, 848–849, 849*f*
  glycogenolysis
    in early fasting state, 844, 844*f*
    glucagon and epinephrine stimulation, 640–641, 640*f*
  metabolism
    acid-base balance and, 877, 877*f*
    allosteric effectors, enzyme regulation, 853–855, 853*f*–855*f*
    covalent enzyme modification, 855–859, 855*f*–858*f*
    in disease, 873–874, 873*f*
    enzyme induction, fasted state, 859–860, 860*f*
    enzyme induction, well-fed state, 859–860, 859*f*
    long-term adaptation, key enzyme changes, 859–862, 859*f*–862*f*
    substrate availability, 852–853
    between well-fed and starved states, 852–862
    well-fed and starved state switching, 852–862
    in well-fed state, 842–843, 843*f*
  nitrogen transport, 757–759, 758*f*
  obesity and insulin resistance, 1109–1110, 1109*f*
  phosphorylase receptor, 639–640, 639*f*
  toxicity
    acetyl coA pathways, 552
    cytochrome P450 in acetominophen-induced toxicity, 440cc
  triacylglycerol-fatty acid cycle, 689, 690cc, 690*f*

Loss-of-fusion mutations, amino acid transporters, 1047
Low-density lipoproteins (LDLs), **108,** 109*t*
  atherosclerosis, 728cc
  cholesterol synthesis, **722,** 722*t,* 723–726, 724*f*–725*f*
  diet and cholesterol, 1114–1115
  hypercholesterolemia treatment, 727cc
  hyperlipoproteinemia, 109cc
  niacin deficiency, 1078
  receptor gene, 326–327
Lufts diseases, 18
Lung function, dipalmitoyllecithin and, 710–711, 710*f*
Luteinizing hormone (LH), 888*f,* 889*t*–891*t,* 891
  estradiol synthesis, 924–925, 926*f*
  membrane receptors, **905,** 905*f*
  oral contraception, 926cc
  ovarian cycle control, 902–904, 904*f*
Lyases, structure and classification, 380–381, 381*f*
Lyesch-Nyhan syndrome, multiplex PCR analysis, HGPRTase gene defect, 268cc
Lysine, 778cl
  degradation, 772–773, 775*f*
  gluconeogenesis and glucose synthesis, 623–624, 623*t*
  histone DNA modification, 318*f*
  metabolites, 786
  side chain structure, **77,** 77–78, 78*f*
Lysine amino oxidase, elastin, **106,** 107*f*
Lysinuric protein intolerance, 776cc
Lysophospholipids, fatty acid distribution, 716, 716*f*–717*f*
Lysosomal acid lipase deficiency, 20cc
Lysosomal enzymes, gout and, 19cc
Lysosomal hydrolases, chondroitin sulfate biosynthesis, 667
Lysosomal storage diseases
  enzyme replacement therapy, 238cc
  N-linked glycoproteins, **661**
  sphingolipidoses, 734–737, 735*f*–737*f,* 736*t*
Lysosomes, **11, 18**
  intracellular digestion, 18–20, 18*f*–19*f,* 19*t,* **249**
  protein targeting, **235,** 237*f*
    I-cell disease, 238cc
    intracellular digestion, **249**

Lysozyme
α-domain globin fold, 101–102, 101*f*-102*f*
enzyme-substrate binding, 388, 389*f*
Lysylhydroxylase deficiency, collagen synthesis defect, 246cc
Lysyl oxidase, **245**
Lytic cycle, oncogenic DNA viruses, 1017cc

M
Macrominerals, 1085–1087
calcium, 1085–1086
magnesium, 1086–1087
Macromolecular-binding specificity, serine proteases, **349**
Macromolecular structures, forces in, 1125
Macronutrients, 1102–1119
Macrophages, inducible (NOSII/iNOS), 447*t*, 449
Macular degeneration, 956cc
Magnesium ions
as enzyme cofactors, 393, 393*f*
physiological roles, 1086–1087
pyruvate dehydrogenase regulation, 551
Maintenance methylase, mismatch repair, 170–172, 170*f*-171*f*, **171**
Major groove
double-stranded DNA (dsDNA), **34**
histone eukaryotic DNA binding, 318*f*
Malabsorption, nutritional status, **1094**
Malate-aspartate shuttle, mitochondrial inner membrane transport, 579, 580*f*
Malate dehydrogenase, 391*f*
Malic enzyme
citrate cleavage pathway, fatty acid lipogenesis, **684**
tricarboxylic acid cycle, **557**
Malignant hyperthermia, 612cc
Malnutrition
assessment, 1064
protein-calorie, 841cc
protein-energy, 1107
Malonyl CoA
allosteric effector regulation, 854
covalent enzyme modification, 858–859
fatty acid synthesis, 680, 680*f*, **692**
Mammalian cell, 12*f*
animal cloning, 293–294
cytochrome P450, 426–427, 427*f*
expression vectors, DNA elements, 283
fatty acid synthase, 682–683, 682*f*
membrane transport energetics, 486–487
nucleus, 15*f*
protein synthesis, 281–282, 282*f*
Mammalian enzyme temperature dependence, 404, 404*f*
Mammalian kidney, aquaporins and, 480cc
Mammary glands, fatty acid synthase, **687**
Manganese, nutritional function, **1094**
Mannokinase, **653**
Mannose-6-phosphate, protein targeting, **235,** 237*f*
MAP kinase cascade (MAPK)
cell death and survival regulation, 1015–1016, 1015*f*
growth factor signal transduction, 1010, 1010*f*
signal transduction, **519,** 519*f*
MAP kinase kinase kinase (MAP-KKK)
cell death and survival regulation, 1015–1016, 1015*f*
growth factor signal transduction, 1010, 1010*f*
MAP kinases, signal transduction, 518–519, 519*f*
Maple syrup urine disease, 778cc
Marasmus, 842cc, **1107**
Mass-action ratio, glycolysis regulation, 605
Mass fingerprinting of peptides, proteomics, **126**–127
Mass spectroscopy, polypeptide sequencing, **127,** 127*f*
"Matchmaker" proteins, DNA replication, cell cycle and, 158
Maternal hypoglycemia, **871**
Matrix, mitochondria, **561**
Matrix metalloprotease enzymes, metastasis and, **1019,** 1019*f*
Maxam-Gilbert DNA sequencing procedure, 260
Maximum velocity, one-substrate enzyme reactions, **400,** 400–405
M band, skeletal muscles, **969**
McArdle disease, 633cc
M-Cdk activating kinase (M-CAK), cell cycle regulation, 1006
Mdm2 ligase, apoptosis induction by p53, 1014–1015, 1014*f*
Mechanism-based inhibitors, enzyme reactions, 410
Megaloblastic anemia, cobalamin structure and function, 1083
Melanin, **783,** 784*f*
Melatonin
biosynthesis, 902*f*
cyclic hormone systems, **901**
light/dark cycles, 901, 902*f*
serotonin metabolites, 785–786, 787*f*
Melting
denaturation as, **36**
double-helical DNA, 36–37, 36*f*-37*f*
Membrane-associated guanylate cyclase, cyclic GMP-based signal transduction, **530**
Membrane-bound ribosomes, **219**
Membrane leaflets, lipid/protein diffusion, 472–473, 472*f*
Membrane receptors
internalization, 906–909
multiple hormone subunits, 905–906
nongenomic steroid effects, **935**
protein hormone signaling, 897–898
Membrane(s). *See also* Plasma membranes
carbohydrates, 463, 465*f*

noncompetitive inhibition, 408–409, 409*f*
uncompetitive inhibition, 408, 408*f*
free enzyme concentration, 401
gout and enzyme action, 400cc
one-substrate enzyme reactions, 399–405
rate constants, 401–402
turnover number (k_{cat}), 402–403
Microarray analysis
disease detection, 296cc
principles of, 296–298, 297*f*-298*f*
Microbodies, **20**
Microchimerism, nested PCR detection, 258cc
Microdomains, lipid-protein complexes, **473**–474, 473*f*
Microhomology regions, nonhomologous recombination, **163**–164
Micronutrients, 1064
MicroRNA (miRNA), **70**
antisense research and therapy, **289**–290
oncogenesis and, 202cc
RNA interference, **201,** 201*f*
translation regulation, **247**
MicroRNAs (miRNAs), translation control, 70
Microsomes, **16**
endoplasmic reticulum and, 16
ribosome binding, **219**
Microtubules, **21**
Mineralocorticoid receptor mutation, 933cc
Minerals
macrominerals, 1085–1087
trace minerals, 1087–1097
Minichromosome maintenance proteins (MCM), DNA replication
cell cycle and, 158
eukaryotic enzymes, **155,** 156*f*
Minor groove
double-stranded DNA (dsDNA), **34**
histone eukaryotic DNA binding, 318*f*
Mismatch DNA repair, **170**–172, 170*f*-171*f*
cancer and, 172cc
Missense mutations, **166,** 166*f*
genetic code and, **213**
hemoglobinopathies and, 214cc
Mitochondria, **11, 17**
ATP synthesis and, 17–18, 17*f*
diseases of, 18cc
electron transport chain, 561–572, 561*f*
cyanide poisoning, 572cc
cytochrome *c* oxidase, 569–570, 569*f*-570*f*, 570cl
inhibitors, 570–572, 571*f*
mitochondrial electron transport, 563–564, 563*f*
NADH-ubiquinone oxidoreductase, 563, 564–565, 564*f*-565*f*
oxidation-reduction reactions, 561–563, 562*t*
succinate-ubiquinone oxidoreductase, 563, 565–566, 566*f*
ubiquinone-cytochrome *c* oxidoreductase, 566–569, 567*f*-569*f*
genes and diseases, 582–583, 582*f*, 582*t*
glycolysis, NADH oxidation, 602
inner membrane, **560**
acetyl unit transport as citrate, 579–581, 580*f*
adenine nucleotide-phosphate transport, 577, 579, 579*f*
calcium transporter, 581, 581*f*
carnitine-acyl group transport, 691–692, 692*f*
substrate shuttles, reducing equivalents, 579, 580*f*
transport systems, 577–582, 578*f*
uncoupling proteins, 581–582, 581*f*
intermembrane space, **560**
membrane structure and compartmentation, 559–561, 559*f*-560*f*
NADPH-adrenodoxin reductase electron donor, 430
nuclear pore complexes and permeability of, 484–485
outer membrane, **560**

Mitochondria (*cont.*)
oxidative phosphorylation, 572–577
ATP synthase, 575–576, 575*f*–577*f*, 575*t*
ATP synthesis-electron transport coupling, 573–575, 573*f*–575*f*
membrane structure and compartmentation, **559**
protein synthesis in, 229
disease and, 239cc
import mechanisms, 237–239
reactive oxygen species, 583–587
rRNA/tRNA mutations, antibiotic-induced deafness, 229cc
subcompartment enzymes, 560*t*
Mitochondrial DNA (mtDNA), **18, 68**
genes and disease, 582–583, 582*f*, 582*t*
matrix location, **561**
restriction mapping, 260cc
RNA species, 68
Mitochondrial neurogastrointestinal encephalopathy syndrome (MNGIE), 828cc
Mitochondrial ornithine transporter deficiency, 762cc
Mitochondrial pathway, apoptosis, 1011–1014, 1012*f*–1013*f*
Mitosis, **157**–158, 157*f*, 1004–1005, 1004*f*, 1005*t*
Mitosol, **17**
ATP synthesis and, 17
Moderately reiterated DNA sequences, 61–62
Molar absorbancy, protein structure, spectroscopic analysis, **132**
Molar extinction coefficient, protein structure, ultraviolet light spectroscopy, **131**–133, 131*f*–133*f*
Molecular binding, by RNAs, 69, 69*f*
Molecular biology, basic principles of, 26
Molecular cell biology, 939–996
Molecular dynamics, protein structure, **120**–121, 121*f*
Molecular exclusion chromatography, protein separation, 123–124, 124*f*
Molecular motors, 967–981
cardiac muscle, 977–978, 978*f*
muscle contraction, 967, 974–979, 975*f*–977*f*
energy reservoirs, 979
myosin classes, 979–981, 980*f*–981*f*
pigmentation mutations, 980cc
skeletal muscles, 967–977, 968*f*–969*f*, 969*t*
actin, tropomyosin, and troponin thin-filament proteins, 970–974, 972*t*, 973*f*
contraction, 974–979, 975*f*–977*f*
myosin muscle filament formation, 968*f*, 968*t*, 969–970
smooth muscle contraction, 978–979
Molecular switch, signal transduction, **511**
Molecular targeting, anticancer agents, 1021cc
Molten-globule state, folded proteins, **113**
Molybdenum, nutritional function, **1094**
Monoacylglycerols, **675**
Monoamine oxidase, signal termination, **950,** 951*f*
Monoamino dicarboxylic acid titration, 84–85, 85*f*
Monoamino monocarboxylic acid, isoelectric pH determination, 84, 84*f*
Monocarboxylic acids, prostaglandins and thromboxane derivatives, 737–738, 738*f*
Monocistronic mRNA, **67**
protein primary structure, 67–68
translation, **210**
Monoclonal gammopathies, plasma proteins, 87cc, 88*f*
Monoclonal tumors, restriction fragment length polymorphism determination, 273cc
Monoenoic acids, fatty acid desaturation, 685
Monogenic obesity, 1108
Monohydroperoxyeicosatetraenoic acids (HPETEs)
leukotrienes, hydroxyeicosatetraenoic acid and lipoxin derivation, 743–744, 744*f*
lipoxygenase and, 742–743, 743*f*
Monooxygenases, monoenoic acid formation, fatty acid desaturation, 685
Monosaccharide alcohol, **1127**
Monosaccharide(s), 1125–1128
derivatives, 1127
protein glycosylation specificity, **232**–233, 233*t*, 234*f*–235*f*
reactions, 1127–1128
transporters, 1050*f*, 1051, 1051*t*
Mosaic membrane model, 466–467, 467*f*
Motor nerve cell, 940–941, 941*f*
M phase, cell cycle
DNA replication, **157**–158, 157*f*
nucleotide metabolizing enzymes, 828–829
regulation, **1004,** 1004*f*, 1005*t*, 1006, 1006*f*
M-phase Cdk (Cdk1), cell cycle regulation, **1006,** 1006*f*
MRE-binding transcription factor, zine protein requirements, 1091–1092
mRNA. *See* Messenger RNA (mRNA)
α-MSH, 887, 888*f*, 889*t*–891*t*, 891
β-MSH, 887, 888*f*, 889*t*–891*t*, 891
Mucopolysaccharides, **664, 1128**
Mucopolysaccharidoses, **664**
chondroitin sulfate biosynthesis, 667, 668cc
enzyme replacement therapy, 238cc
Multidomain protein, tertiary structure, **97**
Multidrug resistance associated proteins (MRP), **494**
serum-conjugated bilirubin, 800cc
Multidrug resistance (Mdr) gene family
ATP-binding cassette (ABC) transporters, **494**
multidrug resistance 1 gene, silent mutations and, 214cc
Multienzyme complex, pyruvate dehydrogenase, 550–551, 550*f*, 550*t*
Multifunctional proteins, inosine 5′-monophosphate synthesis, 813
Multiple acyl-Coa dehydrogenase deficiency (MADD), 774cc
Multiple drug resistance, transmissible resistance, 316cc
Multiple nonsimilar domains, zymogen synthesis, serine proteases, **347**
Multiple sulfatase deficiency, 243cc, 668cc
Multiplex polymerase chain reaction
cloning circumvention, **268,** 269*f*
HGPRTase gene defect, Lesch-Nyhan syndrome, 268cc
Multipotent cells, **13**
Multi-subunit enzymes, cooperativity, 414–417, 415*f*–416*f*
Muscarinic receptors, ligand-gated ion channels, **515**
Muscle light chain kinase (MLCK), endothelial (NOSIII/eNOS), 447*t*, 450–453, 450*f*
Muscle(s)
contraction, 967, 974–979, 975*f*–977*f*
energy reservoirs, 979
energy reservoirs for contraction, 979
glycogenesis, 642, 643*f*
obesity and insulin resistance, 1109–1110, 1109*f*
proteins, familial hypertrophic cardiomyopathies, 971cc
skeletal muscles, 967–977, 968*f*–969*f*, 969*t*
actin, tropomyosin, and troponin thin-filament proteins, 970–974, 972*t*, 973*f*
contraction, 974–979, 975*f*–977*f*
myosin muscle filament formation, 968*f*, 968*t*, 969–970
Mushroom poisoning, enzyme inhibitor, 412cc
Mutagen(s), in cancer, 1023
Mutases, 381
Mutation(s)
in cancer, 1020–1021
coenzymes, 390cc
DNA sequences, 164–167, 166*f*
frameshift mutations
DNA mutation, **167**
genetic code and, **213**
hemoglobinopathies, 213, 215*t*
HIV protein translation, 216cc
slipped DNA, 46, 47*f*
genetic code and, 213
missense mutations, **166,** 166*f*
genetic code and, **213**
hemoglobinopathies and, 214cc
mitochondria, rRNA/tRNA mutations, antibiotic-induced deafness, 229cc
nonsense mutations, **166,** 166*f*
genetic code and, 213, 215*t*
operator-constitutive mutations, **308**
"read through" mutations, termination codons, 215*t*
repressor-constitutive mutations, **307**
silent mutations, **166**
genetic code and, **213**
Hutchinson-Gilford progeria syndrome and multidrug resistance 1 gene, 214cc
suppressor mutations, aminoacyl-tRNA synthetases, **217**
terminator codon formation, 214cc
Myasthenia gravis, 949cc
Myc transcription factor
apoptosis induction by p53, 1014–1015, 1014*f*

pentose phosphate pathway, **648**–649, 649*f*
glucose 6-phosphate carbon dioxide oxidation, 651, 651*f*
regeneration and supply function, 651–652
tricarboxylic acid regulation, 558–559, 558*f*
in well-fed state, 842–843, 843*f*
Nicotinic-acetylcholine receptor, **478,** 482–483, 482*f*–483*f*
ligand-gated ion channels, **515**
neuron-neuron interaction, 943, 944*f*
Nicotinic receptors, ligand-gated ion channels, **515**
Nidogen, laminin and type IV collagen networks, 372, 372*f*
Niemann-Pick C1-like protein (NPC1L1), cholesterol absorption, 1057cc
Niemann-Pick disease
diagnostic testing, 736–737, 736*f*–737*f*
retinitis pigmentosa, 958cc
sphingomyelin in, 730–731
Nigericin, **497,** 497*f*
Night blindness, vitamin A and, **1067**
Nitric oxide (NO)
cardiovascular disease, 531cc
cGMP synthesis and degradation, **531**
hemoglobin transport, 360–366, 361*f*–366*f*
capillary transport and oxygen delivery, 366–367, 366*f*–367*f*
septic shock overproduction, 450cc
therapeutic uses, 452cc
Nitric oxide synthases (NOSs)
cGMP synthesis and degradation, **531**
endothelial (NOSIII/eNOS), 447–453, 447*t*, 450*f*
inducible (NOSII/iNOS), 447–453, 447*t*, 450*f*
isoforms and physiological functions, 447–453, 447*t*, 450*f*
neuronal (NOSI/nNOS), 447–448, 447*t*, 448*f*
properties and enzymatic function, 444–446, 444*f*–446*f*
Nitrogen
amino acid incorporation, 752–757
dietary sources, 752, 752*f*–753*f*, 753*t*
glutamate dehygrodenase incorporation of ammonia, 755–756, 756*f*
glutamine free ammonia production and incorporation, 756–757, 757*f*
liver and kidney transport, 757–759, 758*f*
oxidase removal of amino groups, 757, 757*f*
pyridoxal phosphate cofactor for aminotransferases, 755, 755*f*
transfer mechanisms, 752, 753*f*–754*f*, 754
excretion, nitrogen balance and, 1103, 1104*f*
glutamine donor antagonists, 834, 834*f*
pyrimidine synthesis, 823, 824*f*
urea cycle, 759
Nitrogen balance, **752**
blood urea nitrogen and, 753cc
protein metabolism, 1103, 1104*f*
in stress and injury, 873
Nitroglycerin, historical and biological effects, 451cc

N-linked glycoproteins
congenital disorders of glycosylation, 661, 662cc
dolichol phosphate synthesis, 660–663, 661*f*
N-linked glycosylation, **233,** 235*f*
carbohydrate-protein covalent linkages, **112**
N-methyl-D-aspartate (NMDA) receptors, neuronal (NOSI/nNOS) activation, 447–448, 447*t*, 448*f*
Noncanonical DNA structures, 41–48
antitumor antibiotics, 42
bent DNA, 41–42
cruciform DNA, 42–43, 43*f*
four-stranded DNA, 45–46, 45*f*
slipped DNA, 46, 47*f*
telomerase targeting, anticancer agents, 46
triple repeats and human disease, 48cc
triple-stranded DNA, 43–45, 44*f*–45*f*
Noncatalyzed reactions energy diagram, 384*f*
Noncompetitive inhibition, enzymes, 408–409, 409*f*
Nonconservative substitution, protein primary structure, **90**
Noncovalent forces, folded proteins, 116–119, 116*t*
electrostatic interactions, 118–119, 119*f*
hydrogen bonds, 118, 118*f*
hydrophobic interaction, 116–117, 118*f*
van der Waals forces, 119, 119*f*, 119*t*
Nonelectrolytes, **5**
Nonequilibrium reaction, glycolysis regulation, 605
Nonessential amino acids
biosynthesis, 763–764, 763*f*–764*f*
degradation, 764–766, 764*f*–766*f*
metabolism, 753*f*
sources of, 753*t*
Nongenomic steroid effects, **935**
Nonglobular structured proteins, 103–112, 103*t*
collagen, 103–105, 103*f*, 103*t*–104*t*, 105*t*, 106*f*–107*f*
elastin, 106, 107*f*
glycoprotein covalently bound carbohydrate, 112, 112*f*
keratin and tropomyosin, 106–107, 107*f*
plasma lipoproteins, 107–109, 108*f*, 108*t*–109*t*, 110*f*–111*f*, 111, 111*t*
Nonheme iron
iron deficiency, **1087**
tricarboxylic acid cycle, **555**
Nonhomologous amino acid sequences, homologous protein folding, 101–102, 101*f*–102*f*
Nonhomologous end joining (NHEJ)
gene therapy and, 164cc
nonhomologous recombination, 163–164
Nonhomologous recombination, **158,** 159, 163–164
Nonketotic hyperglycinemia, glycine encephalopathy, 766cc
Nonreceptor tyrosine kinases, cytokine receptors, **521**
Nonsense codons, mRNA genetic code, **212**
Nonsense-mediated decay, cytoplasmic mRNA turnover, 204
Nonsense mutations, **166,** 166*f*
genetic code and, 213, 215*t*
Nonsteroidal anti-inflammatory agents (NSAIDs), prostaglandin production, 741
Norephinephrine
neuronal reuptake, 950cl
signal termination, 950, 950*f*
tyrosine metabolites, **781**
Norepinephrine, 895
neuronal (NOSI/nNOS) activation, 447–448, 447*t*, 448*f*
Northern blot analysis, mRNA detection, **272,** 274*f*
Nuclear envelope, structure and function, **15**
Nuclear factor of activated B cells (NFKB), **521, 932**
Nuclear hormone receptors, coactivators, and corepressors, 935
Nuclear localization sequences (NLS), **484**
receptor serine/threonine kinases, **520**
Nuclear magnetic resonance (NMR), protein structure analysis, 133–134, 134*f*
Nuclear Overhauser effects (NOEs), protein structure analysis, **133**–134
Nuclear pore complex
protein channels and, **484**–485, 484*f*
protein targeting of organelles, **239**–240
structure and function, **15**
Nuclease protection assay (NPA), mRNA detection, **272,** 274*f*
Nucleases
cytoplasmic mRNA turnover and translation, 203–204
DNA backbone stability, 31–32
RNA turnover and, **202**–204
tetrahydrobiopterin synthesis, **818**
Nucleation-Polymerization Mechanism, amyloid plaque formation, 115
Nucleic acids, **27**
DNA/RNA sequence probes, 268, 270–271, 271*f*
editing ezymes, 201cc
function, 26
liposome carriers for, 466cc
microarray analysis, breast cancer, 296cc
proCRH gene sequencing, 894*f*, 895
structural components, 27–30, 27*f*–30*f*
Nucleobases, structural components, 27–30, 27*f*–30*f*
Nucleofilament, polynucleosome packing, **56,** 56*f*
Nucleoids, **2, 53**
cell classification, 2
prokaryotic DNA, 53–54, 53*f*
Nucleolus, **16**
Nucleophilic displacement reaction, 398cl
Nucleophilic substitutions, acyl carbon, 1124
Nucleoside 5′diphosphate reductase, **824,** 824*f*
Nucleoside 5′-triphosphates, ribonucleotide reductase activity, 824, 825*t*
Nucleoside analogs
DNA polymerases, 143
HIV drug resistance and, 144cc
Nucleoside diphosphate kinase, high-energy reactions, 548, 548*f*
Nucleoside diphosphate-sugars, 653*f*, 654
Nucleoside kinases, nucleotide synthesis, 827–828
Nucleoside monophosphate kinase, high-energy reactions, 548, 548*f*
Nucleosides, **27, 1132–1133**
physical properties, 28
purine/pyrimidine nucleotide metabolism, antimetabolites, 832
structural components, 27–30, 27*f*–30*f*
transfer RNA modification, 195
Nucleosomes, **55, 153**
DNA replication, eukaryotic enzymes, 153–157
histone eukaryotic DNA binding and formation of, **317**
structure, 55–56, 55*f*–56*f*
Nucleotide analogues, DNA polymerases, 143
Nucleotide-binding domain-1 (NBD-1), cystic fibrosis transmembrane conductance regulator (CFTR) protein, 495
Nucleotide excision repair (NER), DNA damage, **169,** 169*f*
Nucleotide kinases, nucleotide synthesis, 827–828
Nucleotide(s), **27, 1132–1133**
cell growth inhibition, 834, 834*f*
chemotherapeutic interference, 831–836
biochemical basis for, 835–836
purine/pyrimidine inhibitors, 832–835, 832*f*–833*f*
eukaryotic functional gene sequencing, 59–61, 60*f*
four-letter alphabet, genetic code, 211–215, 211*t*, 212*f*
metabolism, 808–836, 809*t*
cell cycle enzymes, 828–829
coenzyme synthesis, 829–831
deoxyribonucleotide formation, 823–826
distributional variation, 808–809
glutamine, 810, 810*t*
nucleoside/nucleotide kinases, 827–828
5′-phosphoribosyl-1-pyrophosphate, 809–810, 809*f*, 810*t*
purines, 810–817
pyrimidine, 821–824, 826–827
tetrahydrobiopterin, GTP precusor, 817–818, 818*f*–819*f*
uric acid end product, 820–821, 821*f*
physical properties, 28
ribosomal RNA modifications, 66–67
structural components, 27–30, 27*f*–30*f*
sugar formation, carbohydrate metabolism, 652–658
N-acetylglucosamine sialic acid derivation, 657–658, 657*f*
decarboxylation, oxidoreduction and transamidation, 656, 657*f*
intermediate transformation, 653–654, 653*f*
isomerization and phosphorylation, 652–653, 652*f*
nucleotide-linked glucose/galactose epimerization, 654, 654*f*
UDP-glucose oxidation and glucuronic acid formation, 654–655, 655*f*
Nucleotide sequence
lactose operon, 308*f*
tryptophan operon, 311–314, 311*f*–312*f*
Nucleus, **11, 15**
accelerated aging and, 16
DNA/RNA synthesis and, 15–16, 15*f*
eukaryotic cells, 3
Null mice. *See* Knockout mice

  in well-fed state, 842–843, 843*f*
Pentosuria, 656cc
Penzo*(a)* pyrene, DNA damage and mutation, 164
Pepsin
  food digestion and, 1031–1032
  protein digestion, 1044–1045, 1044*t*
Pepsinogen, protein digestion, 1044*t*, **1045**
Peptic ulcer, prostaglandins effects on, 742
Peptidases, protein digestion, 1043–1046, 1044*f*-1045*f*, 1044*t*
Peptide bonds, **80**
  amines and amides, 1124
  amino acids, in proteins, 80–81, 80*f*-81*f*, 82*t*
  biologically active peptides, 81, 82*t*
  elongation and formation of, 223, 224*f*-225*f*, 226
  serine protease hydrolysis specificity, 346–347, 346*t*, 347*f*
  transition state for hydrolysis, 384*f*
Peptide hormones, **884**
Peptide mass fingerprinting, proteomics, 126–127
Peptide neurotransmitters, precursor protein derivation, **951**–952, 952*f*
Peptide(s), **76**
  in brain tissue, 952*t*
  polypeptide gene encoding, 892–894, 893*f*-894*f*
  secretory intestinal, 1035–1306, 1035cl, 1035*t*
Peptidyl site (P site), elongation and peptide bond formation, **223,** 224*f*-225*f*, 226
Peptidyl transferase, elongation and peptide bond formation, **223,** 224*f*-225*f*, 226
Perhexiline, cytochrome P450 metabolism, 442–443
Perilipin, **679**
Perinuclear space, structure and function, **15**
Peripheral membrane proteins, **463, 470**–472, 471*f*, 471*t*
Peripheral nervous system, neuronal (NOSI/nNOS) activation, 447–448, 448*f*
Peripherin, retinitis pigmentosa, 690cc
Perlecan, type IV collagen network, 372–373, 373*f*
Pernicious anemia, 1082–1083, 1082*f*
Peroxisomal oxidation, fatty acids, **700–701,** 701*f*
Peroxisome biogenesis disorders (PBD), 21cc
Peroxisome proliferation response element (PPRE), 862
Peroxisome proliferator-activated receptor α (PPARα)
  gene transcription regulation, 862, 862*f*
  α-lipoic acid formation, **1079**
  steroid hormones, **934**
Peroxisome proliferator-activated receptor γ (PPARγ), 862
  α-lipoic acid formation, **1079**
Peroxisomes, **11, 20**
  fatty acid oxidation, **700–701**
  lipid metabolism and, 20–21
Personalized medicine, DNA polymorphisms, 167cc
PGH synthase, prostaglandins derivation, 739–740, 740*f*
P-glycoproteins, **494**
Phage. *See* Bacteriophages
Phagocytosis, lysosomal intracellular digestion and, 18–19, 19*f*
Pharmacological agonist/antagonist, cell surface receptors, intracellular signal transduction, **509**
Phase angles, x-ray diffraction, three-dimensional protein structure, **129**–131, 130*f*-131*f*
Phenobarbital, cytochrome P450 metabolism, 442
Phenylalanine
  degradation, **767,** 768*f*
  epinephrine synthesis, 895, 895*f*
  side chain structure, **77**
Phenylalanine hydroxylase, 767, 768*f*
Phenylethanolamiine *N*-methyltransferase (PNMT), **895**
Phenylketonuria, 767, 769cc
Phi (φ) bond, secondary protein structure, **92,** 92–96, 92*f*, 93*t*
pH levels, **6**
  alcohol dehydrogenase isoenzymes, 405cc
  amino acid and protein charge properties, 85, 85*f*, 85*t*
  biological fluids, 7, 7*t*
  buffering and control of, 10–11, 10cl, 10*f*
  cytoplasmic pH, sodium/hydrogen (Na^+H^+) exchanger regulation, **490**
  enzyme reaction kinetics, 405, 405*f*
  enzyme-substrate binding, 387, 387*f*
  Henderson-Hasselbalch equation for conjugate acid-base concentrations and, 9–10, 10*f*
  ionizable amino acids and proteins, 83, 83*f*, 83*t*
  monoamino monocarboxylic acid titration, isoelectric pH, 84, 84*f*
  6-phosphofructo-1-kinase glycolysis regulation, 610, 611*f*
  water molecule dissociation, 6–7, 6*t*
Phosphacan, **668**
Phosphatases, calmodulin-dependent calcium activation, 534
Phosphates, mitochondrial inner membrane transport, 577, 579, 579*f*
Phosphatidate phosphatase, triacylglycerol synthesis, **688,** 688*f*
Phosphatidic acid, **458,** 459*f*, **1130**
  intracellular signaling pathways, **535**
  in membranes, 711–712, 711*f*
  phospholipid acids and bases, 708–709, 708*f*-709*f*
  synthesis mechanisms, 713–715, 714*f*-715*f*
  synthesis, 712–713, 713*f*
  triacylglycerol synthesis, **688**–689, 688*f*-689*f*
Phosphatidic acid phosphatase, phosphatidic acid synthesis, **713,** 713*f*
Phosphatidylcholine, **458,** 460*f*
  lipid digestion and absorption, bile acid micelles, 1054–1055 1055*f*
  in phospholipids, 708, 709*f*
  phospholipid synthesis, 714, 714*f*
  fatty acid distribution, 716, 716*f*-717*f*
  sphingomyeline from, 731, 732*f*
  structure and functions, **1085**
Phosphatidylethanolamine, **458,** 459, 460*f*
  asymmetric distribution, 467, 467*f*
  in phospholipids, 708, 709*f*
  phospholipid synthesis, 715, 715*f*

Phosphatidylglycerol, in phospholipids, 709, 709*f*
Phosphatidylglycerol phosphoglyceride, **458,** 460*f*
Phosphatidylinositol, **458,** 460*f*
  asymmetric distribution, 467, 467*f*
  functions, 461cl
  in phospholipids, **708,** 709*f,* 711–712, 711*f*–712*f*
Phosphatidylinositol 3,4,5-trisphosphate (PIP_3), intracellular signaling cascade, 899–901, 900*f*
Phosphatidylinositol-3,4,5-trisphosphate (PIP_3), intracellular signaling pathways, **535,** 536
Phosphatidylinositol 3-kinases, intracellular signaling pathways, **535–536,** 536*f*
Phosphatidylinositol 4,5-bispohsphate (PIP_2)
  intracellular signaling pathways, **535**
  membrane function, 711–712, 711*f*–712*f*
Phosphatidylinositol synthase, phospholipid synthesis, **715,** 716*f*
Phosphatidylserine
  in phospholipids, 708, 709*f*
  phospholipid synthesis, 715, 715*f*
  red blood cell clearance, 710cc
3′-Phosphoadenosine 5′-phosphosulfate (PAPS)
  chondrodystrophies, 667cc
  chondroitin sulfate biosynthesis, 666–668
  cysteine metabolite, 781, 782*f*
  in galactocerebroside, 732–733, 733*f*
Phosphocholine, sphingolipidoses diagnostic testing, 736–737, 736*f*–737*f*
Phosphocholine cytidylyltransferase, phospholipid synthesis, **713,** 714*f*
Phosphocreatine, exercise and, 870–871
Phosphodiesterases
  cardiovascular disease, 531cc
  cyclic GMP phosphodiesterase, **525,** 530–531
  cyclic nucleotides, **528,** 528–530, 529*f*
  nitric oxide mediation, 447
  rod cells, **961–962**
  second messenger system, **900**
  sildenafil and, 449cc
  visual transduction, 961
Phosphodiester bonds, **141**
  DNA replication, chain elongation chemistry, 141–142, 141*f*
  glycerophospholipids, **458**
  RNA structure, 62, 62*f*
Phosphoenolpyruvate (PEP)
  gluconeogenesis hormonal control, 627–628, 627*f*–628*f*
  glucose metabolism, 600
  glucose synthesis, 622, 622*f*
  hydrolysis, 546, 546*f*
  oxaloacetate conversion, **557**
Phosphoenolpyruvate carboxykinase, triacylglycerol-fatty acid cycle, 689, 690cc, 690*f*
6-Phosphofructo-1-kinase
  allosteric effector regulation, 853–855, 853*f*–855*f*
  cardiac isoenzyme, 616–617, 617*f*
  covalent modification, 856–859, 856*f*
  glycolysis regulation, 608–612, **613**
    ATP/AMP regulation, 609–610
    cAMP/fructose 2,6-bisphosphate hormonal control, 612–614, 612*f*–614*f*
    cancer and, 618cl
    citrate regulation, 612
    intracellular pH, 610, 611*f*
    pyruvate kinase, 617, 619, 619*f*
  phosphorylation, bifunctional 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase, 614–615, 614*f*–616*f*
6-Phosphogluconate dehydrogenase, pentose phosphate pathway, **648**–649, 649*f*
6-Phosphoglucono-δ-lactone, pentose phosphate pathway, **648**
Phosphoglucomutase, **652**
Phosphoglucose isomerase, gluconeogenesis, 622, 622*f*
Phosphoglycerates, 381, 382*f*
  glucose metabolism, 599–600, 600*f*
Phosphoglycerides. *See* Glycerophospholipids
Phosphoinositide-3-kinase (PI-3K), intracellular signaling pathways, **535**
Phospholipase A1/A2
  intracellular signaling pathways, **535,** 536
  phospholipid fatty acid distribution, 716, 716*f*
Phospholipase C, **525**
  glycogenolysis in liver, 641, 641*f*
  intracellular signaling pathways, 534–536, 534*f,* 535, **535,** 536*f*
  membrane inositols and, 711–712, 711*f*
Phospholipase D (PLD), intracellular signaling pathways, **535**
Phospholipid(s), **674**
  bilayer structures, 465, 465*f*–466*f*
  lipid digestion and absorption, 1053, 1053*f*
  as membrane components, **458,** 709–712
    dipalmitoyllecithin, 710–711, 710*f*
    inositides, 711–712, 711*f*
  metabolism, 708–718, 708*f*
    biosynthesis, 712–715
    fatty acids, asymmetric distribution, 716
    membrane functions of, 709–712
    phosphatidic acid-base connection, 708–709, 708*f*–709*f*
    plasmalogen synthesis from fatty alcohols, 716–718
  signal transduction, 534–536, 534*f,* 536*f*
Phospholipid scramblase, **468**
Phosphomannose isomerase, **652**
Phosphopentose epimerase, pentose phosphate interconversions, **650,** 651*f*
Phosphoprotein phosphatase
  glycogen synthase regulation, 637–638
  lipid metabolism, fed state, 701
  pyruvate dehydrogenase regulation, **550**
5′-Phosphoribosyl-1-pyrophosphate (PRPP)
  de novo synthesis, **809**–810, 809*f,* 810*t*
  gout, 811cc
  nucleotide coenzyme synthesis, 830–831
  purine synthesis, 813–815, 814*f*–815*f*
  pyrimidine synthesis, 821–823, 822*f*–823*f*
Phosphorus, in sphingomyelin, 730–731, 731*f*–732*f*
Phosphorylase, liver glucose receptor, 639–640, 639*f*
Phosphorylase kinase
  covalent modification, 856–859, 856*f*
  glycogen phosphorylase, 635–636, 636*f*
Phosphorylated intermediates, glucose metabolism, 596, 597*f,* 598
Phosphorylation
  bifunctional 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase, 614–615, 614*f*–616*f*
  covalent modification of enzymes, 855–859, 855*f*–858*f*
  enzyme transition states, proton addition and removal, 386, 386*f*
  glycogen, Lafora disease, 635cl
  G protein-coupled receptors, 526–527, 527*f*
  proteins, phosphorylation in signal transduction, 510–511, 510*f*
  sugar interconversion, carbohydrate metabolism, 652–653
  tertiary protein structure, 97, 97*f*
  translation regulation, **245,** 247
  tricarboxylic acid cycle, 555
Phosphorylation-dephosphorylation, glycogen phosphorylase, 635–636, 636*f*
Phosphorylysis reactions, 1124
Phosphotyrosine binding (PTB) domains, signal transduction, **511,** 512*f*
Photochemistry, visual transduction, 957–958, 957*f*
Photolyase, DNA repair, photoreactivation, **173**–174, 173*f*
Photoreactivation, DNA repair, **173**–174, 173*f*
Photoreceptor cells, **958**
  rods and cones, 957*f,* 958–963, 959*f,* 961*f*–963*f*
Phototransduction cascade, 964*t*
Phrenosine, **462,** 464*f*
Physiological agonist/antagonist, cell surface receptors, intracellular signal transduction, **509**
Phytylmenaquinone, vitamin K, **1073**–1075, 1073*f*
Picolinate carboxylase, 785
Pigmentation, mutations in, 980cc
Pigmented epithelial layer, visual transduction, 957–958, 957*f*
Ping-pong mechanism
  aminotransferase-pyridoxal pyruvate cofactor, 755, 755*f*
  enzyme two-substrate reactions, 405–407, 406*f*
Pinocytosis, **18**
  lysosomes and, 18–19, 19*f*
  protein intracellular digestion, **249**
Pipecolate metabolism, 773, 776*f,* 778cl
π-electron interactions, protein folding, 119, 119*f*
PI-PLCβ enzymes, intracellular signaling pathways, **535**
PI-PLCγ enzymes, intracellular signaling pathways, **535**
Pituitary gland
  hypothalamus and, 893*f*
  tumors, G protein mutations in, 525cc
Plant genetics
  recombinant DNA technology, 294–295
  xanthine oxidase inhibitors, 407cc
Plasma enzyme measurement, clinical applications, 418–419, 419*f*–420*f*
Plasma lipoproteins
  chemical composition, 111, 111*t*
  cholesterol and, 722–726, 724*f*
  generalized structure, 110*f*
  hydrated density classes, 108*t*
  hyperlipoproteinemias, 109
  hypolipoproteinemias, 110
  structure and conformation, 107–109, 108*f,* 108*t*–109*t,* 110*f*–111*f,* 111, 111*t*
Plasmalogen(s), **1130**. *See also* specific plasmalogens
  glycerophospholipids, **460,** 461*f*
  phospholipids, 709, 709*f*
    fatty alcohol synthesis, 716, 717*f,* 718
Plasma membranes
  calcium-transporting ATPases (Ca^{2+}-ATPase) (PMCA), 493–494, 494*f*
  cell structure, **2, 14**
  cholesterol in, **462,** 464*f*

Plasma membranes (*cont.*)
erythrocyte, 458*f*
glucose transporters, 489, 489*f*, 1051*t*
hormone-receptor complexes, clathrin internalization, **907,** 909
as limiting boundary, 14–15, 14*f*
lipid composition, 462–463, 464*f*
lipid rafts, 473–474
luminal/contraluminal, epithelial cell transport, 1037*t*
phosphatidylserine clearance of red blood cells, 710cc
receptors, 474–475, 475*t*
sodium (Na^+) channel, **478**
transepithelial glucose transport, 1041–1042, 1042*f*
transport energetics, 487
Plasma proteins, **85**
disease diagnosis, 87cc
isoelectric pH and electrophoretic separation, 85–86, 86*f*–87*f*
steroid hormone transport, 928–929, 929*f*
Plasmid pSC101, **264**
Plasmid(s), **49, 264**
bacterial transformation, 265–266
α-complementation, 268, 270*f*
foreign gene expression, 281–282, 282*f*
crown gall plasmids, 294–295
recombinant DNA, 264
structure, 49
Plasmin, **418**
fibrinolysis and production of, 994, 994*f*
metastasis and, **1019,** 1019*f*
Plasminogen, **418**
fibrinolysis, 994, 994*f*
metastasis and, **1019,** 1019*f*
Plasminogen activator-inhibitor type 1 (PAI-1)
fibrinolysis, **994**
metastasis and, **1019,** 1019*f*
Plasminogen activator-inhibitor type 2 (PAI-2), metastasis and, **1019,** 1019*f*
Plastocyanin, nuclear magnetic resonance analysis, 134, 134*f*
Platelet activating factor (PAF), **709,** 709*f*
Platelet aggregation, prostaglandins effects on, 742
Platelet-derived growth factor (PDGF), tyrosine regulation, 1008–1009, 1008*f*
Platelet plug, formation mechanisms, 985
Pleckstrin homology (PH) domains, **511,** 512*f*
Pluripotential cells, **13, 294**
Point mutation
DNA sequences, **164**–166, 166*f*
genetic code and, **213**
Poisoning
arsenic, 605cc
enzyme inhibitors and, 411cc
Polarity
amino acid side chains, 86–89, **1131**
phospholipids, 708, 708*f*
protein primary structure, 90
semi-discontinuous DNA synthesis, 145, 145*f*
PolyA-binding protein (PAB), eukaryotic translation, **223**
Polyacrylamide gel electrophoresis, protein separation, 124
Polyadenylation, RNA polymerase transcription, 198, 199*f*
Poly ADP polymerases (PARPs), nucleotide coenzyme synthesis, 830–831
Polyamines
metabolites, 787, 788*f*, 789
prokaryotic DNA, **53,** 53–54, 53*f*
Poly(A) tail, eukaryotic mRNA, **68**
Polycistronic mRNA, **67**
prokaryotes, **210**
protein primary structure, 67–68
tryptophan operon attenuator region, **312**
Polycloning site, recombinant DNA, **264**
Polygenic obesity, 1108
Polyglutamate derivatives, folic acid formation, **1079,** 1080*f*
Polylinker
directional cloning, 265
recombinant DNA, 264
Polymerase chain reaction (PCR), **257**
DNA cloning circumvention, 268
HIV screeningg, 258cc
multiplex analysis, HGPRTase gene defect, Lesch-Nyhan syndrome, 268cc
nested PCR, 257
microchimerism detection, 258cc
overview, 256–257, 257*f*
quantitative real-time PCR, 257–258
site-directed mutagenesis, 287, 287*f*
Polymers, ribonucleoside 5′-monophosphate polymer, 62, 62*f*
Polynucleosomes
higher-structure packing, 56–57
structure, 55–56, 55*f*–56*f*
Polynucleotide phosphorylase
breaking genetic code and, **212**–213
cytoplasmic mRNA turnover and, 204
Polynucleotides, **30, 1133**
backbone stability, 31–32
structure and bonding, 30–32, 30*f*–31*f*
Polyol (aldose) dehydrogenase, cataracts, **955**
Polypeptide hormones
anterior pituitary, 887, 891
cascade, 887, 887*t*
gene coding, 892–895, 892*f*–894*f*
overview, 888*f*, 889*t*–891*t*
Polypeptides, **80**
amino acid peptide bond, 80–81, 81*f*
in antibody molecules, chain structure, 335–337
β sheet conformatin, 93, 94*f*–95*f*
chain structures, type IV collagen network, 370–371, 371*f*
fatty acid biosynthesis, 682–683, 682*f*
genetic code and, 213, 213*t*
myoglobin structure, 354
quaternary structure, 97–98
sequencing, 127–129, 128*f*–129*f*
synthesis and termination, 226–227, 228*f*
tertiary structure, 96–97, 96*f*
unfolded structures, 98–99, 98*f*
Polyproline type II helix, in collagen, **103,** 103–104
Polysaccharides, **1125, 1128**
biosynthesis, 658
carbohydrate digestion and absorption, 1049–1051, 1050*f*, 1050*t*
Polysomes, **219,** 220*f*
Polyubiquitinylation, ATP-dependent proteolysis in proteasomes, **248**–249, 248*f*–249*f*
Polyunsaturated fatty acids
formation and modification, 685–686, 685*f*–686*f*
heart disease risk and, 1114cc
serum cholesterol and, **1114–1115**
Pompe disease
enzyme replacement therapy, 238cc
glycogen storage, 633cc
Poor metabolizers, 442–443
P/O ratio, mitochondrial electron transport and oxidative phosphorylation, 573–575, 573*f*–575*f*
Porcine stress syndrome, 612cc
Pore/channel cells, translocation mechanisms, **476**
Pore-forming toxins, **496,** 496–498, 496*f*–497*f*, 496*t*–497*t*
Porin protein, mitochondrial structure, **560**
Porphobilinogen, heme biosynthesis, 793, 794*f*
Porphobilinogen deaminase, heme biosynthesis, 793, 794*f*
Porphyria
acute intermittent porphyria, 794cc
metabolic derangements, 796*t*, 797
variegate porphyria, **796**
Porphyria cutanea tarda, **795**
Porphyrin, heme biosynthesis, **794,** 796*t*
Porphyrinogen decarboxylase, heme biosynthesis, **793**–794
Porphyrinogens, heme biosynthesis, **793**–794, 793*f*
Positive cooperativity
hemoglobin-oxygen binding, **358**
multi-subunit enzymes, 415
Positive feedback, ovarian cycle control, **903**
Posterior pituitary hormones, hormonal cascade, **886**
Post-transcriptional processing, ribonucleoside 5′-monophosphate polymer, **62,** 62*f*
Posttranslational modifications, **230, 240**
amino acid incorporation and modification of proteins, 240–243, 242*t*, 243*f*
collagen biosynthesis, 243–245, 244*f*, 245*t*
O-linked glycosylation, **233**
partial proteolysis, insulin release and zymogen activation, 240, 241*f*
proteins, 230–235
Potassium (K^+) channel
neuron-neuron interaction, 943, 944*f*
plasma membranes, **478**
primary active transporters, antiport translocation, 491–492, 491*f*–492*f*
subunit composition, 481–482, 481*t*
valinomycin affinity, **496,** 496*f*
Potassium/hydrogen-exchanging ATPase (K^+/H^+-exchanging ATPase), gastric acid secretion, 1043, 1043*f*
Potassium ions, as enzyme cofactors, 394, 394*f*
Power stroke, skeletal muscle contraction model, **976–977**
Precocious puberty, 901cc
Precursor products
messenger RNA, intron removal, 196–198, 197*f*
ribosomal RNA, 195, 195*f*
Pregnancy
metabolism during, 871, 871*f*
prostaglandins effects on, 741–742
toxemia of, mineralocorticoid receptor mutation, 933cc
Pregnane X receptor (PXR)
cytochrome P450 metabolism, 441
steroid hormones, **934**

Pregnenolone
cytochrome P450 synthesis, 433*f*–434*f*, 434
steroid hormone biosynthesis, **919,** 920
Preinitiation complex, eukaryotic transcription factors, 320–325
Pre-initiation complex, protein synthesis, **221**–223
Prekallikrein
clot formation, 989, 989*f*
deficiency, 985cc
intrinsic pathway reactions, 984–985, 984*f*
Premature infants, hypoargininemia in, 762cc
Pre-mRNA, splicing and protein synthesis, 199
Preproinsulin, **304**
Preprooxytocin, 892–893, 894*f*
Preproteins, mitochondrial protein synthesis, **237**–239
Preprovassopressin, 892–893, 894*f*
Presequences, mitochondrial protein synthesis, **237**–239
Pribnow box, prokaryotic transcription, 185–186, 186*f*
Primary active transporters
antiport translocation of sodium and potassion ions, 491–492, 491*f*–492*f*
ATP-binding cassette (ABC) transporters, 494–495, 495*f*
calcium ion translocation, 492–493
mammalian membranes, **487**
mechanisms, 491
plasma membrane calcium transport, calmodulin control, 493–494, 493*f*–494*f*
Primary hyperoxaluria, 781cc
Primary protein structure, **90,** 91*f*
Primase
DNA replication, **141**
DnaG, 152
DNA polymerase α/primase complex, 153–157, 154*f*, 156*f*
replication fork movement, **145,** 146*f*
Primers, **142**
DNA replication, 140–141, 141*f*
chain elongation chemistry, 142
DNA polymerases, 142–143
RNA primers, 156*f*
replication fork movement and removal of, 145
Priming, replication fork movement, 145, 146*f*
Prion diseases, protein infectious agents, 114–115cc, 114*f*–115*f*
Probes, double-helical DNA hybridization, **38**
Pro-carcinogens, DNA damage and mutation, **164**
Procaspase 9, apoptosis, mitochondrial pathway, **1013**
Processivity, replication fork movement, **148**–149, 149*f*
Pro-chiral center, enzyme active site stereochemistry, **388**
Procoagulation, **982**
Procollagen, formation in endoplasmic reticulum and Golgi apparatus, 244–245
Procollagenase type IV, **1019,** 1019*f*
Product formation, rate of, 395–396
Proenzymes
digestive enzymes as, 1033, 1034*f*
serine protease synthesis, **347**
Proflavin, DNA mutation, **167**
Progestational hormones, **916**
Progesterone, **916, 921**
cytochrome P450 synthesis, 433*f*, 434
fertilization, 904–905, 905*f*
formation and secretion, 926*f*
ovarian cycle control, **901**
Progesterone receptor, **931**
Programmed cell death, 1010–1016, 1011*f*–1012*f*, 1014*f*–1015*f*. *See also* Apoptosis
enzyme-linked receptors, **517**
Prohormones, secretory intestinal hormones and neuropeptides, 1035cl
Proinsulin, proteolytic cleavage, 90cl, 91*f*
Prokaryotes, **2**
classification and cellular organization, 2, 3*f*
DNA coding, specific proteins, 58–59
DNA packaging, 53–54, 53*f*
gene expression, 304
genome sequencing, 295*t*
mRNA structures, translation, 210
promoters, transcription and RNA synthesis, 183, 183*f*
transcription in, 185–187, 186*f*–187*f*
enzymatic RNA polymerase action, 192–193, 193*f*
promoter recognition, 185–186, 186*f*
Prokaryotic enzymes
DNA replication, 151–153, 151*f*
transcription, 183–184
RNA polymerase III, 192–193, 193*f*
Prolactin (PRL), 888*f*, 889*t*–891*t*, 891
Proliferating cell nuclear antigen (PCNA), DNA replication
cell cycle and, 158
eukaryotic enzymes, **153**–157, 154*f*
replication fork movement, 149
Proline
degradation, 765–766, 767*f*
side chain structure, **77**
Proline dehydrogenase deficiency, 766cc
Promoter(s), **182, 185**
in cancer, 1023
eukaryotic transcription, 321–322, 322*f*
lactose operons
LacP promoter, **306,** 310*f*
operator sequence and, 307–309, 308*f*
RNA polymerase/regulator protein recognition, 309
mRNA synthesis, 190
prokaryotic transcription, 185–186, 186*f*
RNA transcription, 182
RNA polymerase I, 190–191, 191*f*
sequence, RNA synthesis, 183, 183*f*
Promoter sequence, **183**
Proofreading
aminoacyl-tRNA synthetases, **216**–217
DNA replication, DNA polymerases, **143,** 143*f*
Proopiomelanocortin hormone precursor, **892,** 892*f*, 893*t*, **931**
Propionyl-CoA
gluconeogenesis, 625, 625*f*
odd-chain fatty acids, 695, 695*f*
succinyl coA metabolism, **776**–777, 779*f*
Propionyl-CoA carboxylase, **776–777,** 779*f*
Prostaglandins, **674**
cyclooxygenase synthesis, 738–741, 739*f*–741*f*
enzyme inhibition, 408cc
fat synthesis of, 1112–1113
monocarboxylic acid derivatives, 737–738, 738*f*
physiologic effects, 741–742
steroid hormone receptors, **931**
Prostanoic acid, prostaglandins and thromboxane derivatives, 738, 738*f*
Prostate cancer
quantitative real-time polymerase chain reaction gene analysis, 259cc
testosterone and, 412cc
Prosthetic group
heme-oxygen binding, **355**
iron protoporphyrin IX (heme) prosthetic group, cytochrome P450, 426–427, 427*f*
nitric oxide synthases, 444–446, 444*f*–446*f*
riboflavin coenzyme, **392**
Protanopia, 967cl
Protease-inhibitor complex, **989**
extrinsic pathway inhibition, 990–993, 991*f*
Proteases, serine proteases, 343–353
Proteasomes
ATP-dependent proteolysis, 248–249, 248*f*
defects in, 250cc
Protein C
extrinsic pathway inhibition, 992–993
multidomain structure, 347, 348*f*
thrombosis and defects in, 993cc
vitamin K and, 994–995, 996*f*
Protein-calorie malnutrition, 841cc
Protein carboxylase reactions, vitamin K, 994–995, 995cl, 996*f*
Protein C inhibitor (PCI), extrinsic pathway inhibition, 993
Protein Data Bank, three-dimensional protein structure, **129**
Protein disulfide isomerases, chaperone protein folding, **116**
Protein-energy malnutrition, **1107**
Protein factors
rho factor, RNA transcription and termination, 187, 187*f*
RNA transcription, 182
Protein families, **334,** 334–373
Protein folding, **94**
basic principles, 112–113
chaperone proteins, 116, 117*f*, 231–232
cystic fibrosis and, 231cc
denaturation, 120, 120*f*
glycosylation, 232–233, 233*t*, 234*f*–236*f*
homologous structures, nonhomologous amino acid sequences, 101–102, 101*f*–102*f*
maturation and, 230–235
misfolding and aggregation, Huntington and Alzheimer diseases, 250cc
noncovalent forces, 116–119, 116*t*
electrostatic interactions, 118–119, 119*f*
hydrogen bonds, 118, 118*f*
hydrophobic interaction, 116–117, 118*f*
van der Waals forces, 119, 119*f*, 119*t*
prion diseases, 114–115cc, 114*f*–115*f*
secondary structure, 94
secretory pathway, 231–232, 231*f*–232*f*
unstructured proteins, 98–99, 98*f*
Protein hormones, **884**
signaling, 897–901, 898*f*–900*f*, 898*t*
intracellular signal cascade, second messengers, 899–901, 900*f*
membrane receptors, 897–898
Protein kinase A (PKA)
covalent modification of enzymes, **855**
cyclic AMP intracellular signaling, **529,** 529*f*–530*f*

Protein kinase A (PKA) (*cont.*)
G protein-coupled receptor signaling termination, **527**
intracellular signaling cascade, **899**–901, 900*f*
6-phosphofructo-1-kinase regulation, 614
vasopressin activity, 912, 912*f*, 913*t*
Protein kinase B (PKB), intracellular signaling pathways, 535–536, 536*f*
Protein kinase C (PKC)
gonadotropin-releasing hormone, 912–913, 913*t*, 914*f*
inositols in membranes and, 711–712, 711*f*
intracellular signaling cascade, **899**–901, 900*f*
intracellular signaling pathways, **535**
Protein kinase G
atrial natriuretic factor activity, 913–914, 914*f*–916*f*
intracellular signaling cascade, **899**–901, 900*f*
Protein kinases
calmodulin-dependent calcium activation, 534
cascades, **511**
gestational diabetes mellitus, 911cc
intracellular hormone cascades, 909–914, 915*f*
phosphorylation in signal transduction, **510,** 510*f*
pyruvate dehydrogenase regulation, **550**
Protein-losing enteropathy, plasma proteins, 87cc, 88*f*
Protein-mediated diffusion, membrane transport energetics, **487**
Protein phosphatases, phosphorylation in signal transduction, **510,** 510*f*
Protein-protein interactions, 99–100, 99*f*–100*f*
Protein receptors, plasma membrane and, 15
Protein S
extrinsic pathway inhibition, 993
vitamin K and, 994–995, 996*f*
Protein(s), **76**
adapter proteins, 511, 512*f*
adult requirements, 1104, 1106
amino acid composition, 76–82, 77*f*
abbreviations, 79*t*
absolute configuration, 80*f*
alpha-amino acid central asymmetry, 80
alpha-amino acid side chains, 77–79, 78*f*–79*f*
charge properties and pH, 85, 85*f*–86*f*, 85*t*
chemical reactions, 89, 89*t*
cystine derivation, 79, 80*f*
homologous fold structures, 101–102, 101*f*–102*f*
ionizability, 82–85, 83*t*, 84*f*
peptide bonds, 80–81, 80*f*– 81*f*, 82*t*
pI separation, 85–86, 87*f*–88*f*
sequence determination, 127–129, 128*f*–129*f*
side chain polarity and apolarity, 86–87, 88*f*
anchor proteins, 511, 512*f*
anion exchange protein, **490**
in basal lamina, 368
BH domain, apoptosis, mitochondrial pathway, 1012, 1012*f*
blood coagulation, control, and clot dissolution, 983*t*
clot formation, 985–989
complement system, 336cc–337cc
complexes, networks, and interactomes, 99–100, 99*f*–100*f*
cyclins, **1005–1006,** 1006*f*
degradation and turnover, 248–249, 248*f*–249*f*
nitrogen transport, liver and kidney, 757–759, 758*f*
digestion and absorption, 1043–1049, 1044*f*–1045*f*, 1044*t*, 1047*t*, 1049*f*
DNA coding sequence, pre-mRNA splicing, 199, 200*f*
DNA recombination, *E. coli* key proteins, 162
excess protein-energy intake, 1107–1111
family, **101**
folded proteins
basic principles, 112–113
chaperone proteins, 116, 117*f*, 231–232
cystic fibrosis and, 231cc
denaturation, 120, 120*f*
glycosylation, 232–233, 233*t*, 234*f*–236*f*
homologous structures, nonhomologous amino acid sequences, 101–102, 101*f*–102*f*
maturation and, 230–235
noncovalent forces, 116–119, 116*t*
electrostatic interactions, 118–119, 119*f*
hydrogen bonds, 118, 118*f*
hydrophobic interaction, 116–117, 118*f*
van der Waals forces, 119, 119*f*, 119*t*
prion diseases, 114–115cc, 114*f*–115*f*
secondary structure, 94
secretory pathway, 231–232, 231*f*–232*f*
unstructured proteins, 98–99, 98*f*
function in humans, 76
gap junctions, **484**
GEF^{Ras} protein, **1010**
gene product structure and function, 101
glycation, hyperglycemia and, 852cc
glycosylation, in endoplasmic reticulum and Golgi apparatus, 232–233, 233*t*, 234*f*–235*f*
Golgi apparatus and secretion of, 17, 17*f*
growth and illness, requirements in, 1106
intracellular digestion in lysosomes, 249
intracellular receptors, **507**
iron-sulfur proteins, 394–395
in lens, 954–956, 954*t*–955*t*, 955*f*
liposome carriers for, 466cc
membrane proteins, 463
integral membrane proteins, 468–470, 468*f*–470*f*
membrane leaflet diffusion, 472–473, 472*f*
microdomains, 473–474, 473*f*
peripheral membrane proteins, 470–472, 471*f*, 471*t*
translocation mechanisms, 476–477, 476*f*, 477*t*
transport proteins, 485–487, 485*f*–486*f*
membrane transport, **485,** 485–487, 485*f*–486*f*
eukaryotic protein substrates, 488*t*
metabolism, 1103–1106
mitochondrial import, 237–238
molecular dynamics, 120–121, 121*f*
molecular motors, 967–981
mRNA primary structure information, 67–68
nonglobular structured proteins, 103–112, 103*t*
collagen, 103–105, 103*f*, 103*t*–104*t*, 105*t*, 106*f*–107*f*
elastin, 106, 107*f*
glycoprotein covalently bound carbohydrate, 112, 112*f*
keratin and tropomyosin, 106–107, 107*f*
plasma lipoproteins, 107–109, 108*f*, 108*t*–109*t*, 110*f*–111*f*, 111, 111*t*
nonheme iron, **1087**
nuclear magnetic resonance analysis, 133–134, 134*f*
nutrients, 1030, 1030*t*
vegetable and animal proteins, 1115
phosphorylation in signal transduction, 510–511, 510*f*
plasma proteins, disease diagnosis and, 87
primary structure, 90, 91*f*
peptide bonds, 80–81, 80*f*
prion diseases, 114–115cc, 114*f*–115*f*
prokaryotic DNA coding for, 58–59
protein-energy requirements, 1105cc
proteomic analysis, 125–127
purification, 124–125
receptors, **474,** 474–475, 474*t*–475*t*
retinoblastoma sensitivity (Rb) protein, **1006**–1007, 1007*f*
scaffold, 511, 512*f*
secondary structure, 92–96, 92*f*
separation
charge separation, 121–122, 122*f*–123*f*
molecular mass or size, 123–124
skeletal muscle, molecular masses, 969*t*
spectroscopic analysis, 131–133, 131*f*–133*f*
Src, **1009**
structure-function relationships, 334–373
superfamily, 334–343, **343,** 343*f*
synthesis (*See also* Translation)
overview, 210–251
tertiary structure, 92, 96–97, 96*f*
three-dimensional structure, x-ray diffraction analysis, 129–131
transcription regulation and DNA binding, 322–325
translocation mechanisms, 476–477, 477*t*
uncoupling proteins, 581–582, 581*f*
unstructured, 98–99, 98*f*
vegetable proteins, 1103–1104, 1103*t*, 1104*f*
zine requirements, 1091–1092
Protein sparing, carbohydrate and fat, **1104**
Protein synthesis
bacterial expression vectors, foreign genes, 281–282, 282*f*
biosynthesis (*See* Translation)
elongation and peptide bond formation, 223, 224*f*–225*f*, 226
endoplasmic reticulum and, 16, 16*f*–17*f*
membrane and organelle targeting, 235–240
mitochondrial importation, 237–238
secretory pathway, 235–237, 237*f*, 239*f*
signalling mechanisms, 239–240
mitochondria, 229
posttranslational modifications, 240–245
amino acids, 240–243, 242*t*
collagen biosynthesis, 243–245, 243*f*–244*f*, 245*t*, 246–247cc
proteolysis, insulin release and zymogen activation, 240, 241*f*
pre-mRNA splicing and, 199
ribosomal RNA, 65–67, 66*f*
staphylococcal resistance to erythromycin, 66
translation and, 221–223, 221*t*, 222*f*
Protein Z
extransic pathway inhibition, **992**
vitamin K and, 994–995, 996*f*
Protein Z-dependent kinase inhibitor (ZPI), extrinsic pathway inhibition, **992**

Proteoglycans, carbohydrate metabolism, 663–668
chondroitin sulfates, 664, 666–667, 666*f*
dermatan sulfate, 664–665
glycosaminoglycans, 664–665, 665*f*, 666–667
heparin and heparan sulfate, 665
hyaluronate, 664
keratan sulfate, 665–666
Proteolipids, **463**
Proteolysis
apoptosis and, 249
ATP-dependent mechanism in proteasomes, 248–249, 248*f*
insulin release and zymogen activation, 240, 241*f*
limited proteolysis, **344**
Proteolytic cleaving, proinsulin, 90cl
Proteolytic enzymes, catalytic mechanism classification, 343–347
Proteome, **295**
Proteomics
defined, **125,** 295
enzyme analysis, 420–421
protein expression, 125–127
Prothrombin, clot formation, 987
Prothrombinase complex, 987, 987*f*
Proton acceptors, acids as, **7**
Proton addition and removal, enzyme transition states, 386, 386*f*
Proton donors, acids as, **7**
Proton gradient, oxidative phosphorylation, **572–573,** 572*f*
Protonmotive force, oxidative phosphorylation, **573**
Proton motive force (PMF), membrane transport energetics, **487**
Proton pump
gastric acid secretion, 1043, 1043*f*
Q cycle, 568cl
Protooncogene(s)
cancer biochemistry and, 1023, 1023*f*-1024*f*
cancer cell cycle and, 1016–1017, 1016*t*
growth factor signal transduction, **1010**
transcriptional factors and, 191cc
Protoporphyrin, heme biosynthesis, **793**
Protoporphyrinogen, heme biosynthesis, **793**
Protoporphyrinogen IX oxidase, heme biosynthesis, 791, 793, 793*f*
Protoporphyrinogen oxidase, **795–796**
Protransglutamidase, clot formation, 988, 989*f*
Proximal histidine, heme-oxygen binding, **355,** 355*f*
PRPP amidotransferase, **810**
Pseudogenes, **61**
DNA recombination, 164
Psi (ψ) bond, secondary protein structure, **92,** 92–96, 92*f*, 93*t*
Pteroylmonoglutamic acid, 1079
P-type transporters, **491**
Puberty, precocious puberty, 901cc
Pulmonary system
dipalmitoyllecithin and lung function, 710–711, 710*f*
neuronal (NOSI/nNOS) activation, 447–448, 448*f*
Pulsatile release
hormonal cascade, **887**
ovarian cycle control, 901–905, 902*f*-905*f*
Purification techniques, protein purification, 124–125
Purines, **27, 1132–1133**
antiviral agents, 834–835, 834*f*
cell distribution, 808–809
glycosidic conformation, 29, 29*f*
metabolism inhibitors, 832–834
nucleic acid structure, 27–30, 27*f*-30*f*
nucleoside degradation, immunodeficiency diseases, 820cc
synthesis and degradation, 810–817
adenine/guanine balance and interconversion, 817
AMP/GMP formation, IMP precursor, 813, 814*f*
base and nucleoside salvaging, 815–817, 816*f*-817*f*
IMP formation, 811–813, 812*f*-813*f*
regulatory mechanisms, 814–815, 814*f*-815*f*
tetrahydrobiopterin GTP precursor, 817–819, 818*f*-819*f*
uric acid, 819*f*, 820–821, 821*f*
Puromycin, translation targeting of, **230,** 230*f*
Pyridoxal, coenzyme formation, **1078**
Pyridoxal phosphate, aminotransferase cofactor, 755, 755*f*
Pyridoxal phosphate-pyridoxal coenzyme formation, **392**–393, 393*f*
Pyridoxamine, coenzyme formation, 1078–1079, 1078*f*
Pyridoxine, coenzyme formation, 1078–1079, 1078*f*
Pyrimidines, **27, 1132–1133**
antiviral agents, 834–835, 834*f*
cell distribution, 808–809
dimers, DNA damage and mutation, **164**
glycosidic conformation, 29, 29*f*
interconversions, 825–826
nucleic acid structure, 27–30, 27*f*-30*f*
nucleotide degradation, 826–827, 827*f*
chemotherapeutic agents, 831–836
inhibitors, 832–834
nucleotide metabolism, 821–824
synthesis reactions, 821–823, 822*f*-823*f*
Pyroglutamic acid, amino acid-derived hormone degradation, **896,** 898*t*
Pyrophosphatase, nucleotide-linked sugars, **653**
Pyrophosphorylase, nucleotide-linked sugars, **653**
Pyrroline-5-carboxyate synthetase, glutamic semialdehyde deficiency, 767cc
Pyrrolysine, biosynthesis, 764
Pyruvate
allosteric effector regulation, 853–855, 853*f*-855*f*
hepatic glycogenolysis, early fasting state, 844, 844*f*
in well-fed state, 842–843, 843*f*
Pyruvate carboxylase, 381, 382*f*
anaplerotic reactions, tricarboxylic acid cycle, 557, 557*f*
glucose synthesis, 622, 622*f*
Pyruvate compounds
glucose metabolism, 594*f*-595*f*, 595–596
glycolysis, 593, 593*f*
metabolic sources and fates, 549, 549*f*
Pyruvate dehydrogenase, **549**
allosteric effector regulation, 853–855, 853*f*-855*f*
covalent modification of enzymes, 856–859, 856*f*
deficiency, 552cc
glycolysis, 593, 593*f*
multienzyme complex, 550–551, 550*f*, 550*t*
regulation, 550–551
Pyruvate kinase
α/β-domain structure, 102, 102*f*
cancer and, 619, 619cl
covalent modification, 856–859, 856*f*
glycolysis regulation, 617, 619, 619*f*
hemolytic anemia and deficiency of, 618cc
Pyruvoyl enzymes, 765cl

Q
Q cycle, 568cl
Quantitative real-time polymerase chain reaction (qRT-PCR), **257,** 257–258
prostate cancer gene analysis, 259cc
Quaternary protein structure, **92,** 97–98
Quencher, protein structure, spectroscopic analysis, **132**
Quiescent cell, division cycle, **1005**
Quinone, vitamin K as derivative, **1073**–1075, 1073*f*

R
Rab3, **947**
Racemase, 381, 382*f*
Radioactive decay, 397
Raffinose, 1051
Randle hypothesis, 677cc
Random-coil conformation, polynucleotides, **31,** 31*f*
Random primer DNA labeling, **270**–271
Random-sequential reaction, **405,** 406*f*
Ran protein, **484**
Ras protein
apoptosis, MAPK pathway regulation, 1015–1016, 1015*f*
growth factor signal transduction, 1009–**1010,** 1009*f*-1010*f*
signal transduction, 518–519, 519*f*
Rate-limiting step, metabolic pathway regulation, **417**
Rate of formation, one-substrate enzyme reactions, 399, 399*f*
R conformational state
Bohr effect, 360–366, 361*f*-366*f*
hemoglobin deoxy-conformation, **360,** 361*f*-362*f*
oxygen-hemoglobin binding, 2,3-bisphosphoglycerate, **365,** 365*f*
Reactive oxygen species (ROS), 583–587
cellular damage, 587, 587*f*
mitochondrial damage, 586–587
Reading frame, genetic code and, 213
"Read through" mutations, termination codons, 215*t*
RecA protein
DNA recombination, **162**
SOS response, DNA repair, 175–176, 176*f*
RecBCD protein, DNA recombination, **162**
Receptor-ligand interactions, downstream signaling, 512–513, 512*f*-513*f*
Receptor-mediated endocytosis, protein intracellular digestion in lysosomes, **249**
Receptor(s)
cell surface receptors, intracellular signal transduction, 509–514
effectors and second messengers, 509–510, 510*f*
GTP-binding proteins, 511
ligand-receptor interaction and downstream signaling, 512–513, 512*f*-513*f*
ligands and receptor-ligand interactions, 509
protein phosphorylation, 510–511, 510*f*
signaling components and cascades, 511, 512*f*
termination, 513–514
cytokine receptors, 520–521, 522*f*
enzyme-linked receptors, 516–520
ligand-gated ion channels, **508, 514,** 514–516, 514*f*-515*f*

Receptor(s) (*cont.*)
membrane receptors, **474,** 474–475, 474*t*–475*t*
secreted molecules, 507–508, 507*f*–508*f*
steroid hormones, 929–934, 930*f*
subtypes, cell surface receptors, intracellular signal transduction, **509,** 509*f*
Receptor serine/threonine kinases, 519–520, 520*f*
Receptors for advanced glycation end products (RAGEs), hyperglycemia and, 852cc
Receptor tyrosine kinases (RTK)
cancer chemotheraphy, 518cc
signal transduction, **517,** 517–519, 517*f*–518*f*
Receptosomes, membrane receptor internalization, **906,** 908*f*
Recognition sequence, solute molecule transport, 485–486, 485*f*
Recombinant DNA, **262**
applications for, 288–295
in agriculture, 294–295
antisense nucleic acids, 289–290, 289*f*
cloned animals, 292–294
gene therapy, 290, 291cc
knockout mice, 292, 293cc, 293*f*
short-interfering RNA gene expression regulation, 290cc
transgenic animals, 291–292, 292cc, 292*f*
whole-animal molecular techniques, 290–294
bacterial transformation, 265–266
antibiotic resistance, 266, 267*f*, 268
cloning vectors, 264, 264*f*
α-complementation, bacterial selection, 268
directional cloning, 265, 265*f*
formation of, 262, 264*f*
gene library of molecules, 266
polymerase chain reaction, cloning circumvention, 268
Recombinant Factor VIIa, coagulation and, 990cc
Recombinant tissue plasminogen activator (rt-PA), 344cc
Recombination. *See* DNA recombination
Recommended dietary allowance (RDA), 1065
Recommended protein intake (RPI), 1104, 1106
renal diseae and, 1105cc
Recovery mechanism, solute molecule transport, **486**
Red blood cells, phosphatidylserine clearance, 710cc
Redox couple, electron transport chain, **561**
Redox reactions, free-energy changes, 562–563
Reducing equivalents
mitochondrial inner membrane transport, 579, 580*f*
NAD/NADPH in catabolism and anabolism, **543**
Reducing sugar, 1127–1128
Reductant, **561**
5α-Reducatase, **920**
Reduction reactions
ascorbic acid functions, 1084, 1084*f*
metal ions, 394–395
Reductive biosynthesis, pentose phosphate interconversions, **649**–651, 650*f*
Refinement, x-ray diffraction, three-dimensional protein structure, **130**–131
Refsum disease, fatty acid oxidation, 696cc
Regulatory molecules, fatty acids as, 701, 702cc
Regulatory subunits, enzyme activity, 417, 417*f*
Regulon, SOS response, DNA repair, 175–176, 176*f*
Relaxed-control plasmids, recombinant DNA, **264**
Relaxed DNA, 49–51, 50*f*–51*f*
Release factor (eRF1), polypeptide synthesis, **226**–227, 228*f*
Release mechanisms, solute molecule transport, **485,** 485–486
Releasing hormones, hormonal cascade, **886–887,** 887*t*
Renal osteodystrophy, 1070cc
Renaturation, double-helical DNA, 36–37, 36*f*–37*f*, **37**
Renin-angiotensin system, **923,** 926*f*
Reoriented intermediates, N-linked glycosylation, **233**
Repair of DNA. *See* DNA repair
Repeated extragenic palindromic (REP) elements, prokaryotic DNA protein coding, 59
Repeated sequences, eukaryotic DNA, 61–62
Repeating sequences, antibody molecules, 335*f*, 339
Repetitive DNA, structure, **61,** 61–62
Repetitive sequences, prokaryotic DNA protein coding, **59**
Replication, **26**. *See* DNA replication
eukaryotic chromosomes, 54–55, 54*f*
nucleic acids, 26
Replication bubble, DNA replication, eukaryotic enzymes, **155**–157, 156*f*
Replication Factor C (RFC), DNA replication, 153–157, 154*f*
Replication fork
movement of, 145–149, 146*f*
parental strand separation, DNA replication, 144, 144*f*
rewinding and repair, 175
Replication protein A (RPA), DNA replication, **153**–157, 154*f*
Replicon, recombinant DNA, **264**
Replisome, DNA replication and, **150,** 150*f*
Repression, **305**
Repressor
lactose operon, **306**
tryptophan operon, 310–311
Repressor-constitutive mutations, **307**
Resistin, obesity and insulin resistance, 1109
Resonance forms, high-energy compounds, **546,** 546*f*
Resonance isomers, peptide bonds, **80**–81, 80*f*
Respiratory alkalosis, pH levels in blood and, 7cc
Respiratory burst, mitochondrial reactive oxygen species, 585, 585*f*
Respiratory control, tricarboxylic acid regulation, 558–559, 558*f*
Respiratory cycle, hemoglobin oxygen delivery, 366–367, 366*f*–367*f*
Respiratory distress syndrome (RDS), dipalmitoyllecithin and, 711cc
Response elements, eukaryotic transcription, **322**
Resting potential, rod cells, **961**
Restriction endonucleases, **31, 58, 258**
bacterial transformation, 265–266
DNA backbone stability, 31–32
DNA hydrolysis, 258–259, 259*f*
DNA sequencing, 58, 58*f*–59*f*
recombinant DNA formation, 262, 264*f*
site-directed mutagenesis
DNA flanking regions, 284, 285*f*
single nucleotides, 285–287, 286*f*–288*f*
Restriction fragment length polymorphism (RFLP)
clonal origin of tumors, 273cc
Southern blot technique, **271,** 272*f*
Restriction mapping
DNA defined segments, 259–260
evolution and, 260cc
restriction endonucleases, 259, 259*f*
Restriction site bank, recombinant DNA, **264**
Retina
ATP derivation, anaerobic glycolysis, 956
membrane layers, 957*f*
11-*cis*-retinal protein, **958,** 959*f*, 962*f*, 964*f*, 965
Retinal dystrophy, Leber congenital amaurosis, 965cc
Retinitis pigmentosa
Niemann-Pick disease, 958cc
peripherin gene mutation, 690cc
Retinoblastoma sensitivity (Rb) protein, cell cycle regulation, **1006**–1007, 1007*f*
Retinoic acid receptors (RAR), **932,** 933*f*–934*f*
vitamin A, **1066**
Retinoid X receptors (RXR), **932,** 933*f*, 934
Retinol, vitamin A, 1066
11-*cis*-retinol, **958**
Retinyl phosphate, vitamin A, 1066
Retrograde strands, semi-discontinuous DNA synthesis, **145,** 145*f*
Reuptake mechanisms, serotonin, **950**
Reverse cholesterol transport, 725, 725*f*
Reverse genetics, antisense research and therapy, **289**–290
Reverse-Hoogsteen triplets, triple-stranded DNA structure, **43,** 43–45, 44*f*–45*f*
Reverse-phase high-performance liquid chromatography (HPLC), protein separation, **124,** 125*f*
Reverse transcriptase
mRNA template for DNA synthesis, 275–276, 275*f*–276*f*
transposition, **163**
Reverse-transcriptase polymerase chain reaction (RT-PCR)
DNA synthesis, **276,** 276*f*
mRNA detection, **272,** 274*f*
Reverse transcriptases, HIV therapy resistance and, 144cc
Reverse transcription, **26**
nucleic acids, 26
RNA genome replication, 158
Reversible reactions, 397, 397*f*
turnover number (k_{cat})/Michaelis constant (K_m) ratios, 403
Reye-like syndrome, 694cc
RFLP. *See* Restriction fragment length polymorphism
Rh factors, neonatal isoimmune hemolysis, 798cc
Rhodanese, 781
Rho-dependent/rho-independent terminators, RNA transcription, **187,** 187*f*
Rhodopsin, **958,** 958*f*–959*f*, 961
Rhodopsin kinase, visual cycle, **963,** 963*f*
Rhythmic cyclic release, hormonal cascade, **887**
Riboflavin
coenzyme formation, 392, 392*f*
FAD/FMN coenzyme formation, **1077,** 1077*f*
Ribonuclease P
structure, 69
transfer RNA cleavage, 194
Ribonucleases, side chain and terminal acid dissociation constants, 82–83, 83*t*
Ribonucleic acid. *See* RNA

Ribonucleoprotein particles (RNPs), **16, 217**
endoplasmic reticulum and, 16
riboomes, translation with, 217–220
RNA in, 68
Ribonucleoside 5′-diphosphates, deoxyribonucleotide formation, 824–825, 824*f*
Ribonucleosides
5′-monophosphate polymer, 62, 62*f*
nucleic acid structure, 27–30, 27*f*-30*f*
Ribonucleotide reductase, 824–825, 824*f*, 825*t*
Ribose 5-phosphate, pentose phosphate pathway, **648**–649, 649*f*
D-Ribose, structural components, 27–30, 27*f*-30*f*
Ribosomal protein, bacterial operation regulation, **314**–315, 314*f*-315*f*
Ribosomal RNA (rRNA)
mitochondrial mutations, 229cc
precursor products, 195, 195*f*
protein synthesis, 65–67, 66*f*
stringent response, 315
synthesis, RNA polymerase I, 190–191, 191*f*
Ribosomes, **16, 217**
classification and composition, 218*t*
endoplasmic reticulum and, 16
structure and function, 218–219, 218cl, 219*f*
Ribozyme, **26**
catalytic RNA, 68–69, 68*f*-69*f*, **226**
structure and function, 26
Ribulose 5-phosphate, pentose phosphate pathway, **648**–649, 649*f*
Ricin, translation targeting of, 230
Rickets, 1071
Rieske iron-sulfur protein, mitochondrial electron transport, **566**
Rifampicin, RNA polymerase and transcription, **184**
Right-handed DNA, 49–51, 50*f*
Rigor, **979**
Rigor mortis, **979**
RNA, **16, 26**. *See also* Transcription
catalytic ribozymes, 68–69, 68*f*
DNA replication, telomerases, 156–157, 157*f*
function, 26
genome replication, 158
hydrolysis, 31, 31*f*
in mitochondria, 68
molecular binding, 69, 69*f*
nuclear structure and function, 15–16, 15*f*
nucleases and turnover of, 202–204
processing reactions, **182,** 193–199
messenger RNA, 196, 196*f*
pre-mRNA splicing, 199
ribosomal RNA, 195, 195*f*
RNA polymerase II enzyme recruitment, 196–198, 197*f*-199*f*
splicing mutations and human disease, 198
transfer RNA modification, 193–195, 194*f*
ribonucleoprotein particles, 68
sequencing, nucleic acid probes, 268, 270–271, 271*f*
splicing
eukaryotic functional gene sequencing, 60–61, 60*f*
mutations and human disease, 198, 199*f*
pre-mRNA splicing and protein synthesis, 199
structure, 62–64
intramolecular base pairing, secondary structure, 62, 62*f*-63*f*
ribonucleoside 5′-monophosphate polymer, 62, 62*f*
tertiary structure, 63–64, 63*f*-64*f*
translation control, 69–70
types of, 65–70
RNA catalysis, elongation and peptide bond formation, **226**
RNA helicase, eukaryotic translation, **223**
RNA hybridase (RNase H), replication fork movement, **145**
RNA-induced silencing complex (RISC), translation regulation, **247**
RNA interference (RNAi), **201,** 201*f*
antisense research and therapy, **289**–290
translation regulation, **247**
RNA polymerases, **141**
antibiotic and toxin targeting, 185cc
assembly sites, eukaryotic gene expression, **317**
DNA replication, 141
lactose operon
promoter recognition, 309
repressor, 306
RNA polymerase I, transcription by, **190**–191, 191*f*
RNA polymerase II
elongation and transcription, 196, 196*f*
eukaryotic transcription enzymes, 196–198, 197*f*
initiation complex, 320, 321*f*, 322
transcription by, 189–190
RNA polymerase III, transcription, **191**–193, 192*f*-193*f*
subunit composition, 185*t*
transcription catalysts, **183**–184
elongation, 187
eukaryotic transcription, 188–189
initiation, 186–187, 186*f*-187*f*
termination, 187, 187*f*
Rnase H, DNA replication, **153**–157
RNA silencing, translation regulation, **247**
RNA synthesis
DNA sequence information, 182–183
transcription, 182–183, 183*f*
initiation of, 186–187, 186*f*-187*f*
Rod cells
outer segments of, **958**
photoreceptor cells, 957*f*, 958–963, 959*f*, 961*f*-963*f*
sensitivity and response time, 967cl
Rossmann fold, liver alcohol dehydrogenase, **391,** 391*f*
Rough endoplasmic reticulum (RER)
mammalian cell, 16–17, 17*f*
protein export, **231**–232, 231*f*-232*f*
Rous sarcoma virus, expression vector, **283**
Rubenstein-Taybi syndrome, 319cc
RuvA/RuvB complex, DNA recombination, **162**
Ryanodine receptor, calcium-based signal transduction, **533**

S
Salivary glands, digestive enzyme secretion, 1033, 1034*f*
Salt bridges, deoxyhemoglobin, **360,** 362*f*
Salt linkages, folded proteins, **118**–119, 119*f*
Salts, **5**
crystal lattice structure, 5
Sanfilippo syndrome, 668cc
Sanger procedure, enzymatic cleavage, **260**–261, 260*f*-261*f*
α-Sarcin, translation targeting of, **230**
Sarcomeres, skeletal muscles, 967, 968*f*-969*f*
Sarcoplasmic reticulum (SERCA)
calcium-transporting ATPases (Ca^{2+}-ATPase), 493, 493*f*
skeletal muscles, 967
Satellite DNA, DNA sequences, **61,** 61–62
Saturated fatty acids (SFA), **1129**
diet and, **1114**–**1115**
Scaffold proteins, signal transduction, 511, 512*f*
Scavenger receptor B-1 (SCARB-1), cholesterol absorption, 1057cc
SCF complex, cell cycle regulation, **1006**
Screening libraries, bacteriophages, 278, 278*f*
Scurvy, collagen synthesis and, 247cc
Sea of lipid, **466**
Secondary active cotransport, nutrients, **1042**
Secondary active transporters, membrane transport energetics, **487**
Secondary bile acids, chemistry and synthesis, 1058
Secondary interactions, peptide bonds, **347**
Secondary protein structure, **92,** 92–96, 92*f*
Second law of thermodynamics, energy-rich components, **544**
Second messengers
hormones, **884**
intracellular signaling cascade, 898–901, 900*f*
intracellular signaling molecules, **508**
cell surface receptors, **509,** 509–510, 510*f*
protein phosphorylation, signal transduction, 511
phosphatidylinositols, 461cl
Second-order reactions, product formation, 396
Secretagogues, enzyme regulation, 1033–1034, 1033*t*, 1034*f*-1035*f*, 1036
Secreted molecules
classification, 507
receptors for, 507–508, 507*f*-508*f*
signal transduction, **504**
Secretin, digestion and, 1035*t*, **1036**
Secretory pathway
protein export, 231–232, 231*f*-232*f*
protein sorting, 235–237, 237*f*, 239*f*
Sedoheptulose, pentose phosphate interconversions, **650**–651, 650*f*
Selenium, in selenoproteins, 1093–1094
Selenocysteine, 78*f*, **79**
aminoacyl-tRNA synthetases, 212cc
biosynthesis, 764, 764*f*
elongation and peptide bond formation, **226**
Selenocysteinyl-tRNA synthesis, **212**
Selenoproteins, 765cc
selenium in, 1093–1094
Self-regulated ribosomal proteins, **314–315,** 314*f*-315*f*
Self-splicing mechanisms, ribozymes, 68–69, 68*f*
Semiconservative replication, DNA, **140,** 140–141, 140*f*
Semi-discontinuous DNA synthesis, **145,** 145*f*
Senescent cell(s), division cycle, **1005**
Senile cataracts, **955**
Separation techniques, mRNA, 275
Septic shock, nitric oxide overproduction in, 450cc
Sequence determination
amino acid composition of proteins, 127–129, 127*f*-129*f*
polynucleotides, **30**

Sequence homology of visual pigments, 966cl
Sequence-specific DNA-binding proteins, detection of, 272–273, 274*f*, 275
Sequential, non-overlapping reading frame, codon-anticodon interactions, **212**–215, 213*t*–214*t*, 214*f*
Sequential mechanism, two-substrate enzyme reactions, **405,** 406*f*
Sequential model of enzyme cooperativity, **415,** 415–417, 417*f*
Serine
biosynthesis, 763, 764*f*
covalent modification, 855–859, 855*f*–858*f*
degradation, 765, 766*f*
glycosyl linkage, 112, 112*f*
O-glycosyl bonds, **659,** 659*f*
intracellular hormone cascades, **909**
metabolite derivation, 778, 780*f*
6-phosphofructo-1-kinase regulation, 614, 614*f*
side chain structure, **77**
sphingosine formation, 729, 729*f*
Serine dehydratase, degradation, **765,** 766*f*
Serine palmitoyltransferase, sphingosine synthesis, **729**
Serine proteases, **334, 343,** 343–353, 344*f*
biochemistry and physiology, 345*t*
catalytic mechanisms, 352, 352*f*
peptide bond hydrolysis, 346–347, 346*t*, 347*f*
protein inhibitors, 352, 353*t*
sequence homology, 351, 351*t*
structure-function relationships, 350–351, 350*f*
tertiary structure of catalytic domains, 348–350
tumor cell metastases, 345cc
X-ray crystallography of, 349*t*
zymogen synthesis, 347–348, 348*f*
Serine/threonine kinase, signal transduction, **517,** 519–520, 520*f*
Ser-Lys-Leu (SKL) tripeptide, protein targeting of organelles, **240**
Serotonin, 785–786, 787*f*
N-acetyltransferase conversion, **901**
degradation, 951, 952*f*
digestion and, **1034**–1035, 1035*f*
light/dark cycles, 901, 902*f*
neuronal reuptake, 950cl
signal termination, **950,** 952*f*
Serotonin transporters (SERT), 950cl
Serpins
extrinsic pathway inhibition, 990–993, 991*f*
serine protease inhibition, **352**
Serum cholesterol, diet and, 1114–1115
Serum-conjugated bilirubin, 800cc
Serum proteins, isoelectric pH and electrophoretic separation, 86, 88*f*
7TM receptors, 475
Severe combined immune deficiency disease (SCID), gene therapy, 291cc
Sex hormone-binding globulin (SHBG), steroid hormone transport, **928**–929, 929*f*
Sex hormones
cholesterol conversion, 919–921, 920*f*
ovarian cycle control, 902–904, 903*f*–904*f*
structure and functions, **916**
Short-chain fatty acids, colon metabolism, 877–878, 878*f*
Short interfering RNA. *See* Small interfering RNAs (siRNAs)
Short interspersed element (SINE)
DNA sequences, 61–62
nonhomologous recombination, **163**
Short-patch repair, DNA mutation, **168**
Shotgun sequencing, human genome, 298–**299**
Sialic acid, **462**
N-Acetylglucosamine derivation, **657**–658, 657*f*
in gangliosides, 733–734, 733*f*, 734*t*
Side chains
alpha-amino acid structure, 77–79, 78*f*–79*f*
amino acids, polar/apolar properties, 86–89
apolipoproteins, 111, 111*f*
cleavage reaction, cytochrome P450 steroid hormone synthesis, 434, 434*f*
in collagen, 105, 106*f*
folded proteins, 113
protein structure, fluorescence spectroscopy, 132–133, 132*f*
tertiary protein structure, 96–97, 96*f*–97*f*
Signaling complexes, ion channel receptors, **516**
Signal molecules, membrane receptors, **474–475,** 474*t*–475*t*
Signal peptidase, secretory pathway, **232**
Signal peptide, protein export, secretory pathway, **231**–232, 231*f*–232*f*
Signal recognition particle (SRP), protein export, secretory pathway, **231–232,** 231*f*–232*f*
Signal transducers and activators of transcription (STATs), 521
Signal transduction
calcium-based, 532–534, 532*f*–533*f*
cascades/pathways, **508**
cyclic AMP
signaling mechanisms, 529–530, 529*f*–530*f*
synthesis and degradation, 528–529, 529*f*
cyclic GMP-based, 530–531
cytokine receptors, 520–521, 522*f*
enzyme-linked receptors, 516–520
G protein-coupled receptors, physiology and extracellular ligands, 523–525, 524*f*
growth factors, **517**
cell cycle regulation, 1008–1010, 1008*f*–1010*f*
receptor tyrosine kinase, 517–519, 517*f*–518*f*
serine/threonine kinases, 519–520
GTP-binding regulatory proteins, 511
insulin receptors, 910–911, 911*f*
intercellular, 504–507
autocrine signaling, 505*f*, 506–507
endocrine siganling, 505–506, 505*f*
juxtacrine, contact-dependent, signaling, 505, 505*f*
paracrine signaling, 505*f*, 506
synaptic/neuronal signaling, 505*f*, 506
intracellular, 504, 504*f*
cell surface receptors, 509–514
pathway-network integration, 537, 537*f*
phospholipid-based, 534–536, 534*f*, 536*f*
secreted signaling molecules, 507
Signatures, **101**
Sildenafil
mechanism of action, 449cc
nitric oxide/cGMP signaling, 531cc
Silent mutations, **166**
genetic code and, **213**
Hutchinson-Gilford progeria syndrom and multidrug resistance 1 gene, 214cc
Simian virus 40 (SV40)
expression vector, **283**–284
genome of, 215*f*
Single copy repeated sequences, 61–62
Single nucleotide, site-directed mutagenesis, 284–287, 286*f*–288*f*
Single nucleotide polymorphisms (SNPs), 271–272
dye-terminator sequencing, 262, 263*f*
nutrigenetics and, 1118–1119
personalized medicine and, 167cc
protein gene product structure and function, 101
Single-strand conformation polymorphism (SSCP), **271**–272
sudden infant death mutation detection, 274cc
Single-stranded DNA-binding proteins (SSBs)
DNA replication, **152**–153
parental strand separation, DNA replication, **144,** 144*f*
Site-directed mutagenesis, **284,** 284–288
DNA flanking regions, deletion and insertion mutations, 284, 284*f*–285*f*
single nucleotides, 284–287, 286*f*–288*f*
type VII collagen, 286cc
Site-specific recombination, 163
Skeletal muscle
contraction, 974–977, 975*f*–977*f*
covalent enzyme modification, 858–859
glycogen content, 630, 630*f*
glycogenolysis in
epinephrine stimulation, 641, 641*f*
neural control, 641–642, 642*f*
neuronal (NOSI/nNOS) activation, 447–448, 448*f*
proteins, 969*t*
Skeletal muscle(s), 967–977, 968*f*–969*f*, 969*t*
actin, tropomyosin, and troponin thin-filament proteins, 970–974, 972*t*, 973*f*
contraction, 974–979, 975*f*–977*f*
myosin muscle filament formation, 968*f*, 968*t*, 969–970
Sleep, tryptophan and carbohydrates and, 775cl
Sliding clamps, DNA replication
eukaryotic enzymes, **153**–157
replication fork movement, **148**–149, 149*f*
Sliding filament model, muscle contraction, 967
Slipped DNA, 46–47, 47*f*
Slow-reacting substance of anaphylaxis (SRS-A), **745**
Smac/DIABLO protein, 1012*f*, **1013**–1014
SMAD proteins, **520**
Small interfering RNAs (siRNAs)
antisense research and therapy, **289**–290
gene expression regulation, 290cc
RNA interference, **201,** 201*f*
translation regulation, 70, **248**
Small intestine
amino acid transporters in, 1046–1048, 1047*t*
digestion and, 1032
pancreatic zymogen activation, 1044*t*, 1045–1046, 1045*f*
saccharides, 1049, 1050*t*
sodium chloride absorption, 1039, 1039*f*
Small nuclear ribonucleoproteins (snRNPs), mRNA precursor removal, **196**–198, 197*f*
Small ubiquitin-related modifier proteins (SUMO), 251cl
Smooth endoplasmic reticulum (SER), mammalian cell, 16–17, 17*f*
Smooth muscle contraction, calcium regulation, 978–979, 979*f*

SNARE protein family, Golgi apparatus and secretion of, 17, 17*f*
Sodium/amino acid transporters, amino acid translocation, **490**
Sodium (Na^+) channel
  control and selectivity, **478**
  primary active transporters, antiport translocation, 491–492, 491*f*–492*f*
  rod cells, 961
  sodium chloride absorption, 1037–1039, 1038*f*–1039*f*
  subunit composition, 481–482, 481*f*–482*f*, 481*t*
Sodium chloride (NaCl)
  absorption, 1037–1039, 1038*f*–1039*f*
  secretion, 1039–1040, 1040*f*–1041*f*
Sodium cholate micelle, digestion, 1055–1057, 1055*f*
Sodium dodecyl sulfate (SDS), polyacrylamide gel electrophoresis, **124**
Sodium/glucose transporter (SGLT), glucose and amino acid translocation, **489,** 489–490, 489*f*
Sodium glucose transporter 1 (SGLT1), **1042**
Sodium/hydrogen (Na^+H^+) exchanger, cytoplasmic pH regulation, **490**
Sodium-independent chloride-bicarbonate exchanger, **490**
Sodium ions, nutrient transport, 1041–1042, 1041*f*
Sodium motive force (SMF)
  glucose and amino acid translocation, **489,** 489–490, 489*f*
  membrane transport energetics, **487**
Sodium/potassium (Na^+/K^+)-exchanging ATPase
  in neurons, 942, 943*f*
  primary active transporters, antiport translocation, **491,** 491–492, 491*f*–492*f*
  sodium chloride
    absorption, 1037–1039, 1038*f*–1039*f*
    secretion, 1039–1040, 1040*f*–1041*f*
Sodium/proton exchanger 3 (NHE3), sodium chloride absorption, 1039, 1039*f*
Sodium pump, **491**
Solenoid arrangement, **56**
Solute molecule diffusion
  membrane translocation, 476*f*
  transport, 485–486, 485*f*
Solute transport, epithelial cells, transcellular/paracellular mechanisms, 1036–1037, 1036*f*, 1037*t*
Somatic mutation, carcinogenesis and, 191
Sorbitol
  cataracts, **955**
  glucose synthesis, 626, 626*f*
SOS response, DNA repair, **175**–176, 176*f*
Southern blot technique, DNA fragment identification, **271,** 272*f*
Specific activity, protein purification, 125
Spectroscopic analysis, protein structures, 131–133, 131*f*–133*f*
Spermatogenesis, **925**
Spermatozoa, fructose in, 626
S phase, cell cycle
  DNA replication, **157**–158, 157*f*
  nucleotide metabolizing enzymes, 828–829
  regulation, **1004,** 1004*f*
Sphinganine, 729, 729*f*
Sphingolipidoses, as lysosomal storage diseases, 734–737, 735*f*, 736*t*, 737*f*
Sphingolipids, **1130**. *See also* Glycosphingolipids; Prostaglandins; Thromboxanes
  ceramide derivatives of sphingosine, 730, 730*f*
  as membrane components, **460,** 462, 462*f*–464*f*, 462*t*
  sphingomyelin, 730, 731*f*–732*f*
  sphingosine synthesis, 729, 729*f*
  structure, 731*f*
Sphingomyelinase reaction, sphingolipidoses diagnostic testing, 736–737, 736*f*–737*f*
Sphingomyelins, **460,** 462*t*, 463*f*, **1130**
  asymmetric distribution, 467, 467*f*
  phosphorus component, 730–731, 731*f*–732*f*
  structure and functions, **1085**
Sphingosine, **460,** 462*f*
  ceramide derivatives from fatty acid, 730, 730*f*
  synthesis, 729, 729*f*
Splice junction recognition mechanisms, messenger RNA intron removal, 196–198, 197*f*
Spliceosome, messenger RNA intron removal, **197**–198, 197*f*
Splicing, **60**
  eukaryotic functional gene sequencing, 60–61, 60*f*
  mutations and human disease, 198, 199*f*
  pre-mRNA splicing and protein synthesis, 199
  RNA export and quality control, 199–201
Squalene, cholesterol synthesis from farnesyl pyrophosphate, 721–722, 721*f*–723*f*
SRC-1 protein, cytochrome P450 metabolism, 442
Src-homology type 2/type 3domains
  growth factor signal transduction, **1009**–1010, 1009*f*
  myosin 1, 980
  signal transduction, **511,** 512*f*
Src protein, **1009**
SREBP cleavage activating protein (SCAP), **327**
Stacking interactions, double-helical DNA, 34–36, 35*t*, 36*f*
Staphylococcal resistance, erythromycin, 66cc
Starch
  carbohydrate digestion and absorption, 1049–1051
  glycolysis, 593
Stargardt muscular dystrophy, 495
Start signal, mRNA genetic code, **211**–212
Starvation, 842cc
  energy requirements and hormone homeostasis, 849–850, 850*t*
  enzymes in, 860
  ketone bodies, **940**
Starve-feed cycle, 840, 840*f*, 842–852
  cancer and, 868–869, 869*f*
  covalent enzyme modification, 858–859
  early fasting state, 844, 844*f*
  early refed state, 847
  energy requirements, reserve, and caloric homeostasis, 849–850, 849*t*–850*t*
  fasting state, 845–847, 845*f*–846*f*
  glucose homeostasis, 850–852, 851*f*
  interorgan metabolic interactions, 847–849, 848*f*–849*f*
  liver metabolism, 852–862
  well-fed state, 842–844, 843*f*
Steady-state concentration, protein folding and denaturation, 120, 120*f*
Steady-state potential, rod cells, **961**
Stearoyl CoA desaturase, monoenoic acid formation, fatty acid desaturation, **685**
Stem cells, cloning and, 294
Stem-loop RNA structure, RNA transcription and termination, 187, 187*f*
Stereochemistry, 1124–1125
  enzyme active sites, 388, 388*f*
  enzyme-catalyzed reactions, 389cl
Stereoid receptor superfamily, **884,** 934*f*
Stereoisomers, **1124–1125**
Stereo tracing, x-ray diffraction, three-dimensional protein structure, 130, 131*f*
Steric hindrance
  doexyhemoglobin, 359–360, 359*f*, 361*f*–362*f*
  folded proteins, van der Waals forces, **119,** 119*f*, 119*t*
Steroidal anti-inflammatory agents, prostaglandin production, 741
Steroid hormones, **674, 884,** 917*t*, **1131**
  amino acid synthesis, 895–897
  "ball-and-stick" representations, 918*f*
  biosynthesis, 919–921, 919*f*–920*f*
  cholesterol precursor, 718–719, 719*f*
  cytochrome P450 synthesis, 432, 433*f*–434*f*, 434–435
  metabolism, 921–922, 921*f*
  plasma-binding proteins and transport of, 928–929, 929*f*
  pregnancy and production of, 435cc
  receptors
    intracellular receptor proteins, 929–934
    nongenomic steroid effects, 935
    nuclear hormone receptors, activators, and corepressors, 935
    orphan receptors, 934–935
  structure and function, 916, 916*f*, 916*t*, 917*f*–918*f*
  synthesis regulation, 922–928, 922*f*, 923*t*
    aldosterone, 923–924, 923*t*, 924*f*–925*f*
    estradiol, 924–925, 926*f*
    vitamin D_3, 926–928, 927*f*
Steroidogenic acute regulatory (StAR) protein, 922–923, 922*f*
Steroid response element (SRE), 327–328
Steroids, **1131**
Sterol-response-element-binding proteins (SREBP), **860,** 862
  protein 1a (SREBP-1a), 327–328, 327*f*–328*f*
Stoichiometry, fatty acid synthesis, 683
Stop codon, polypeptide synthesis termination, 226–227, 228*f*
Stop signals, mRNA genetic code, **212**
Straight-chain fatty acids, β-oxidation, 691–693, 692*f*
Strand elongation, replication fork movement, 145
Streap3 ferrireductase, 1089
Streptokinase, **418**
Streptomycin, translation and targeting of, **229**–230
Stress, metabolism and, 872–873, 872*f*
Stringent factor, **315**
Stringent response/control
  recombinant DNA, **264**
  rRNA/tRNA synthesis, **315,** 315*f*
Strong electrolytes, **5**
  water molecule dissociation, 5–6
Structural genes, **304**
  lactose operon operator sequence and, 307–309, 308*f*
Structural isomorphism, **33**
Structural motif, secondary protein structure, **94,** 94–95, 95*f*
Strychnine, neuron-neuron interaction, 943, 944*f*
Subacute cerebellar degeneration (SCD), Lambert-Eaton myasthenic syndrome, 948cc
Subclinical nutritional deficiencies, 1064

Subcloning, DNA segment definition, **279**
Suberoylanilide hydroxamic acid (SAHA), epigenetic cancer treatments, 57cc
Substance P, neuropeptide derivation, **953**
Substrates
cytochrome P450, 431–440, 432*t*, 433*f*
lipophilic substrates, 436–440, 437*f*–439*f*, 437*t*
steroid hormone synthesis, 432, 433*f*–434*f*, 435, 435cc
enzymes, 383, 383*f*
allosteric control *vs.*, 414cc
covalent binding, 386–387, 387*f*
distal substrate bond modification, 388, 389*f*
pH levels, 387, 387*f*
three-point attachment site, 388, 389*f*
metabolic pathway control, 852–853
nitric oxide synthases, 446
rate of disappearance, 396–397, 397*f*
solute molecule transport, 485–486, 486*f*
translocation mechanisms, **476**–477
turnover number (k_{cat}) and concentration, 402–403
in well-fed, fasting, and starving states, 849–850, 850*t*
Substrate shuttles
glycolysis
anaerobic glycolysis, 601–602
oxidoreduction pathways, 602–603
mitochondrial inner membrane transport, 579, 580*f*
Succinate dehydrogenase, tricarboxylic acid cycle, **555**
Succinate thiokinase, tricarboxylic acid cycle, **555**
Succinate-ubiquinone oxidoreductase, mitochondrial electron transport, 563, 565–566, 566*f*
Succinylcholine, **483**
Succinyl CoA, tricarboxylic acid cycle, **554–555,** 556–558, 556*f*
Succinyl CoA synthetase, tricarboxylic acid cycle, **555**
Sucrose hydrolysis, **1050**
Sudden infant death syndrome (SIDS)
acyl coA dehydrogenase deficiency, 694cc
single-strand conformational polymorphism, 272
single-strand conformation polymorphism mutation detection, 274cc
Sugar puckering, nucleoside/nucleotide structure, **29,** 29*f*
Sugar(s)
interconversions, carbohydrate metabolism, 652–658
N-acetylglucosamine sialic acid derivation, 657–658, 657*f*
decarboxylation, oxidoreduction and transamidation, 656, 657*f*
intermediate transformation, 653–654, 653*f*
isomerization and phosphorylation, 652–653, 652*f*
nucleotide-linked glucose/galactose epimerization, 654, 654*f*
UDP-glucose oxidation and glucuronic acid formatin, 654–655, 655*f*
reducing sugar, 1127–1128
Suicide inhibitors
cytochrome P450, 444
enzyme reactions, **410**
Sulfatases, chondroitin sulfate biosynthesis, 667
Sulfatide, **462,** 464*f*
as galactocerebroside sulfuric acid ester, **732–733,** 733*f*
Sulfation defects, chondrodystrophies, 667cc
Sulfhydryl reagents, glycolysis, 603, 603*f*
Sulfonylurea receptor, ATP-binding cassette (ABC) transporters, **494**
Sulfuric acid ester, sulfatide as, **732–733,** 733*f*
Sunlight, vitamin D synthesis, 1067–1072
Supercoiling, **45, 148**
eukaryotic DNA, 56*f*
replication fork and parental strand untwisting, 148
triple-stranded DNA structure, 45
Superfolds, homologous structures, nonhomologous amino acid sequences, **101,** 101–102, 101*f*–102*f*
Superhelical DNA, **49,** 49–51, 50*f*–51*f*
Superhelical stress, triple-stranded DNA structure, **45**
Superhelix
in collagen, **104,** 106*f*
in keratin and tropomyosin, 106–107, 107*f*
Superoxide dismutase, mitochondrial defenses, 587, 587*f*
Superoxides
mitochondria, 584–585, 585*f*
nitric oxide synthases, 446
Supershift mechanism, electrophoretic mobility shift assay, **273,** 274*f*
Suppressor mutations, aminoacyl-tRNA synthetases, **217**
Surfactant, pulmonary, dipalmitoyllecithin and, 710–711, 710*f*
Svedberg coefficient, protein separation, **123,** 123*f*, 123*t*
Symmetrical tail-to-tail aggregation, 969*t*, 970
Symport mechanism
electrochemical-potential-driven transporters, 488
solute molecule transport, **486,** 486*f*
Synapses, neuron-neuron interaction, 943, 944*f*–945*f*
Synapsin, **945,** 946*f*–947*f*
Synaptic junction, **945**
signal termination, 948, 950–951
Synaptic signaling, 505*f*, 506
Synaptic vesicles, **945,** 945*t*, 946*f*–947*f*
SV-2, **947**
Synaptobrevin/VAMP, **946**
Synaptophysin, **946**
Syn conformation, nucleoside/nucleotide structure, **29**
Syndecan, **668**
Synonymous mutations, **166**
Syntaxin, **946**
Synthase, **381**
Synthetase, **381–382**
Synthetic pathways, endoplasmic reticulum and, 16, 16*f*–17*f*
Sypnaptotagmin, **946**

T
Tamoxifen, gene receptor targeting, 326cc
Tandem affinity purification (TAF), **99**–100, 99*f*–100*f*
Tandem replicons, DNA replication, eukaryotic enzymes, 153, 155*f*
Tangier disease, 110cc
Target cell, hormonal cascade, **886**
Targeting elements, translation regulation, **247**
TATA binding protein (TBP), 320–321, 320*f*
TATA box
LDL receptor gene promoter, 326–327, 327*f*
mRNA synthesis promoters, **190**
Taurine, cysteine metabolite, 781
Tautomeric forms, double-helical DNA structure, 32–33, 32*f*
Tay-Sachs disease, 734
diagnosis, 737
T conformational state
Bohr effect, 360–366, 361*f*–366*f*
hemoglobin deoxy-conformation, **360,** 361*f*–362*f*
oxygen-hemoglobin binding, **365,** 365*f*
Telomerase
anticancer agent targeting, 46cc
cancer immortality and, 1018
DNA replication, eukaryotic enzymes, **156**–157, 157*f*
Telomeres, **54, 151**
DNA replication
eukaryotic telomerases, 157, 157*f*
linear genome termination, 150–151, 151*f*
eukaryotic chromosomes, 54–55, 54*f*
four-stranded DNA, 45–46, 45*f*
Telopeptides, in collagen, **105**
Temperature, enzyme reaction kinetics, 404
Template-Directed mechanism, amyloid plaque formation, 115
Templates, **140, 142**
DNA replication, 140–141, 141*f*
DNA polymerases, 142–143
RNA synthesis, transcription and, 182–183, 183*f*
Terfenadine, CYP3A4 inhibition, 438, 438cc, 438*f*
Terminal repeat sequences, bacterial transposons, **316**
Termination
polypeptide synthesis, stop codon requirement, 226–227, 228*f*
RNA transcription, **182,** 183*f*
prokaryotes, 187, 187*f*
signal transduction
cell surface receptors, 513–514
ion channel receptors, 516
synaptic junctions, 948, 950–951
Termination codons, mRNA genetic code, **212**
Terminator codons, mutations and formation of, 214cc
Terpenes, **1131**
Tertiary protein structure, **92,** 96–97, 96*f*
serine proteases, 348–350
Testosterone, **916, 921**
metabolism, 921–922, 921*f*
prostate cancer and, 412cc
Testosterone-estrogen-binding globulin (TeBG), steroid hormone transport, **928**–929, 929*f*
Tetracyclines
pBR322 gene resistance, **266,** 267*f*, 268
translation targeting of, **230**
Tetrahedral structure, **4**
water molecules, 4–5, 4*f*
Tetrahydrobiopterin
deficiency, 786cc
GTP precursor, **817,** 817–819, 818*f*
phenylalanine degradation, **767,** 768*f*
Tetrahydrofolate
antifolate inhibition, 832–834

folic acid one-carbon metabolism, 1079–1082, 1080*f*-1081*f*
Tetraiodo-L-thyronine (T_4), **896,** 897*f*-898*f*
Tetraplexes, four-stranded DNA, **45,** 45–46, 45*f*
Tetrapyrrole ring, cobalamin structure and function, 1082–1083, 1082*f*
TFII-H complex
nucleotide excision repair, 169
transcription-coupled DNA repair, 170
xeroderma pigmentosum, 170cc
Thalassemia, messenger RNA synthesis, 197cc, 198, 199*f*
α-Thalassemia, 215cc
Therapeutic cloning, **294**
Thermodynamics
energy-rich components, 543–548
dietary components, caloric value, 545–546
enzyme reactions, energy changes, 547
free energy availability, 544–545
high-energy bond energies, 547–548
hydrolysis groups, 546
enzyme mechanisms, 382–383
Thermogenesis, calcium-transporting ATPases (Ca^{2+}-ATPase), **493**
Thiamine
deficiency, **1076**
thiamin pyrophosphate coenzyme formation, 1075–1706, 1075*f*
Thiamine pyrophosphate (TPP), **550**
pentose phosphate interconversions, **650**–651, 650*f*
thiamin formation of coenzyme, 1075–1706, 1075*f*
tricarboxylic acid cycle, **554**
Thin filaments, skeletal muscles, **969**
Thiocysteine, metabolite formation, 781, 782*f*
Thioesterases, fatty acid synthase formation, **687**
Thio-ester-linked acyl anchors, membrane proteins, 470–471, 471*t*
6-Thioguanine, purine/pyrimidine nucleotide metabolism, 832
Thiohemiacetal, glucose metabolism, 597*f*, 598–600
Thiolate ligands, cytochrome P450, 426–427, 427*f*
Thiolysis, fatty acids, **691**
Thiophorase, ketone body formation, 700
Thiopurine base analogs, drug development and, 166cc
Thioredoxin
deoxyribonucleotide formation, 824–825
vitamin K and, 995
Thioredoxin reductase, selenium and, 1093–1094
Thiosulfate, metabolite formation, 781, 783*f*
3′-end terminus, transfer RNA, 194–195, 194*f*
Three-dimensional protein structure, x-ray diffraction analysis, 129–131, 130*f*-131*f*
Threonine
covalent modification, 855–859, 855*f*-858*f*
degradation, 767, 768*f*
O-glycosyl bonds, **659,** 659*f*
intracellular hormone cascades, **909**
side chain structure, **77**
Thrombin
clot formation, 987, 987*f*-988*f*
extrinsic pathway inhibition, 991, 992*f*
formation of, 984, 984*f*
receptor, **985,** 986*f*
Thrombomodulin, **668**
extrinsic pathway inhibition, 992–993, 993cl, 994*f*
Thrombosis, protein C pathway defects, 993, 993cc
Thromboxanes, **1129**
cyclooxygenase and, 741, 741*f*
monocarboxylic acid derivatives, 737–738, 738*f*
platelet aggregation, 742
thromboxane A_2, platelet plug formation, **985,** 986*f*
Thymidylate synthase, 825
Thymine, **27**
nucleic acid structure, 27–30, 27*f*-30*f*
Thyroglobulin, thyroid hormone synthesis, **896,** 897*f*-898*f*
Thyroid gland, 1091
Thyroid hormones, **884**
iodine synthesis, 896, 897*f*-898*f*, 1091
receptors, **932**
Thyroid-stimulating hormone (TSH), 887, 888*f*, 889*t*–891*t*, 891
membrane receptors, **905,** 906*f*
second messenger system, 899–901, 900*f*
Thyrotropin. *See* Thyroid-stimulating hormone
Thyrotropin-releasing hormone (TRH)
gene encoding, 895
second messenger system, 899–901, 900*f*
Thyroxine, **896,** 897*f*-898*f*
Tiazofurin, glutamine nitrogen donor enzyme inhibition, 834, 834*f*
TIGAR regulator, cancer and, 618cl
Tight binding mechanism, enzyme transition state, 385, 385*f*
Tissue factor
clot formation, 985–986, 986*f*
coagulation initiation, 983–985
hemostasis, **982**
Tissue factor pathway inhibitor (TFPI), extrinsic pathway inhibition, 990–993, 991*f*
Tissue inhibitor of metalloproteinases (TIMPs), metastasis and, **1019,** 1019*f*
Tissue plasminogen activator (t-PA), fibrinolysis, **994,** 994*f*
Titin muscle protein, polypeptide chain, 81, 82*t*
TnC-TnI complex, 973–974, 973*f*
Tocopherols, **1072–1073,** 1072*f*
Tocotrienols, **1072–1073,** 1072*f*
Tolerable upper intake level, nutritional assessment, 1065
Topoisomerases, **152**
as antibiotics, 152cc
disease treatment and, 52cc
DNA replication, replication fork and parental strand untwisting, 148, 149*f*
structure, 51–53, 51*t*, 53*f*
type I, **51**
DNA replication, 153–157
replication fork movement, 148
type II, **52**
circular genome termination, DNA replication, 150
DNA replication, 153–157
replication fork movement, 148
Topological constraints
DNA replication, **152**–153
replication fork and parental strand untwisting, **148**
Topological domains, superhelical DNA, **51,** 51*f*
Total metabolism, caloric value of dietary components, 545–546, 545*t*
Total urine nitrogen (TUN), 753cc
Toxemia of pregnancy, mineralocorticoid receptor mutation, 933cc
Toxic metabolites
cytochrome P450 metabolism, **437,** 438–440
genetic polymorphisms, 442–443
vitamin D, 1072
Toxins
glutathione response, 790, 790*f*
heterotrimeric G proteins, 527
nicotinic-acetycholine channel and, 483
pore-forming toxins, 496–498, 496*f*-497*f*, 497*t*
RNA polymerase targeting, 185cc
translation and targeting of, 229–230
Trace minerals, 1087–1094
chromium, 1093
copper, 1092–1093
iodine, 1091
iron, 1087–1091
selenium, 1093–1094
zinc, 109–1092
Transaldolase, pentose phosphate interconversions, **650**–651, 650*f*
Transamidation, sugars, **655–656,** 655*f*
Transaminases. *See* Aminotransferase
Transamination, tricarboxylic acid cycle, **556**
Transcellular epithelial cell transport, 1036–1037, 1036*f*, 1037*t*
Trans configuration, amino acid peptide bonds, **81,** 81*f*
Transcortin, steroid hormone transport, **928**–929, 929*f*
Transcript, RNA incorporation, **182**
Transcription, **26**
attenuation, operon control, amino acid biosynthesis, 313–314
bacterial units, 304–305
DNA repair and, 201–202
enzyme regulation of, 860–861, 861*f*
in eukaryotes, 187–193, 188*f*-189*f*
active chromatin, 188, 188*f*
enzymatic RNA polymerase action, 192–193, 193*f*
RNA polymerase I, 190–191, 191*f*
RNA polymerase III, 191–192
mechanisms of, 182–187
DNA sequence information, 182–183, 183*f*
RNA polymerase catalyst, 183–184
RNA synthesis, 182–183, 183*f*
nucleic acids, 26
in prokaryotes, 185–187, 186*f*-187*f*
enzymatic RNA polymerase action, 192–193, 193*f*
Transcription-coupled DNA repair, **170**
Transcription factor-binding sites, eukaryotic gene expression, **317**
Transcription factors
carcinogenesis, 191cc
cardiovascular disease and, 326cc
eukaryotic gene expression, **317**
regulation of, 325–328
eukaryotic transcription
modular design, 322
preinitiation complex, 320–325, 320*t*
promoters, 321–322, 322*f*
protein motifs, DNA binding and regulation, 322–325
RNA polymerase III, 191–192, 192*f*
TFIID and variants, 320–321
zinc finger proteins, 323
TFII-H, 169–170, 170cc

Trans-dominant operator mutations, **308**
Transducin, **961**
Transducing proteins, intracellular signal transduction, cell surface receptors, **509–510,** 510*f*
Transesterification, DNA replication, chain elongation chemistry, 142
Trans expression, double-stranded RNA, 70
Transfection
  antisense research and therapy, 289–290
  eukaryotic cell expression vectors, **282**–284, 283*f*
    mutant cell nutrient requirements and utilization, 283
Transferases, structure and classification, 380, 380*f*
Transferrin, iron deficiency and, **1087,** 1089, 1089*f*
Transferrin receptor-2 (TfR2), hepcidin synthesis, 1090, 1090*f*
Transferrin-receptor complex, 1089
Transfer RNA (tRNA), **65**
  amino acid activation, 65
  aminoacylation and protein synthesis, 216–217, 217*f*
  as bilingual translator, **210**–211
  cleavage modification, 193–194, 194*f*
  cloverleaf structure, 62, 63*f*
  codon recognition, mRNA, 65
  L-shaped conformation, 64, 64*f*
  mitochondrial mutations, 229cc
    myopathies, 583cc
  mRNA translation, codon-anticodon interactions, 212–215, 213*t*–214*t*, 214*f*
  nucleoside modification, 195
  ribosomes and, 219, 219*f*–220*f*
  stringent response, 315
  tertiary structure, 63, 63*f*
  3′-end addition, 194–195, 194*f*
Transformation, **26, 265**
  DNA into bacteria, 265–266
  sugar interconversion, carbohydrate metabolism, **652,** 652*f*
Transforming grwowth factor-beta (TGF-β), **519**
Transformylase, protein synthesis in mitochondria, **229**
Transgenic animals
  DNA fragment cloning, 279
  mice, Huntington disease research, 279cc
  models, 292cc
  production of, **291**–292, 292*f*
Transition metals, as enzyme cofactors, 393–395, 393*f*–395*f*
Transition(s), DNA mutation and, **166**
Transition state
  acids and bases, 385
  carbonyl group, 386
  enzyme models, 383–386, 384*f*
  oxidations, 386
  partially charged bonds, 385–386, 385*f*–386*f*
  proton addition and removal, 386
  tight binding, 385, 385*f*
Transition-state inhibitors, enzyme reactions, 410
Transketolase
  pentose phosphate interconversions, **650**–651, 650*f*
  Wernicke-Korsakoff syndrome and anomalies in, 651cc
Translation, **26, 210**
  antibiotics and toxin targeting, 229–230
  apparatus and components of, 210–220
  codon-anticodon interactions mRNA reading, 212, 212*f*, 215*f*, 215*t*
  messenger RNA transmission, 210
  nucleotide alphabet, genetic code, 211–212, 211*t*
  ribosomes for protein biosynthesis, 217–219, 218*t*, 219*f*–220*f*
  transfer RNA aminoacylation for protein synthesis, 216–217, 217*f*
  transfer RNA bilingual molecule, 210–211
  basic principles, 210, 221–230
  antibiotic and toxin targeting, 229–230, 230*f*, 230*t*
  elongation and peptide bond formation, 223–226, 224*f*–225*f*, 227*f*
  initiation, 221, 221*t*, 222*f*, 223
  polypeptide termination, 226–227, 228*f*
  translation directionality and colinearity with mRNA, 221
  cytoplasmic mRNA turnover and, 203–204, 204*f*
  energy costs of, 229
  genetic code, four-letter alphabet, 211–215, 211*t*, 212*f*
  mRNA colinearity, 221
  nucleic acids, 26
  regulation of, 245, 247–248
  ribosomes, 217–220
  RNA control of, 69–70
Translesion synthesis, DNA repair, **174,** 174*f*
Translocase, peptide bond formation, **226**
Translocase of inner membrane (TIM) complex, mitochondrial protein synthesis, **237**–239
Translocase of outer membrane (TOM) complex, mitochondrial protein synthesis, **237**–239
Translocation
  molecules through membranes, 475–477, 476*f*, 477*t*
  primary active transporters, antiport mechanism, 491–492, 491*f*–492*f*
  solute molecule transport, **485,** 485*f*
Translocon, secretory pathway, **232**
Transmembrane domains, β-adrenergic receptor, 905–906, 907*f*
Transmembrane electrical potential, in neurons, 942
Transmembrane proteins
  integral (intrinsic) membrane proteins, **468,** 468–470, 468*f*–470*f*
  side chain polarity, 89
7-Transmembrane domain receptors, **524,** 524*f*
Transmissable multiple-drug resistance, 316cc
Transmissible spongiform encephalopathies, 114–115cc, 114*f*–115*f*
Transponsons, *Tn3* structual genes, **316**–317, 316*f*
Transporter cells, translocation mechanisms, **476**
Transposable elements. *See* Transposons
Transposases
  bacterial transposons, **316**
  nonhomologous recombination, **163**
Transposition, nonhomologous recombination, **163**
Transposons
  bacterial, 316–317, 316*f*
  nonhomologous recombination, **163**
Transversions, DNA mutation and, **166**
Trehalase, **1051**
Trehalose, 1051
Triacylglycerol-fatty acid cycle, 689, 690cc, 690*f*
Triacylglycerols, **1129–1130**
  basic structure, **674,** 674*f*
  carbohydrate intake and, 1118cc
  digestion, 1051–1052, 1052*f*
    bile acid micelles, 1055–1057, 1055*f*
  fatty acids as, 674*f*, **675**–676, 676*f*
    storage, 687–689, 690*f*
  fatty acyl coA and glycerol 3-phosphate synthesis, 688–689, 688*f*–689*f*
  glycogen formation, early refed state, 847
  hydrolysis and mobilization of, 689
  hydrophobicity, 676–677
  liver metabolism and, 859–860, 859*f*
  metabolism regulation, 679*t*
  transport
    fasted state, 679–680, 689, 690*f*
    fed state, 678–679
  in well-fed state, 843–844, 843*f*
Tricarboxylic acid (TCA) cycle, **548, 552**–559
  acetyl group conversion, 555
  amino acid transfer, 754, 754*f*
  anaplerotic reactions, 557, 557*f*
  biosynthetic intermediates, 555–557, 556*f*
  fumarase deficiency, 555cc
  glucose synthesis, 622–624, 624*f*, 624*t*
  glycolysis, 593, 593*f*
  nervous system function, 940–941
  reactions, 553–555, 554*f*–555*f*
  regulation of activity, 557–559, 558*f*
Trichromatic color vision, 966
Tricostatin A, epigenetic cancer treatments, 57cc
Trifunctional protein, fatty acid oxidation, 693
Triglycerides, obesity and insulin resistance, 1109–1110, 1109*f*
Triglyceride transfer protein, A-β-lipoproteinemia, 1058cc
Trihydroxyphenylalanine (TOPA), metabolites, 784, 785*f*
Triiodo-L-thyronine (T_3), **896,** 897*f*–898*f*
  retinoic acid receptor, 934*f*
Triose phosphate isomerase, α/β-domain structure, 102, 102*f*
Tripeptide transporters, amino acid absorption, 1046–1048, 1047*t*, 1048*f*
Triple-helix assembly, procollagen formation, **244**–245
Triple-stranded DNA
  human disease and, 48cc
  structure, 43–45, 44*f*–45*f*
Triplet expansion
  DNA mutations, 166–**167,** 166*f*
  human disease and, 48cc
tRNA nucleotidyltransferase, transfer RNA 3′-end terminus addition, 194–195, 194*f*
Tropomyosin, 106–107, 107*f*
  in muscle(s), 972–973, 976*f*
  pre-mRNA splicing and, 199, 200*f*
Troponin, 973–974, 973*f*, 976*f*
  as myocardial infarction markers, 974cc
Troponin C, calcium-transporting ATPases (Ca^{2+}-ATPase) in plasma membranes, **494**
Trypanosomal parasites, phospholipids and, 712
Trypsin
  aggregation, 970cl
  pancreatic autodigestion, 1045cc
  peptide bonds, 346–347, 347*f*
  peptide hydrolysis stabilization, 352*f*
  proteolysis, 240, 241*f*
  sequencing, **128**

serine proteases and amino acid sequencing, 349, 349*t*
sequence homology, 351, 351*t*
tertiary structure, 96–97, 96*f*
zymogen activation, 1044*t*, 1045, **1046**
Trypsinogen, proteolysis, **240,** 241*f*
Tryptophan, **310**
degradation, 771–772, 773*f*
metabolites, 784–785
operon, **310,** 310–314, 311*f*
attenuator region, **312,** 312–313, 312*f*–313*f*
repressor protein control, 311–312
side chain structure, **77**
sleep and, 775cl
Tryptophan dioxygenase, **771**
Tryptophan hydroxylase deficiency, 787cc
Tuberculosis, RNA polymerase targeting, 184–185
d-Tubocurarine, **483**
Tubulin, **21**
Tumor lysis syndrome (TLS), 821cc
Tumor necrosis factor α (TNFα)
obesity and insulin resistance, 1109–1110, 1109*f*
in stress and injury, **873**
Tumors
clonal origin of, restriction fragment length polymorphism determination, 273cc
metastases, serine proteases, 345cc
Tumor suppressor genes
cancer biochemistry and, 1023, 1023*f*–1024*f*
cancer cell cycle and, 1016–1017, 1016*t*
pathways, 1018, 1018*f*
Tumor suppressor p53. *See* p53 protein
Turnover number (k_{cat}), **402**
calculation, 404
Michaelis-Menten equation, 402–403
reversible reactions, 403
substrate concentration, 402–403
Turnover rate, nervous system function, **941**
Twisted β-sheet, nonhomologous amino acid sequences, **102,** 102*f*
Twisting mechanism, replication fork and parental strand untwisting, **148**
Two-dimensional electrophoresis, proteomics, **125**–127, 126*f*
Two-dimensional nuclear magnetic resonance (2-D NMR), protein structure analysis, **133**–134
Two-substrate enzyme reactions
inhibitors, 410
ping-pong mechanism, 405–407, 406*f*
sequential mechanism, 405, 406*f*
Tyrosine
degradation, 767, 770*f*
epinephrine synthesis, 895, 895*f*
intracellular hormone cascades, **909**
metabolite derivation, 781–782, 783*f*
platelet-derived growth factor regulation, 1008–1009, 1008*f*
side chain structure, 77
thyroid hormone synthesis, 896, 897*f*–898*f*
Tyrosine kinase
cytokine receptors, 521
insulin receptor transduction, 909*f*–911*f*, 910–911
intracellular hormone cascades, **909**
molecular targeting of anticancer drugs, 1021cc
signal transduction, 516, 517*f*
Tyrosinemias, 769cc

U
Ubiquinol-cytochrome *c* oxidoreductase
mitochondrial electron transport, 566–569, 567*f*–569*f*
Q cycle, 568cl
Ubiquinone, mitochondrial electron transport, 563, 564–565, 564*f*–565*f*
Ubiquitin
ATP-dependent proteolysis in proteasomes, **248**–249, 248*f*–249*f*
defects in, 250cc
small ubiquitin-related modifier proteins, 251cl
UDP-glucose
glucuronic acid formation, 654–655, 654*f*–655*f*
nucleotide-linked sugars, **653**–654
UDP-glucose-4-epimerase, **654,** 654*f*
UDP-glucose dehydrogenase, **654,** 657*f*–658*f*
UDP-glucose pyrophosphatase, **653**–654
Ultracentrifugation, protein separation, 123, 123*f*
Ultraviolet light spectroscopy
protein structure, 131–133, 131*f*–133*f*
x-ray diffraction, three-dimensional protein structure, 131cl
UMP synthase, pyrimidine metabolism, 822
Uncompetitive inhibition, enzymes, 408, 408*f*
Unconventional myosins, 967
Uncouplers, mitochondrial electron transport and oxidative phosphorylation, 573–575, 574*f*
Uncoupling proteins, mitochondrial inner membrane transport, 581–582, 581*f*
Uniport mechanism
glucose transporters, **488,** 488–489
solute molecule transport, **486,** 486*f*
Universal genetic code, mRNA codons, **211**
Unsaturated compounds, 1124
Unsaturated fatty acids, **1129**
β-oxidation, 695
Unstructured proteins, 98–99, 98*f*
Upregulation, membrane receptors, **475**
Uracil, **27**
nucleic acid structure, 27–30, 27*f*–30*f*
Uracil DNA glycosylase (UNG), DNA base excision repair, **168**
Urea cycle
allosteric effector regulation and enzyme induction, 760–761, 760*f*
amino acid metabolism, 759–761, 759*f*–761*f*
enzyme synthesis, 759–760, 759*f*–760*f*
deficiencies, 762cc
metabolic disorders, 761, 761*f*
nitrogen atoms, ammonia-aspartate sources, 759
Urease, cirrhosis and, 873–874, 873*f*
Uric acid
gout and overproduction of, 811cc
purine degradation, **818,** 819*f*, 820–821, 821*f*
Uridine, **27**
nucleic acid structure, 27–30, 27*f*–30*f*
Uridine 5′-triphosphate (UTP) conversion, pyrimidine metabolism, 822–823, 823*f*–824*f*
Urobilinogens, **800**
Urobilins, **800,** 800cl
Urochrome, 800cl
Urogenital system, neuronal (NOSI/nNOS) activation, 447–448, 448*f*
Urokinase plasminogen activator (uPA), **1019,** 1019*f*
angiogenesis, 1020
Uroporphyrinogen decarboxylase, heme biosynthesis, 793*f*, **794–795**
Uroporphyrinogen III synthase, heme biosynthesis, **793,** 795*f*

V
Vaccines
antibody molecules and, 338cc
DNA vaccines, 28cc
Valine
aminotransferase reaction, 754, 754*f*
metabolism, 776, 779*f*
side chain structure, 77, 78*f*–79*f*
Valinomycin, **496,** 496*f*–497*f*
Valium. *See* Benzodiazepines
Valproic acid, **950**
van den Bergh reaction, **800**
van der Waals contact distance, folded proteins, **119,** 119*f*, 119*t*
van der Waals forces
folded proteins, **119,** 119*f*, 119*t*
macromolecular structures, 1125
Variable (V) regions, antibody molecules, **336,** 339
Variable surface glycoprotein (VSG), phospholipids and, 712
Variegate porphyria, **796**
Vascular endothelial growth factor (VEGF), angiogenesis and, **1019–1020,** 1020*f*
Vascular endothelial growth factor receptor-3 (VEGFR-3), cornea ATP derivation, **953**
Vascuolar proton pump, **947**
Vasoactive intestinal peptide (VIP), digestion and, 1035*t*, **1036**
Vasopressin, **893**
protein kinase A activity, 912, 912*f*, 913*t*
Vegetable proteins, 1115
in diet, 1103–1104, 1103*t*, 1104*f*
Vegetarian diet, 1103–1104, 1103*t*, 1104*f*
protein-energy requirements in children, 1105cc
Velocity plot, enzyme-catalyzed reaction, 399, 399*f*
Versican, **668**
Very-long-chain fatty acids, 674–675, 675*f*
Very low-density lipoprotein (VLDL), **679**
cholesterol synthesis, **722,** 722*t*, 723–726, 724*f*–725*f*
diabetes mellitus type 1 and, 868
diabetes mellitus type 2 and, 865–866, 865*f*, 866cc
A-β-lipoproteinemia, 1058cc
niacin deficiency, 1078
obesity and insulin resistance, 1109–1110
in well-fed state, 843*f*, 844
Very-low-density lipoproteins (VLDLs), **108–109,** 109*t*
type IV hyperlipoproteinemia, 109cc
Vesicle associated membrane protein (VAMP), **946**
Vesicle transport, **946**
Vesicular structures, lipid formation, 463–465, 465*f*
Viagra. *See* Sildenafil
Virus-transformed eukaryotic cells, foreign gene expression, 282–284, 283*f*
Visible light, x-ray diffraction, three-dimensional protein structure, 131cl
Vision
macular degeneration and loss of, 956cc
vitamin A and, 1067
Visual cycle, 961–963, 963*f*
Visual pigments
color vision, 965

Visual pigments (*cont.*)
photoreceptor cells, 958–963, 959*f*–963*f*
sequence homology, 966cl
Visual transduction, photochemical, biochemical, and electrical events, 957–958, 957*f*
Vitamin A
photoreceptor cells, **958**
plant carotenoids, 1065–1067, 1066*f*
Vitamin B_{12}, structure and function, 1082–1083, 1082*f*
Vitamin C. *See* Ascorbic acid
hydroxylation and reduction, 1084, 1084*f*
Vitamin D, 1067–1072
Vitamin D_3, 926–928, 927*f*, **1067,** 1069*f*
Vitamin E, **1072–1073**
selenium and, 1093
Vitamin K
protein carboxylase reactions, 994–995, 995cl, 996*f*
quinone derivative, **1073**–1075, 1073*f*
Vitamin(s)
anticonvulsant drugs and, 1075cc
fat-soluble vitamins, 1065–1075
water-souble, 1075–1085
Voltage-dependent anion channel (VDAC), mitochondrial structure, **560**
Voltage-gated ion channels
channelopathies, 971cc
control and selectivity, **478**
Lambert-Eaton mysthenic syndrome, 948cc
neuron impulses, 942, 943*f*
sodium, calcium, potassium, and chloride channels, 481–482, 481*t*
Von Gierke disease, 633cc
von Willebrand factor
clot formation, **988,** 989*f*
platelet plug formation, 985
V-type transporters, **491**

W
Warfarin, vitamin K and, 995*f*
Water molecules
acetyl group-acetyl CoA conversion, 555
electrolyte dissociation, 5–6, 5*f*
glycolysis, 593, 593*f*
hydrogen bonds, 4–5, 4*f*–5*f*
in lens, 954–956, 954*t*–955*t*, 955*f*
lipid solubility limits in, 1051–1052, 1052*f*
pH levels, 6–7, 6*t*
solvent properties, 5
Water permeability, aquaporins and, 479–481, 480*f*–481*f*
Water-soluble second messenger, intracellular signal transduction, **510**
Water-soluble vitamins, 1075–1085
ascorbic acid functions, 1084, 1084*f*
choline and carnitine functions, 1085, 1085*f*
energy-releasing, 1075–1079
α-lipoic acid, 1079
niacin, NAD/NADP formation, 1077–1078, 1078*f*
pantothenic and biotin formation, 1079
pyridoxine formation, 1078–1079, 1078*f*
riboflavin, FAD/FMN coenzyme formation, 1077, 1077*f*
thiamin-thiamin pyrophosphate conversion, 1075–1076, 1075*f*
hematopoietic vitamins, 1079–1083
folic acid metabolism, 1079–1082, 1080*f*–1081*f*
vitamin B_{12}, 1082–1083
Watson-Crick base pairing, **33**
DNA model, 33–34, 33*f*–34*f*
transfer RNA, 64, 64*f*
Weak acids, **7**
classification, 7
homeostasis in animals and, 9cl
Weak electrolytes, **5**
water molecule dissociation, 5–6
Wee1 kinase, cell cycle regulation, **1006**
Wernicke-Korsakoff syndrome, transketolase anomalies, 651cc
Wobble hypothesis, codon-anticodon interactions, **212**–215, 213*t*–214*t*, 214*f*
Wolman disease, 20cc
Writhing of double helix, replication fork and parental strand untwisting, **148**

X
Xanthine oxidase inhibitors, plant isolation of, 407cc
Xanthine oxidoreductase (XOR), purine synthesis, 820–821, 821*f*
X chromosome, trichromatic color vision, 966
Xenobiotic substrates
activation, **437**
cytochrome P450 exogenous metabolism, 431, 436–440, 436*f*, 437*t*
inactivation, **437**–438
toxic metabolites, **437**
Xeroderma pigmentosum (XP), nucleotide excision repair, **169,** 170cc
XIAP protein, 1012*f*, **1014**
X-ray crystallography
hemoglobin and myoglobin, 355–357, 356*f*, 357*t*
serine protease tertiary structure, 349*t*
X-ray diffraction
protein structure, 120–121
three-dimensional protein structure, 129–131, 130*f*–131*f*
X-S-NO transport, hemoglobin oxygen delivery, 366–367, 366*f*–367*f*
Xylitol dehydrogenase, pentosuria and deficiency of, 656cc
Xylulose 5-phosphate, pentose phosphate interconversions, **650,** 651*f*
L-Xylulose reductase deficiency, pentosuria and deficiency of, 656cc

Y
YACs. *See* Yeast artificial chromosomes
Yeast artificial chromosomes (YACs)
DNA fragment cloning, **278**–279
Huntington disease research, 279cc
Yeast two-hybrid assay, protein complexes, **99**–100, 99*f*–100*f*

Z
Z disk, skeletal muscles, 969, 969*f*
Z-DNA, **38**
conformation, 38–41, 39*f*–41*f*, 40*t*
Zidovudine (AZT), resistance to, nucleoside analogs and, 144cc
Zinc
deficiency, **1092**
protein requirements, 1091–1092
Zinc finger protein, transcription regulation and DNA binding, **322,** 323–324, 324*f*
Zinc ions, as enzyme cofactors, 393–394, 393*f*–394*f*
Zone electrophoresis, protein separation, 122
Z protein, bilirubin conjugation, 798–799
Zwitterion form
glycerophospholipids, **460**
monoamino dicarboxylic acid titration, 84–85, 85*f*
monoamino moncarboxylic acid titration, 84
Zymogens, **344**
blood coagulation, 995cl
digestive enzymes and, 1033, 1034*f*
protein digestion, 1044*t*, 1045–1046, 1045*f*
proteolysis and activation of, **240,** 241*f*
serine protease synthesis, 347–348, 348*f*

Abbreviations in Biochemistry

A (or Ade)	adenine
Ab	antibody
ABC	ATP-binding cassette
Ach	acetylcholine
ACP	acyl carrier protein
ACTH	adrenocorticotropic hormone
acyl CoA	acyl derivative of CoA
ADH	antidiuretic hormone
AdoMet	S-adenosylmethionine
ADP	adenosine diphosphate
Ag	antigen
ALA	δ-aminolevulinic acid
Ala	alanine
AMP	adenosine monophosphate
ANF	atrial natriuretic factor
Arg	arginine
ARS	autonomously replicating sequence
Asn	asparagine
Asp	aspartate
ATP	adenosine triphosphate
ATPase	adenosine triphosphatase
BAC	bacterial artificial chromosome
BCAA	branched-chain amino acid
BMR	basal metabolic rate
bp	base pairs
BPG	D-2,3-bisphosphoglycerate
C (or Cyt)	cytosine
CaM	calmodulin
cAMP (cyclic AMP)	3′,5′-cyclic adenosine monophosphate
CAP	catabolite gene activator protein
CBC	cap binding complex
CDK	cyclin dependent kinase
cDNA	complementary DNA
CDP	cytidine diphosphate
CETP	cholesteryl ester transfer protein
CMP	cytidine monophosphate
CoA or CoASH	coenzyme A
CoQ	coenzyme Q (ubiquinone)
CRE	cAMP response element
CRP	cAMP receptor protein
CTP	cytidine triphosphate
cyclic AMP	3′,5′-cyclic monophosphate adenosine
cyclic GMP	3′,5′-cyclic monophosphate guanosine
Cys	cysteine
d	2′-deoxyribo
Da	Dalton
DAG	1,2-diacylglycerol
dd	dideoxy
DFP	diisopropylfluorophosphate
DHAP	dihydroxyacetone phosphate
DHF	dihydrofolate
DNA	deoxyribonucleic acid
Dol	dolichol
Dopa	3,4-dihydroxyphenylalanine
dsDNA	double-stranded DNA
dTDP	thymidine diphosphate
dTMP	thymidine monophosphate
dTTP	thymidine triphosphate
EcoRI	EcoR1 restriction endonuclease
EF	elongation factor
EGF	epidermal growth factor
ER	endoplasmic reticulum
FAD	oxidized flavin adenine dinucleotide
$FADH_2$	reduced flavin adenine dinucleotide
Fd	ferrodoxin
fMet	formylmethionine
FMN	flavin mononucleotide (oxidized form)
$FMNH_2$	flavin mononucleotide (reduced form)
FOX	fatty acid oxidation
Fp	flavoprotein
G (or Gua)	guanine
G	Gibbs free energy
GABA	γ-aminobutyric acid
Gal	galactose
GDP	guanosine diphosphate
Gi	inhibitory G protein
Glc	glucose
GIn	glutamine
Glu	glutamate
Gly	glycine
GMP	guanosine monophosphate
Gs	stimulatory G protein
GSH	glutathione reduced
GSSG	glutathione oxidized
GTP	guanosine triphosphate
Hb	hemoglobin
HbCO	carbon monoxide hemoglobin
HbO_2	oxyhemoglobin
HDL	high density lipoprotein
hESC	human embryonic stem cell
HMGCoA	β-hydroxy-β-methylglutatyl CoA
hnRNA	heterogeneous nuclear RNA
HPETE	monohydroperoxy-eicosatetraenoic acid
HPLC	high-performance liquid chromatography
HSP	heat shock protein
HX	hypoxanthine
Hyp	hydroxyproline
IDL	intermediate density lipoprotein
IDP	inosine diphosphate
IF	initiation factor
If	intermediate filament
IgG	immunoglobulin G
IMP	inosine monophosphate
IP_3 ($InsP_3$)	inositol 1,4,5 trisphosphate
IRE	insulin response elements
IS	insertion sequence
ITP	inosine triphosphate
J	joule
Kb	kilo base pair
Kcal	kilocalories

k_{cat}	enzyme turnover number
kDa	kiloDalton
kJ	kilojoule
K_m	Michaelis-Menten constant
LDL	low density lipoprotein
Leu	leucine
Ile	isoleucine
Lys	lysine
m	milli (10^{-3})
M	molar (mol/L)
Mb	myoglobin
MbO_2	oxymyoglobin
Met	methionine
MetHb	methemoglobin
miRNA	microRNA
mol	mole
mRNA	messenger RNA
mtDNA	mitochondrial DNA
N	Avogadro's number
NAD^+	oxidized nicotinamide adenine dinucleotide
NADH	reduced nicotinamide adenine dinucleotide
$NADP^+$	oxidized nicotinamide adenine dinucleotide phosphate
NADPH	reduced nicotinamide adenine dinucleotide phosphate
NANA	N-acetylneuraminic acid
NDP	nucleoside diphosphate
NSAID	nonsteroidal anti-inflammatory drug
NTP	nucleoside triphosphate
ORC	origin recognition complex
oriC	origin of chromosomal replication
P	phosphate
PAF	platelet activating factor
PBG	porphobilinogen
PC	phosphatidylcholine
PCR	polymerase chain reaction
PE	phosphatidylethanolamine
PEP	phosphoenolpyruvate
PG	prostaglandin
Phe	phenylalanine
Pi	inorganic orthophosphate
PI	phosphatidylinositol
PIP_2	phosphatidylinositol 4,5-bisphosphate
PIP_3	phosphatidylinositol 1,4,5-trisphosphate
PKU	phenylketonuria
PLP	pyridoxal 5-phosphate
PMF	proton motive force
PMN	polymorphonuclear
pol	DNA polymerase
PPAR	peroxisome proliferator activated receptor
PPi	inorganic pyrophosphate
Pro	proline
PRPP	phosphoribosyl pyrophosphate
Q	ubiquinone (CoQ)
R	gas constant
RE	restriction endonucleases
RER	rough endoplasmic reticulum
RF	release factor
RFLP	restriction fragment length polymorphism
RNA	ribonucleic acid
RNAi	interference RNA
RNase	ribonuclease
RQ	respiratory quotient (CO_2 production/O_2 consumption)
RXR	retinoid X receptor
rRNA	ribosomal RNA
S	Svedberg unit
SAM	S-adenosylmethionine
Ser	serine
SER	smooth endoplasmic reticulum
SH	sulfhydryl
sHSP	small heat shock proteins
siRNA	small inhibitory RNA
SMF	sodium motive force
SMP-DNA	slipped-mispaired DNA
SNARE	synaptosome-associated protein receptor
SNP	single-nucleotide polymorphism
snRNA	small nuclear RNA
snRNP	small nuclear ribonucleoprotein
SRP	signal recognition particle
SSB	single-strand binding protein
T (or Thy)	thymine
T_3	triiodo-L-thyronine
TCA	tricarboxylic acid cycle
TF	transcription factor
TG	triacylglycerol
THF	tetrahydrofolate
TTP	thymidine triphosphate
T_m	melting temperature
TM	transmembrane
TNFα	tumor necrosis factor α
TPP	thiamin pyrophosphate
tRNA	transfer RNA
Trp	tryptophan
Tyr	tyrosine
U (or Ura)	uracil
UDP	uridine diphosphate
UDP-galactose	uridine diphosphate galactose
UDP-glucose	uridine diphosphate glucose
UMP	uridine monophosphate
UTP	uridine triphosphate
Val	valine
VEGFR-3	vascular endothelial growth factor receptor-3
VLDL	very low density lipoprotein
V_m	maximal velocity
XMP	xanthosine monophosphate
YAC	yeast artificial chromosome

The Genetic Code[a]

5′ Base	U	C	A	G	3′ Base
U	UUU Phe	UCU Ser	UAU Tyr	UGU Cys	U
	UUC Phe	UCC Ser	UAC Tyr	UGC Cys	C
	UUA Leu	UCA Ser	UAA Stop	UGA Stop	A
	UUG Leu	UCG Ser	UAG Stop	UGG Trp	G
C	CUU Leu	CCU Pro	CAU His	CGU Arg	U
	CUC Leu	CCC Pro	CAC His	CGC Arg	C
	CUA Leu	CCA Pro	CAA Gln	CGA Arg	A
	CUG Leu	CCG Pro	CAG Gln	CGG Arg	G
A	AUU Ile	ACU Thr	AAU Asn	AGU Ser	U
	AUC Ile	ACC Thr	AAC Asn	AGC Ser	C
	AUA Ile	ACA Thr	AAA Lys	AGA Arg	A
	AUG Met	ACG Thr	AAG Lys	AGG Arg	G
G	GUU Val	GCU Ala	GAU Asp	GGU Gly	U
	GUC Val	GCC Ala	GAC Asp	GGC Gly	C
	GUA Val	GCA Ala	GAA Glu	GGA Gly	A
	GUG Val	GCG Ala	GAG Glu	GGG Gly	G

[a] The genetic code comprises 64 codons, which are permutations of four bases taken in threes. Note the importance of sequence: three bases, each used once per triplet codon, give six permutations: ACG, AGC, GAC, GCA, CAG, and CGA, for threonine, serine, aspartate, alanine, glutamine, and arginine, respectively.

Nonuniversal Codon Usage in Mammalian Mitochondria

Codon	*Usual Code*	*Mitochondrial Code*
UGA	Termination	Tryptophan
AUA	Isoleucine	Methionine
AGA	Arginine	Termination
AGG	Arginine	Termination

Abbreviations for the Amino Acids

	Abbreviation	
Amino Acid	*Three Letter*	*One Letter*
Alanine	Ala	A
Arginine	Arg	R
Asparagine	Asn	N
Aspartate	Asp	D
Asparagine or aspartate	Asx	B
Cysteine	Cys	C
Glycine	Gly	G
Glutamine	Gln	Q
Glutamate	Glu	E
Glutamine or glutamate	Glx	Z
Histidine	His	H
Isoleucine	Ile	I
Leucine	Leu	L
Lysine	Lys	K
Methionine	Met	M
Phenylalanine	Phe	F
Proline	Pro	P
Selenocysteine	Sec	U
Serine	Ser	S
Threonine	Thr	T
Tryptophan	Trp	W
Tyrosine	Tyr	Y
Valine	Val	V
